My Thanks

I must express my great appreciation to Geoff Moss from the UK, who has provided me with information about spelling errors, inconsistencies, and general errors in many of these articles. Geoff has done the thing that I cannot do - looked at the articles with detachment, and has spotted and brought to my attention several howling blunders as well as the general editorial help.

Geoff, my sincere thanks and appreciation for what has been many hours of work. This

short acknowledgement is scant reward, but I really appreciate the help and assistance.

In addition, I would like to thank the many readers who have pointed out various additional errors and omissions - Your help in ensuring that the information on these pages is as accurate as possible is appreciated, *always!*

Although it goes without saying (but I will say it anyway :-) the contributed articles and projects from all over the world have added considerably to the overall value and range of topics covered in these pages, and on behalf of all the readers of The Audio Pages, I thank you for you efforts. Writing a clear and descriptive technical article is not an easy task, but your perseverance is acknowledged, and I am grateful that you have taken the time to share your knowledge.

May the flow of input continue - for anyone who would like to contribute, please do not hesitate to contact me.

Upcoming Articles

At any given time, there are usually articles in production either by myself or contributors. It is no longer possible (or sensible) to leave hints as to what may or may not be coming, since it is so easy to get sidetracked by something new that comes along. Feel free to offer suggestions, or offer your own contribution.

1.0 - Introduction

In the article Benefits of Biamping, I discussed the many advantages that are to be had by using separate amplifiers for bass and mid+high. There is also a section devoted to tri-amping (for a typical 3-way system). Essentially, the ideal arrangement is to use a separate amplifier for each loudspeaker driver in the system. Although there are still many who consider this to be overkill, the advantages are so compelling that there is no reason not to adopt this approach as a matter of course.

Of course, if the speaker arrangement uses two drivers in parallel (for example the well known MTM or D'Appolito topology), a single amp may drive both mid-woofers - dual amplifiers will usually not give any major benefit in this setup.

One area of the original article was not covered in sufficient detail - driver control. While I firmly believe that the ideal situation is to damp a resonant body at the source, this is not always feasible or even possible. There is also the occasional driver that simply cannot be controlled from "an ohm away" - i.e. it may require that the source (amplifier) is hard-wired to the driver, with an absolute minimum of resistance or impedance between the two. Some compression drivers (for horn speakers) are an example, where even a few hundred milliohms may allow the driver to do "its own thing" rather than

faithfully reproduce the applied signal.

Driver control (AKA "damping factor" - somewhat erroneously IMO) is a much touted parameter, and is considered important by the majority of hi-fi enthusiasts/ audiophiles. Indeed, even where a defined amplifier output impedance is used (such as 4 ohms, as used in my own system), this is done to provide a specific loading to the voice coil motor to control the back-emf that is developed in any electromagnetic loudspeaker driver. The most commonly sought after figure is zero ohms, implying an infinite "damping factor", but the laws of physics conspire to make this unrealistic.

However, a damping factor of (say) 100 or more is easily achieved, even with typical loudspeaker cables and amplifiers ... or is it?

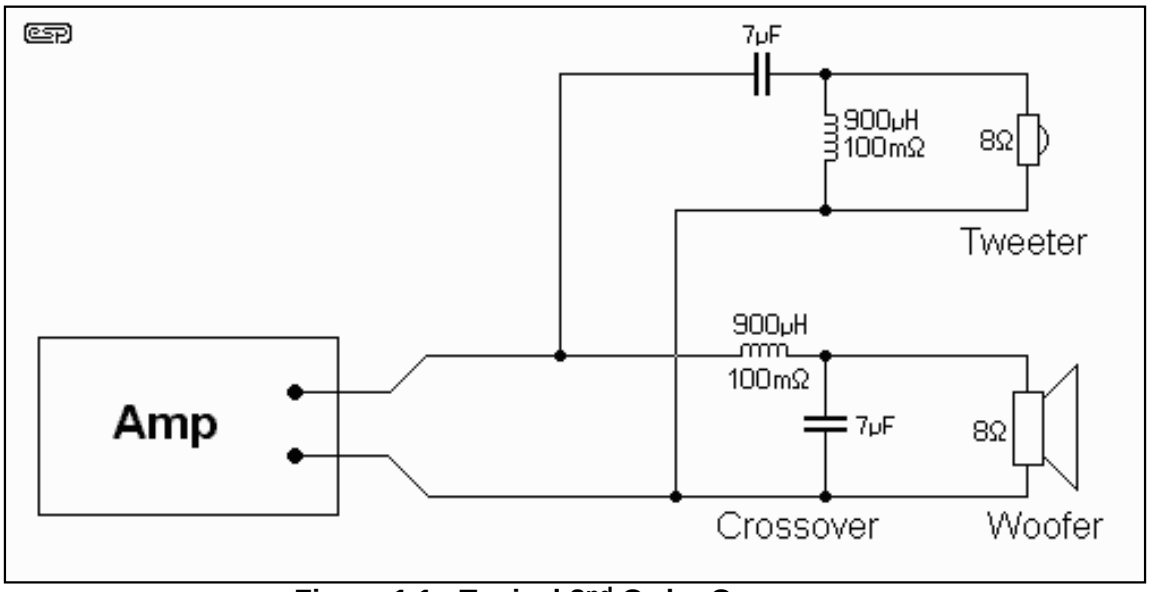

Figure 1.1 - Typical 2nd Order Crossover

There is no attempt on my part to add impedance compensation networks, notch filters, or any of the other typical additions to the circuit, and for convenience I have used purely resistive "speaker drivers". My one concession to a conventional design here is that I included 100mΩ resistance in the inductors. Any additional circuitry will affect the impedance seen by the driver - in some cases it will introduce an advantage, in others a disadvantage. I shall leave it to the reader to determine the specific differences (with a little guidance, of course).

One may rest assured though, that the performance changes due to extra circuitry will only modify the performance to a marginal degree - the primary issues remain unchanged.

2.0 - How Many Ohms?

For the sake of this discussion, we will assume a perfect amplifier, with an output impedance of zero ohms, and zero ohm speaker cables. I know this is unrealistic, but it shows the real situation very clearly - "real" components will be worse - always!

The exact parameter we will examine is the impedance "seen" by the loudspeaker driver, over a range of frequencies from well below the crossover frequency, to well above. Conventional logic indicates that

this should be as low as possible over the entire frequency range. There has been a concerted effort by amp makers to ensure that their products output impedances are as low as possible to satisfy this requirement. Valve (tube) amps are naturally different in this respect, although that is not part of this discussion.

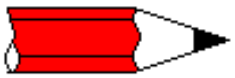
Figure 1.1 shows the crossover connections used, and the circuit is a conventional 2-way, 2nd order (12dB/octave) Butterworth type. Note that *all* versions of crossover will have similar response characteristics, although there are significant differences that will be looked at a little later in this article.

2.1 - The Crossover - a Different View

To see exactly what happens (and why), we need to redraw the crossover network so that it can be examined from the loudspeaker driver's perspective. As shown below, we see each section of the crossover (high and low pass). This is exactly the same crossover as shown in Figure 1.1, but redrawn. Since we are looking only at the damping, the amplifier is irrelevant and has been removed from the picture. It is assumed (along with speaker leads) to have zero impedance.

Remember that for this exercise, we are looking at the impedance seen by the loudspeaker, as this has a direct effect on the ability of the amplifier to damp the back-EMF (Electro-Motive Force) from the motor assembly. The back-EMF is produced whenever the cone is moved by a current, or the current is removed or changes direction. Inertia of the cone and suspension means that it cannot move or stop instantly, so there will be "overshoot" and "undershoot" caused by the cone continuing to move after the applied current has stopped.

A simple demonstration can be done to show that the speaker does indeed "generate" a voltage and current. Take a small speaker (not a tweeter), and connect it to an unused input on your preamp. Advance the gain of the amp slowly, whilst gently tapping on the cone. "Thump, thump" says your hi-fi. You can even speak into the loudspeaker, and it will act as a microphone.



Be careful - if you increase the gain too far, you may get acoustic feedback - potentially at **very** high volume levels. This will do little for your hearing, and may also damage loudspeakers. Make sure you keep the "microphone" as far from the speakers as possible to minimise the likelihood of feedback.

This simple test shows that loudspeakers do indeed generate a signal, and it is this signal that the amplifier is meant to absorb, by means of "damping factor". A back-EMF signal is generated every time your amplifier sends a signal that causes the cone to move - namely, all the time when you are listening to music (or home theatre). It is this signal that we will investigate in this article, and no other parameters. All dynamic (electro-magnetic) loudspeaker drivers do this - bar none. It should be obvious that if you short circuit the speaker that you used as a microphone, then you will hear no sound from it - this is maximum damping factor, and is what is *meant* to happen with your loudspeakers.

The phenomenon that you have experienced by using a loudspeaker as a microphone also happens with your real speakers! The woofer *will* produce a signal that is picked up by the midrange or tweeter, which in turn *will* generate a signal. This signal *should* be dissipated entirely by the amplifier to prevent (as far as is possible) the cone moving in sympathy with the soundwaves. As we shall see, this cannot happen

as it should with a passive crossover!

Even electrostatic drivers will do the same thing (although by a different mechanism entirely), but their mode of operation is such that the generated signal is of extremely small amplitude (perhaps a few millivolts at the very most). We shall not concern ourselves with this.

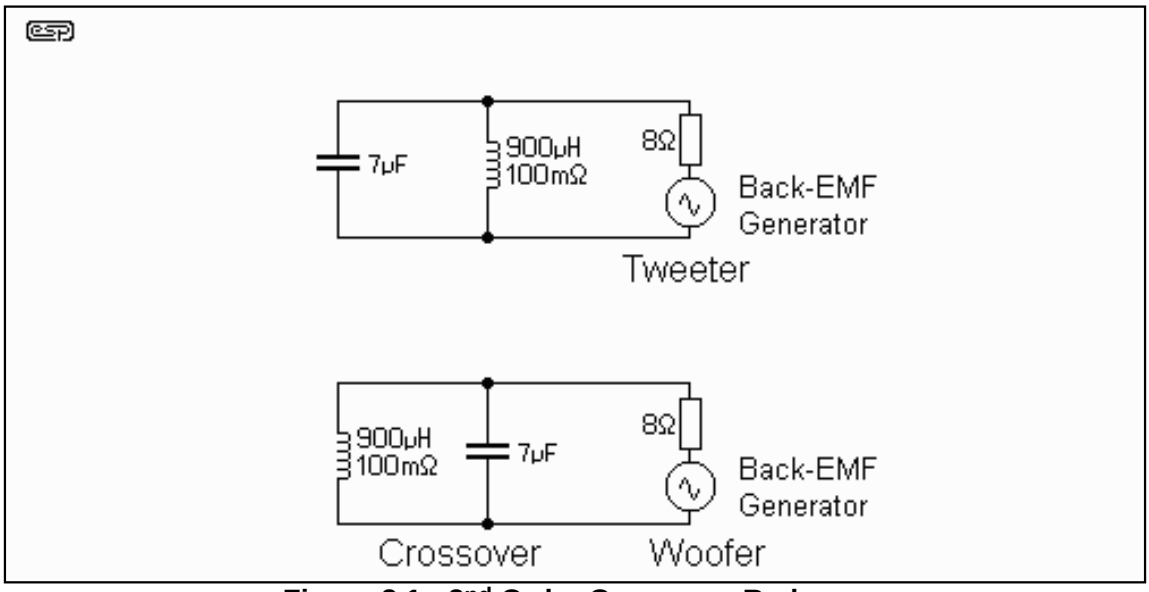


Figure 2.1 - 2nd Order Crossover Redrawn

The generators in series with each "driver" in the above diagram are to simulate the back-EMF from real-world drivers, and this is exactly the equivalent circuit that exists in reality. The only difference is that I used 8Ω resistors rather than the complex impedance of real drivers. This changes nothing, but makes the following graphs more comprehensible, without the wild fluctuations that would only confuse the issue.

Figure 2.1 shows the crossover network as it is seen by the loudspeaker. The amplifier and speaker leads no longer exist, as they were assumed from the beginning to have zero impedance. The crossover now appears as a simple parallel LC network, with resonance tuned to the crossover frequency. For those who know what this means, the implication is obvious. For the remainder, we have a parallel tuned circuit, and with ideal components (no losses), its impedance is infinite at resonance! That means that at resonance, there is no damping whatsoever, and the "damping factor" is ... zero!

But wait - there's more! Let's look at the impedance of this network over a couple of octaves below and above the crossover frequency. This gives a more balanced perspective, and we can determine the effective damping over a sensible range. The damping within the stop band (i.e. the band of frequencies the crossover network section rejects) is not so important, as the signal applied to the driver is minimal anyway. There is still the potential for considerable energy within the first octave above the crossover frequency (X_f) for a low pass section, and an octave below for a high pass section, so this is still of some importance.

Figure 2.2 shows the impedance curve of a 2kHz XO, looking backwards from the loudspeaker into its crossover section. I have shown the low and high pass sections here, but they cannot be separated because they are identical (as one would expect, since the inductance and capacitance are in parallel in both cases). There may be small differences with real components having some tolerance, but they do

not affect the picture significantly.

Indeed, even adding a 1Ω resistor in series with the short circuit shown (and thereby introducing some real-world losses into the parallel networks), there is only a small change. Naturally, it does not improve the situation.

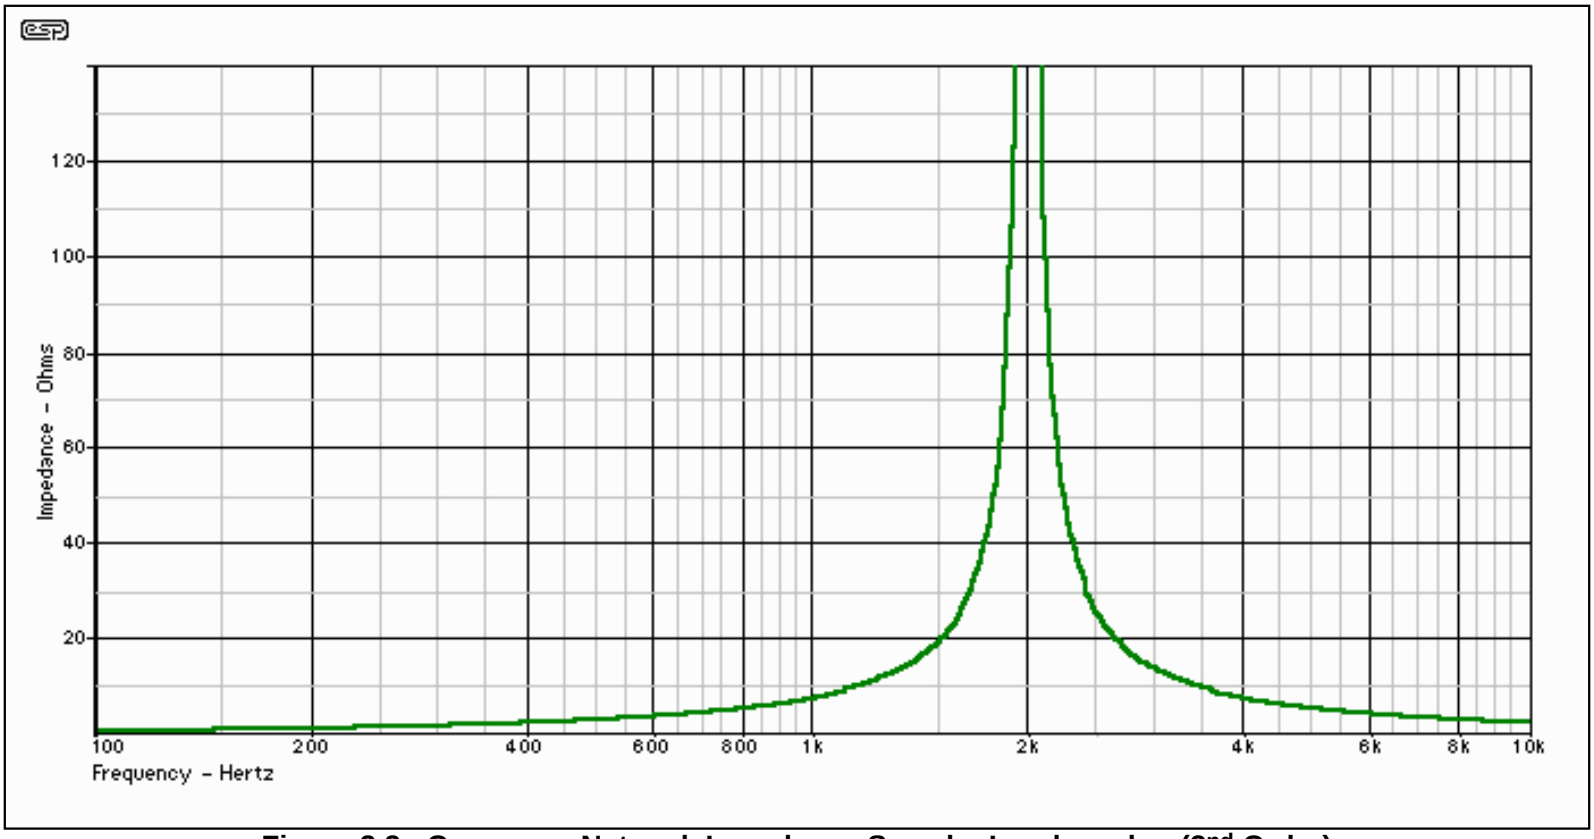

Figure 2.2 - Crossover Network Impedance Seen by Loudspeaker (2nd Order)

The high pass filter impedance response is shown in red, and the low pass in green, although only one is visible since they are perfectly overlayed.

At one octave, the impedance is nominally the same as the design impedance, so for an 8Ω speaker, the network impedance is also 8Ω one octave above and below X_f. This means that the driver sees a damping factor (DF) of one! And this with a perfect amplifier, and superconducting speaker leads. This is not only unexpected, but is potentially quite unsatisfactory, as there is little to damp the loudspeaker back-EMF, so allowing perhaps significant overshoot and undershoot, with inevitable "smearing" in the time domain. Transients will not be right, as the loudspeaker is still able to contribute a significant amount of its own "signature" to the reproduced sound.

What about moving further away from X_f ? Well, things improve, but not as much as you might expect or desire. At 2 octaves (500Hz and 8kHz), the parallel tuned circuit has an impedance of 3 ohms, so the DF is now ...

$$DF = Z_{speaker} / Z_{source} = 8 / 3 = 2.66$$

This is a far cry from the DF of between perhaps 50 to several hundred presented by the amplifier, and

for many drivers may be unsatisfactory. Even at one decade (200Hz or 20kHz (i.e. 3.16 octaves either side of the XO frequency of 2kHz), the impedance is still 1.17 Ohms, giving a DF of only 6.8 - in a 3-way system, it is probable that the low-mid XO will be close by the 200Hz figure, and this will introduce even more problems!

2.2 - The Active Solution

With an active crossover, the amplifier is connected directly to the driver, and the only thing between them is the loudspeaker cable. The amplifier presents the maximum damping factor at all times, regardless of frequency, and is not affected by the crossover network, since that is also active, and located before the power amp.

The loudspeaker driver now has the maximum control that the amplifier can provide, across the entire frequency range - not just the crossover network's pass band. The difference in damping is quite obvious, and although some (very well behaved) drivers will show little improvement, the vast majority will be much better controlled, and this will show in an impulse measurement. Not at all uncommonly, it will also show up on a swept sinewave frequency response measurement as well, with the amplitude of peaks and dips generally reduced (albeit marginally in most cases).

Well apart from the other advantages of an active system, this is perhaps one of the most compelling reasons to use an active system rather than passive. Not only is it possible to achieve the maximum damping, but if it is determined that a particular driver is best suited to some defined impedance, this can be provided by the amplifier, and will be stable across the frequency range. In some cases, just a series resistor will be sufficient, and even though there will be some power loss, if it makes the driver behave the way it should, then any small power loss is a small price to pay.

In short, there is simply no comparison between the two systems. A passive XO will *always* add (usually) undesirable impedance to that seen by the driver(s), the impedance is frequency dependent, and ranges from perhaps an ohm or so to almost infinite. The potential for uncontrolled cone movement, intermodulation distortion and loss of performance is so great that it is impossible to determine in advance, but it is all negated in one fell swoop by using a fully active system.

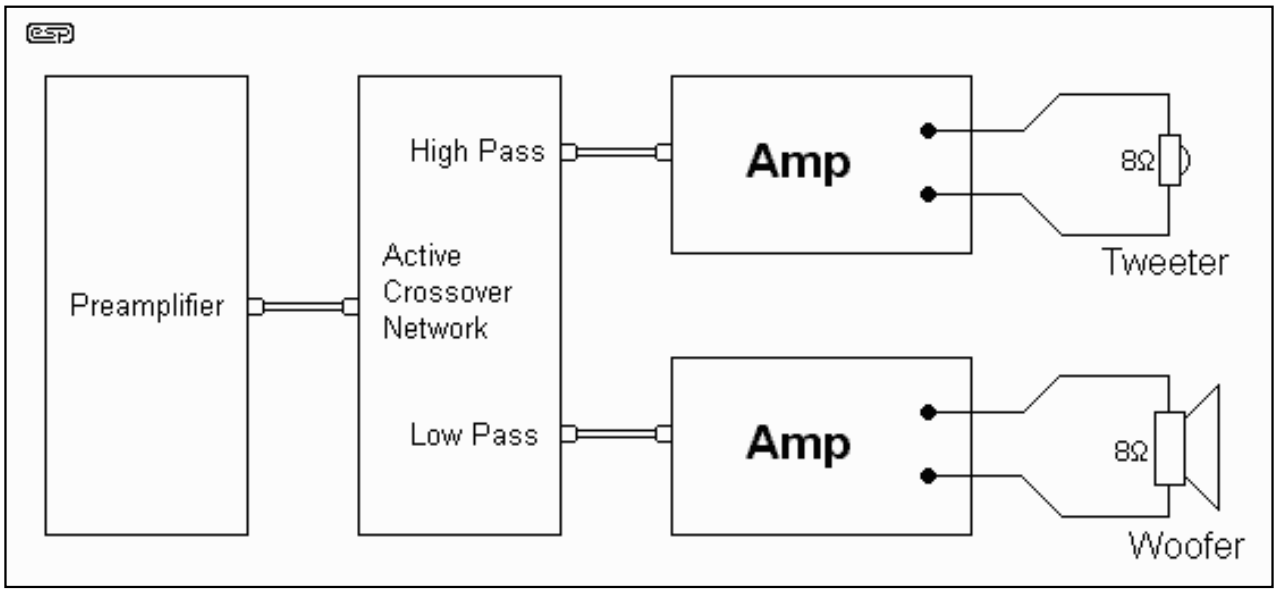

Figure 2.3 - Block Diagram of an Active 2-Way Loudspeaker System

Figure 2.3 shows the essential parts of an active 2-way system. This may be expanded to 3-way, and used with 3-way speakers, or 2-way speakers and stereo subs. Four-way systems - or more - are easily achieved. In contrast to a passive crossover (whether fully optimised or not), each driver has its own amplifier, and each amp has to reproduce less power, and over a narrower frequency range. This allows each amp to have an easier time with a less complex load, potentially reducing amplifier heating and overload - even at high listening levels. For a complete rundown of the other benefits, see The Benefits of Biamping (Not Quite Magic, But Close).

The important point here is that each driver has its own amplifier - there is nothing in between except for the cable, and amplifier control is maximised. The demands on the cable are also minimised (assuming that you believe this to be a critical component), and cheap speaker leads in an active system will provide far better performance than expensive leads with a passive crossover.

2.3 - Other Network Orders

First, let's look at a 1st order network, as this is the network of choice for many audiophiles. Notwithstanding any other problems it may have (due to the shallow rolloff slope), the impedance seen by the drivers is shown below.

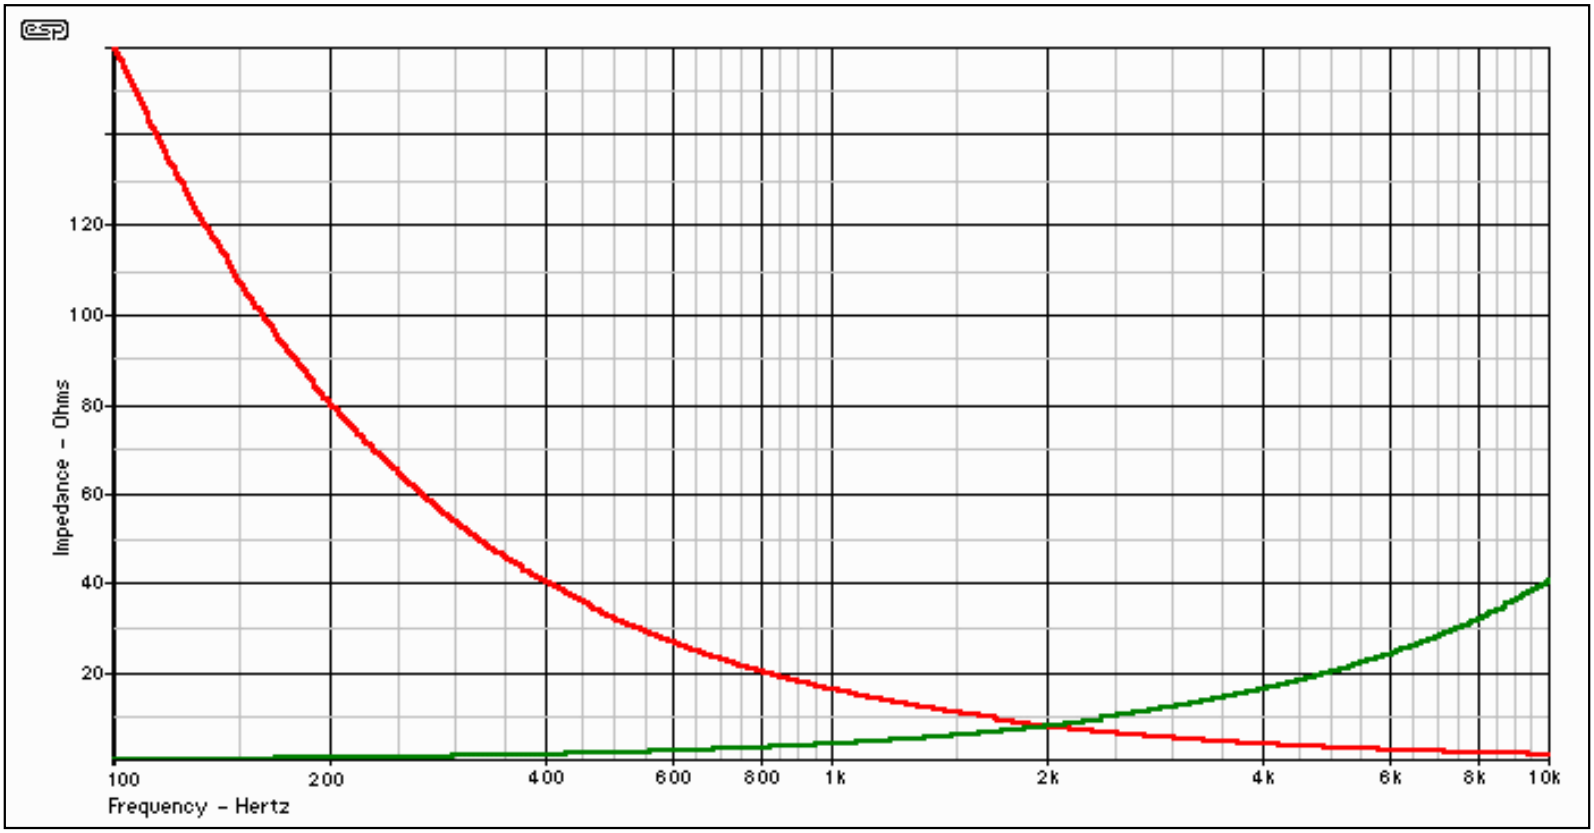

Figure 2.4 - Crossover Network Impedance Seen by Loudspeaker (1st Order)

Again, the high pass filter impedance response is shown in red, and the low pass in green. At the crossover frequency, the impedance is equal to the speaker design impedance, or 8Ω in this case. This provides a DF of 1 - significantly better than a second order filter, but still somewhat shy of ideal. At 1

octave below X_f, the low pass section shows 4Ω - still better than the second order which gave a DF of 2.66 at the same frequency. At one decade, impedance is around 800mΩ, again, an improvement over the second order filter. Unlike second order filters, a first order filter keeps increasing its impedance in the stop band, and at 1 octave above X_f stop band impedance is 16Ω, rising to 80Ω at one decade.

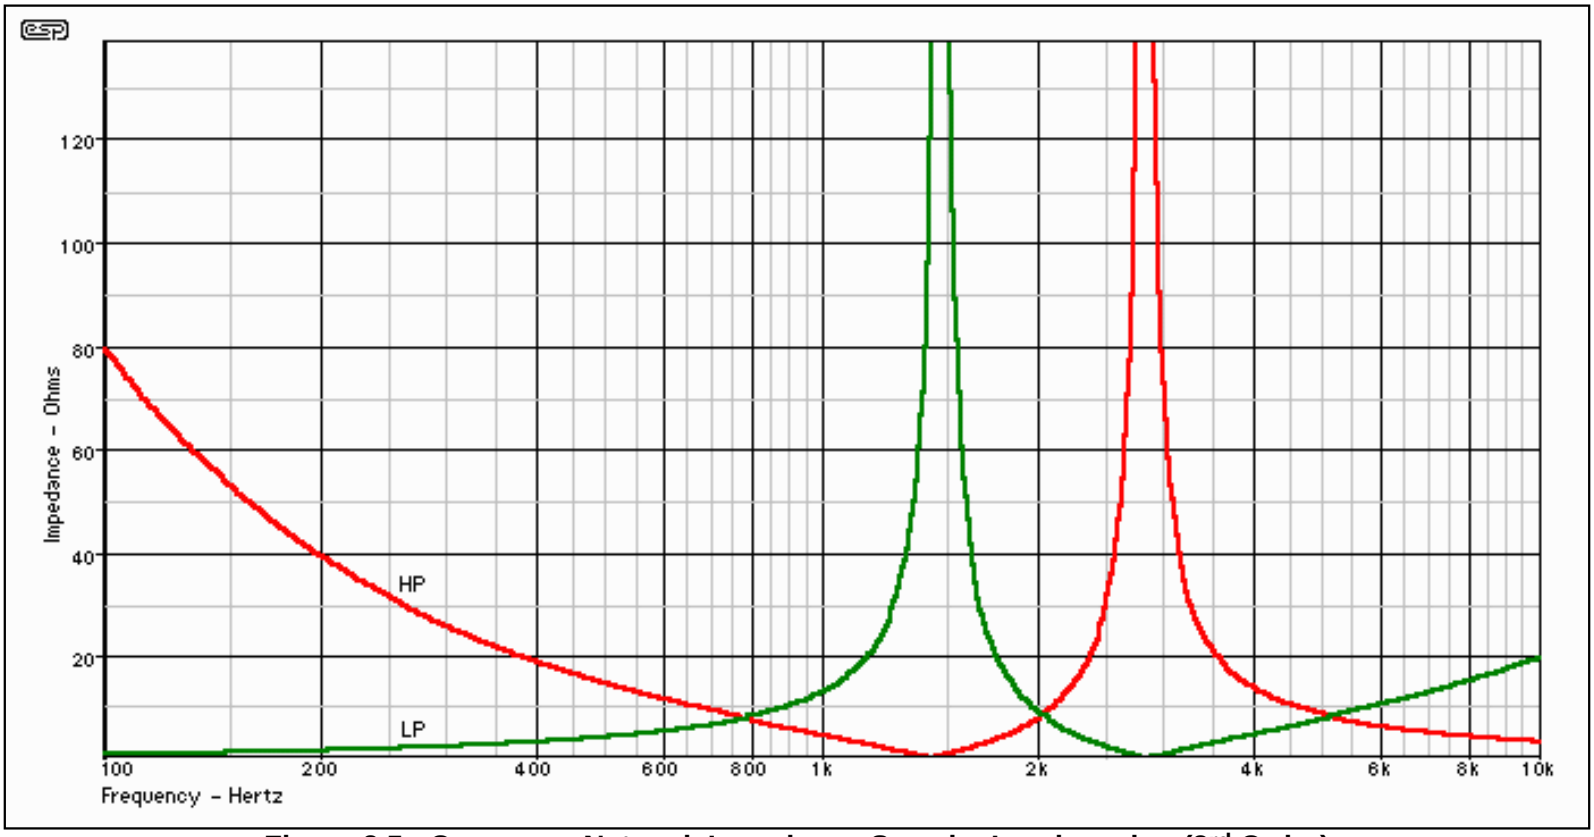

Figure 2.5 - Crossover Network Impedance Seen by Loudspeaker (3rd Order)

Here is where things get *really* interesting (colours as before). Note that there are two peaks of almost infinite impedance (the maximum is not shown, but will typically be in excess of 200Ω). These are at 1.46kHz (theoretically 1.414Khz in fact) for the low pass section, and 2.8kHz (2.828kHz) for the high pass. This means that there is a point where the loudspeaker driver sees almost infinite impedance to back-EMF, within the normal passband! That this will cause some unexpected results is fairly obvious, but it is unpredictable unless you know the drivers' behaviour at these frequencies, when driven by a high impedance source.

What of the other frequencies - 1 octave and one decade away from the crossover frequency? Because of the behaviour of the third order network, we need to look at X_f as well.

Impedance at X_f is 8.45Ω, and at 1 octave either side of that frequency, the impedance is about 13Ω. This gives a DF of 0.95 at X_f, and 0.6 at the one octave points (within the passband - impedance is much lower in the stopband, at around 4.7Ω). At one decade, passband impedance is 1.58Ω and stopband impedance is about 39Ω.

Interestingly, the impedance in the stop-band (again at those "magic" frequencies of 1.414kHz and 2.828kHz), the impedance seen by the drivers is extremely low, at only a few milli-ohms. This is clearly

visible in Figure 2.5 but is of little consequence in reality.

2.4 - Zobel (and Other) Networks

By adding (for example) a Zobel or series LC network to the tweeter to reduce the effect of the impedance peak at resonance, the impedance seen by the tweeter will be lower than indicated above. The woofer is (of course) unchanged by this, but again, a woofer Zobel used to equalise the rising impedance due to voice-coil inductance *will* have an effect.

Don't imagine for an instant that it will cure the problem, because it won't. The impedance to back-EMF will still be a great deal higher than you ever imagined, and damping factor will be around unity at best. There is no network that can be placed in parallel with the loudspeaker that will solve the problem, with the possible exception of a 0.1Ω resistor!

That would be a very bad idea indeed, unbelievably very bad in fact. Your amplifier would see almost a dead short, and even if the amp had an infinite current capacity, a 10W amp would be expected to produce 800 Watts (*all dissipated as heat in the 0.1Ω resistor!*). Don't even think about it!

But ... there **is** something you can do. It is called an active system, and you can at last obtain the genuine damping that any amplifier can produce, which is always going to be better than any passive crossover can provide.

What of bi-wiring or "passive biamping"? Not a sausage worth of difference, I'm afraid. Certainly, there may be some minor improvements in some cases, but they have nothing to do with driver damping. In my opinion, passive biamping (using two amps, but retaining the passive crossovers) is a waste of an amplifier. The same two amps with an active crossover (with the passive XO removed completely from the circuit) will outperform the passive biamp arrangement by such a margin that it's not even worth *considering* - let alone actually doing it.

3.0 - Conclusion

This aspect of active versus passive crossovers has received scant attention elsewhere, but it is very obvious that it is a major contributor to the audible difference between the two systems, even when all else seems equal. As has been shown, there is a major difference between the two types of speaker management, and this is probably the most significant (and important) distinction.

It must be understood that passive networks appear to be of sensibly low impedance from the amplifier's perspective, but behave entirely differently towards the driver's back-EMF. This seemingly contradictory situation is caused by the low output impedance of the amplifier, and this causes the impedance of the crossover filters to be asymmetrical (input-output vs. output-input).

Nothing here is magic, nor is it falsified or "tarted up" for the purposes of this article. Remember that I already stated that we would assume a zero impedance source for all tests. Note that every test shown here can be easily duplicated, using nothing more than a signal generator and a small amplifier wired in series with the loudspeaker (as depicted in Figure 2.1). You will not be able to measure impedance

directly, but the voltage obtained at the crossover's output terminal is directly related to the impedance.

It is very apparent that with a passive crossover, things are not as we would like them to be. Each variant has problems, and as with all things, a passive crossover is a compromise. IMO, this is not a compromise I am willing to make, as the performance is too unpredictable - this explains why so many passive designs require a considerable amount of tweaking before they sound their best - and may still disappoint the listener in critical listening sessions.

One of the great claims (which is completely true) for first order crossovers is that they have excellent transient response. This may well be true of the filter, but what of the loudspeaker? The degree of control offered is not good, although surprisingly (or not), it is better than second or third order filters. All passive filters will cause the amplifier to have a rather tenuous grip on the driver behaviour at best, and in extreme cases may allow a speaker to go "AWOL" at some frequencies.

In contrast, an active design minimises these problems. The driver is under the control of the amp to the maximum extent possible, regardless of frequency, passband, stopband, topology, order, etc. The use of high order (e.g. 24dB/octave Linkwitz-Riley) filters is seen by some audiophiles as a retrograde step, since transient performance is much worse than low-order filters. Be that as it may, the additional control that the amp has over the driver's behaviour *improves* the transient performance, and especially so at (or near) the crossover frequency - the most critical frequency point(s) in the design of any loudspeaker.

In this day and age, amplifiers and active crossovers can be built for (almost) peanuts - ok, not *great* amplifiers perhaps, but when used in an active system they can *still* outperform a megabuck top-of-the-line amp driving the same loudspeaker drivers through a passive crossover network.

The next step will be (of course) digital crossovers. I have one, and the ability to fine tune the network, apply delay to fully time align the respective loudspeakers, and the sheer control that each amplifier has over each connected driver, means that it is possible to make loudspeakers better than ever before. I use my digital for loudspeaker testing and development - my listening system uses an analogue 24dB/octave L-R crossover, and "time alignment" is achieved by reversing the phase of the tweeter. Not perfect, but it outperforms just about anything else I've heard. A full digital loudspeaker management system will be the next addition, and I already know just how good it will sound.

The days of the analogue active crossover are far from numbered, as this is still a good way for the budget-conscious audiophile to get the very best from available loudspeaker drivers, and with far fewer compromises than would be the case for a passive system. The overall cost will not be greatly higher for the DIY types, and the chances of success are improved beyond compare.

Not considered an active system yet? Do yourself a favour - it is extremely unlikely that you'll ever regret it.

Introduction

Most people would tend to think that bi-amping a hi-fi system (or even a sound reinforcement system) is unnecessary, or only for the most esoteric of systems. This is not the case, as the following article will attempt to demonstrate. There are very real advantages to using bi-amplification instead of the standard arrangement we commonly use, where one power amplifier must drive all the loudspeakers in the enclosure, along with the typical passive crossover network which can - at times - have a mind of its own!

If you are in a position to spend $25,000 or more for a pair of speakers, then this is approaching the 'cost no object' arena, but the majority of people cannot afford such luxuries, and must settle for something a little more pedestrian. As a result, very few systems will be as good as they can be. Biamping is not a simple tweak, and is not to be taken lightly. Make no mistake though, its application *will* improve almost any loudspeaker available, with very few exceptions.

Note
Some of the terms used in the descriptions of various design configurations may be registered trade marks. These terms (where used) are not to be taken as a reference to any particular product, company or corporation - they are used only in their generic or common technical sense and infer no affiliation with any third party.

The following is a technical article, and is not an attempt to sell any product. It is informative and all ideas herein are a combination of common knowledge (and sense), and/or my own thoughts on the subject. No reference material is quoted, since none was used (other than computer simulation of various filter types to ensure that I am not speaking through my hat).

1.0 - The Basics of Bi-Amplification

Bi-amping is a technique which uses one amplifier for the low frequencies, and another for mid and high frequencies. The choice of crossover frequency is not too critical, provided that the amplifier powers are properly balanced to achieve the maximum benefit, and the drivers used are operating well within their frequency and power limits.

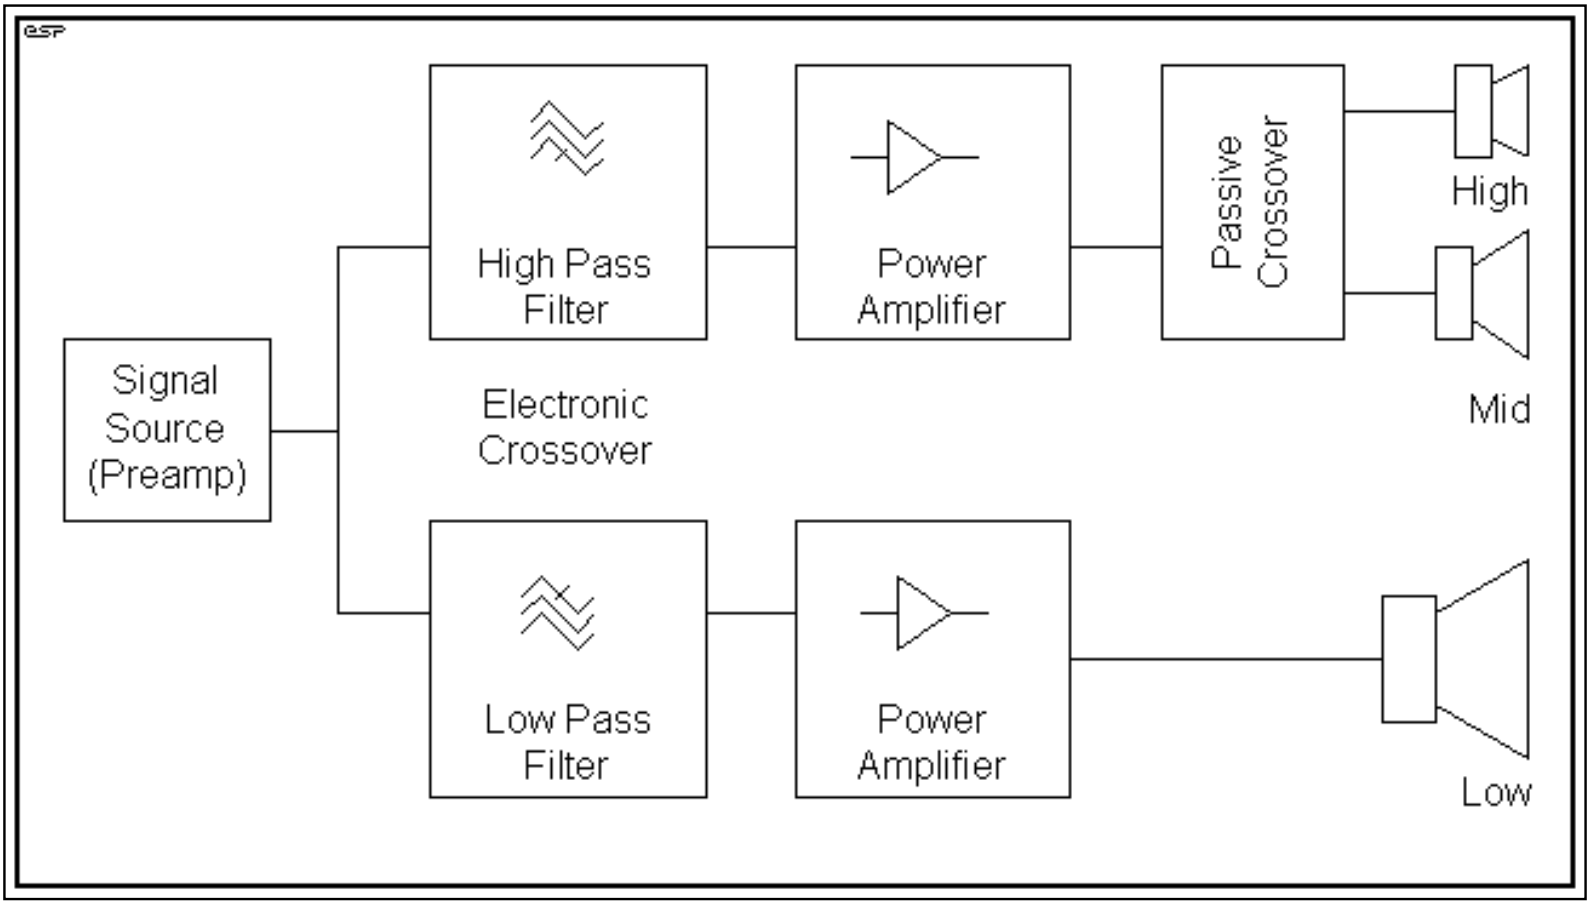

Figure 1 - Bi-Amplification Block Diagram

Figure 1 shows the basic concept in block diagram form. Only one channel of the stereo pair is shown, the remaining channel is identical. Note that the midrange to high frequency crossover retains a passive design - more on this later in the article.

In a simple form (using really simple electronic crossovers and little amps) biamping can be used even for computer speakers, clock radios and the like. The cost of the little amps is low, and the sonic improvement can be quite dramatic. I used to have a sub-woofer on my clock radio (really) and it actually sounded quite decent - at least insofar as a clock radio *can* sound decent.

As a solution to just about any amplifier-speaker combination, biamping has to be the way to go. At the highest or lowest ends of the audio equipment range, a biamped system will sound better than conventional passive crossovers, and one amp doing all the work.

The Most Common Question About Biamping

The most common question I get is ...

> "Do I need to disconnect the passive crossover in my speakers?"
> The answer is ... **Yes**, otherwise you are not really biamping at all.

Generally speaking, the mid to high section needs to be retained since a typical biamp setup will

only eliminate the bass to mid+high network. These sections are nearly always completely separate networks, although it may not seem like it when you first have a look at the board.

Equally important is the selection of the electronic crossover frequency. It must be the same as the original, within a few 10s of hertz. The only exception is where you might obtain information from the manufacturer of the speaker that allows the frequency to be modified. In general, I strongly suggest that you determine the original crossover frequency, and stay with it.

When the crossover is modified, make sure that you retain all the parts, along with the original connections. A drawing (including all component values) and photograph will be of great assistance when you want to restore the speakers to normal prior to selling them - it is unlikely that you will ever want to do this for your own use - not after you have enjoyed the benefits of biamping for any length of time.

Passive biamping (where two amplifiers are used in a bi-wiring connection) is, IMHO, a waste of money. Although there may be some moderate sonic benefits, they are not worth the expense of the extra amplifier.

1.1 - Terminology

In writing this article I have endeavoured to keep technical terms to a minimum. Unfortunately, this is quite impossible (for me anyway), so if you are not familiar with the terminology used, please refer to the Glossary of Terms, now in a separate page.

This includes some terms which are not in the body of the article, but are useful nonetheless since they may be encountered elsewhere.

1.2 - Speaker Sensitivity

Initially, let us look at an "ideal" situation, where the loudspeakers for low and midrange plus high frequencies have the same sensitivity (say 90dB / watt @ 1 metre). This means that in free space (without reflections from walls etc.), the speaker will provide an output of 90dB SPL (Sound Pressure Level) measured at a distance of 1 metre with an input power of 1 Watt. This will usually be measured with band limited noise, so the speaker's little peaks and dips will not overly influence the measurement.

The high frequency driver (tweeter) is of minimal interest at this point in the discussion, so will simply be lumped in with the midrange to give mid+high.

1.3 - Power Distribution and SPL

With typical program material (whatever that is), it has been determined that the "equal power" frequency between low and mid+high is between 250Hz and 350Hz. This is defined as the frequency where the bass and mid+high amplifier power requirements are equal. So with our 90dB/Watt/Metre speakers above we could assume that 100W amplifiers might be appropriate.

This will allow an absolute maximum of just over 110dB at one metre. You may think that is loud (you would probably be right, too), but this is the peak single-frequency SPL, and allows for transient signals - ensuring that at no time does the amplifier clip (cut-off the tops or bottoms of the waveform). This introduces distortion which quite apart from sounding awful, causes listener fatigue and places loudspeaker drivers at risk of damage.

The Speaker Damage popup has more information on this topic for those who are interested. In addition, it is suggested that you look at the article Why Do Tweeters Blow When Amplifiers Distort? for further details

The actual (averaged) SPL at one metre will be somewhere in the vicinity of 90 to 100dB, depending upon the program material. The average SPL at the listening position cannot be determined without complete analysis of the room's acoustics (for a typical room you will lose another 6 to 10dB), so for simplicity we will use the 1 metre SPL as a reference value.

Thanks to a reader, here is a small table that shows the power distribution at different crossover frequencies. The table came from a loudspeaker manual "LOUDSPEAKER ENCLOSURE DESIGN AND CONSTRUCTION" published by FANE.

X-over Frequency (Hz)	Power to Bass (%)	Power to Mid +High (%)
250	40	60
350	50	50
500	60	40
1,200	65	35
3,000	85	15
5,000	90	10

Note that according to this table, the equal power point is 350Hz (which I calculated, since it was left out of the original). This is slightly different from my own measurements, but the error is of no consequence, regardless of who is right. As can be seen, the power requirement falls quite rapidly after 1200Hz, and although not shown, it also falls off with reducing frequency.

Since the last statement will possibly cause some discomfort or indeed confusion (after all, everyone knows that a subwoofer needs more power than the main speakers), I should explain myself. Most of the time in this article, I refer to power as average power, and indeed the average power falls with frequency below about 100Hz or so. The peak power is a different matter, and depends to a very great degree on the type of music.

The table assumes equal efficiencies for the bass and mid+high drivers. Should they be different, then a correction factor must be added in. For example, if the bass driver were to be 3dB less efficient than the mid+high drivers, then the bass power must be doubled (and of course vice versa). If the difference is less than 3dB, you may safely double the power anyway, or calculate the actual power needed - this I shall leave as an exercise for the reader.

This is a very important point, and cannot be over-emphasised. Some subs (particularly those using the "Extended Low Frequency" ELF™ technique) will need a huge amount of additional power at the bottom end because of the way they are driven. It is not easy to give a simple formula (so I'm not going to :-) to calculate the power needed, because there are so many variables.

Do not be tempted to reduce bass power below about the 40% level regardless of crossover frequency, because although the average power might be quite low, it is usually of relatively high peak amplitude. The wide dynamics of the bass content require an amplifier capable of far more power than might be imagined if clipping is to be avoided. Clipping is something that one should avoid at all costs, because apart from sounding horrid, it also places loudspeakers at risk. Having said that, some peak clipping in a subwoofer will be inaudible, provided the remainder of the signal is clean.

In general, I suggest that the bass amplifier should have at least the same power as that used for the mid+high frequencies, but if any equalisation is used (such as the Project 71 Linkwitz Transform circuit), this may need to be increased dramatically.

1.4 - Actual vs Effective Power

If we assume that our 100 Watt amplifiers will be handling exactly the same peak amplitudes with typical program input, then we have a total of 200 Watts for the combined program material. So, where does the magic come into this? This amp combination will sound (and measure) as if it were 400 Watts - twice as much "effective" power as there is real power. For this to make sense, we need to back track a little.

Imagine a sine wave signal of 100Hz at an amplitude of 28V RMS. For an 8 ohm load, this equates to about 100W (98 actually). The same amplitude at 1000Hz will be exactly the same power. Now add the two signals together, in the same way that signals add together in music. We are interested only in the peak amplitude, the RMS value indicates that the power is only 3dB higher, but it is only when an oscilloscope is used that the true picture emerges.

We will now see a low-frequency waveform, with a higher frequency waveform superimposed - the high frequency signal will be riding up and down the path of the low frequency signal. If we were to perform a calculation (or simply measure the combined signal with an oscilloscope), we will see that the peak amplitude has doubled. The effective RMS value (most multimeters will get this wrong unless they are true RMS types) is 40 Volts, and this would imply 200W. Although this is the real RMS voltage, it totally underestimates the amplifier power needed to reproduce it cleanly. An oscilloscope shows 80V peak for the same waveform, so the amplifier must be

capable of passing an 80V peak signal - a 400W amplifier.

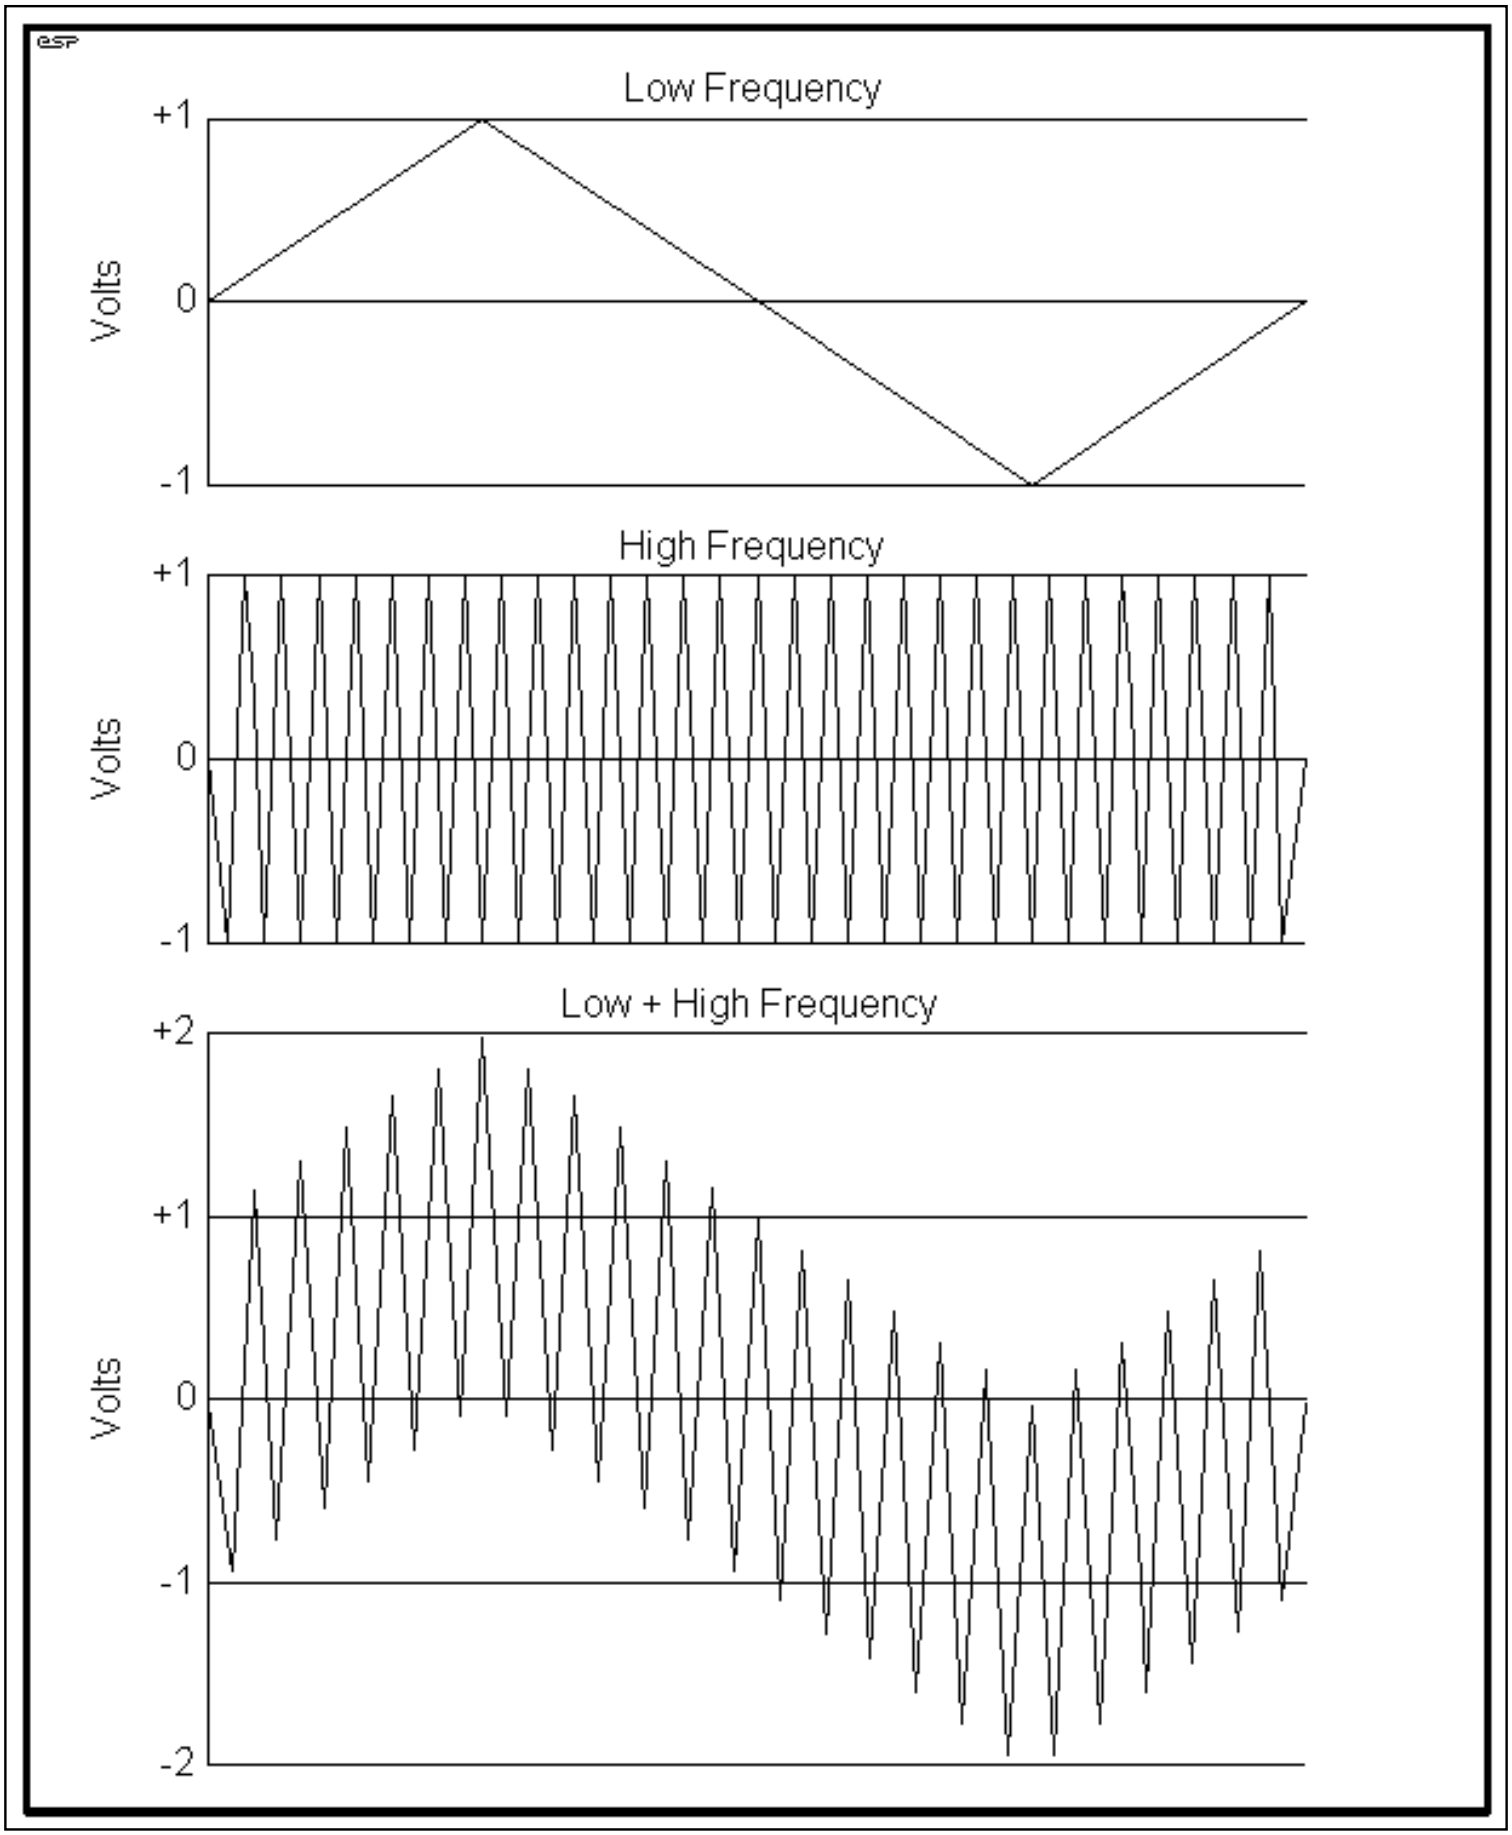

Figure 2 - Addition of Waveforms

To illustrate this point, Figure 2 shows two signals, each of 1 Unit peak amplitude. As can be seen, when the two are combined, the amplitude is much greater. The maximum peak amplitude is now 2 Units - double the peak voltage and four times the peak power of each signal individually. Power increases as the square of voltage, so twice the (peak) voltage is four times the power. Real ('RMS') power increases by 3dB or double the power, but this is a misleading figue and cannot be used. An oscilloscope is essential.

Note: Peak-to-peak amplitude is actually double the values quoted above, but since amplifiers are generally symmetrical (capable of equal positive and negative voltage swings) it is more convenient to simply refer to the peak amplitude only.

This is not to say that the actual music will be symmetrical. It isn't, but it is completely unpredictable in nature. As a result, it is possible (for example) to set up an amplifier asymmetrically and adjust the phase to suit with a switching circuit, since it will change. AM radio actually does this (or they used to) - a circuit is used to switch the phase so that slight over modulation causes more transmitter power, but never reduces it below the acceptable minimum. I shall not be going into details, since I believe few audiophiles would find this acceptable - I know I wouldn't.

All signal sources have the same characteristics as shown above in Figure 2, even a solo voice or musical instrument. In these cases, the fundamental frequency forms the low frequency component, while the harmonics 'ride the wave' as it were. Not surprisingly, the 'equal power' frequency will change (often dramatically) from the 250 to 350Hz range quoted above, but the basic principle does not alter.

Completely beside the point (but interesting anyway) is that in many musical instruments, the harmonics are actually at a greater amplitude than the fundamental. (File this away under 'Useless Information'.)

Note: It must be explained here that the 3dB effective power increase is the absolute maximum that can be obtained. In most cases it will be less - I have examined sections of music where the power gain was less than 1dB, and it can be reasonably safely assumed that the real gain will lie somewhere between 1-2dB in most cases. The real figure depends a lot on the type of music, the actual crossover frequency, and the peak to average ratio of the two separated signals. Just this topic alone is sufficient for a complete article in its own right.

1.5 - Separating The Signals

A passive crossover will separate the two signals shown above and feed each to the appropriate loudspeaker in the system. The amplifier must be capable of handling the entire composite waveform, so for our previous example of 100 Watts for each signal individually, must be capable

of 400 Watts to reproduce the waveform without distortion.

If we now we separate these signals again - prior to the power amp - and using an electronic crossover, we have an entirely different situation. (Note: It is assumed for the sake of this article that the crossover frequency is near the halfway point between the two discrete frequencies of Figure 2.) Each signal is now supplied to its own 100W amplifier (there will be but a hint of the other frequency still visible on an oscilloscope, since the filters are not "perfect") and thence to the loudspeakers. The amplifiers are not clipping, both signals are reproduced at their original power, and the effective result is that we are emulating a 400 Watt amp with two 100 Watt units.

By way of comparison, the waveforms in Figures 3A, 3B and 3C show what happens if the composite waveform is fed into a single 100 Watt amplifier, and we try to obtain the same power output as before. Once the amplifier's output voltage attempts to exceed the internal power supply voltage, the amplifier clips the tops and bottoms of the waveform - resulting in harsh distortion and placing tweeters at extreme risk due to the additional high frequency energy which is created by the sharp transitions of the clipped waveform, and even more so by the compression of the signal (see Speaker Damage). This also adds a considerable amount of intermodulation distortion to the signal, so the distortion is not just harmonic, but can also be discordant (not harmonically related). This is the worst kind of distortion, and sounds really gross.

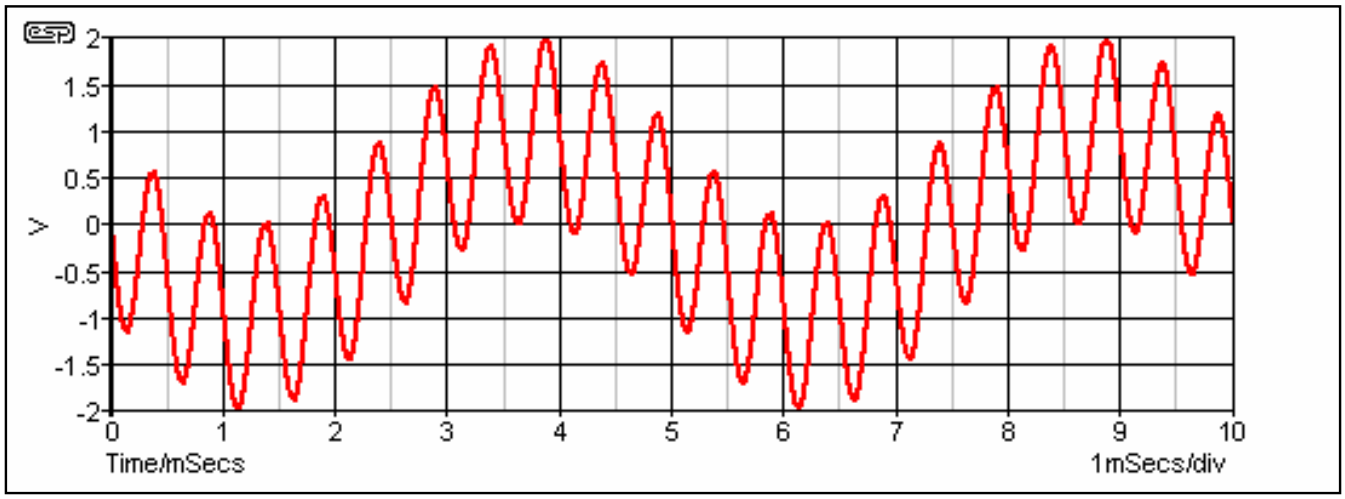

Figure 3A - Unclipped Waveform Expected from 400W Amplifier

Using the same principle outlined above, we add a 200Hz signal and a 2kHz signal, each having 1 unit (1V) amplitude. The result is a combined signal with a peak amplitude of 2 units. Again, if we equate 1 unit (1V) with a nominal 100W, then 2V is 400W.

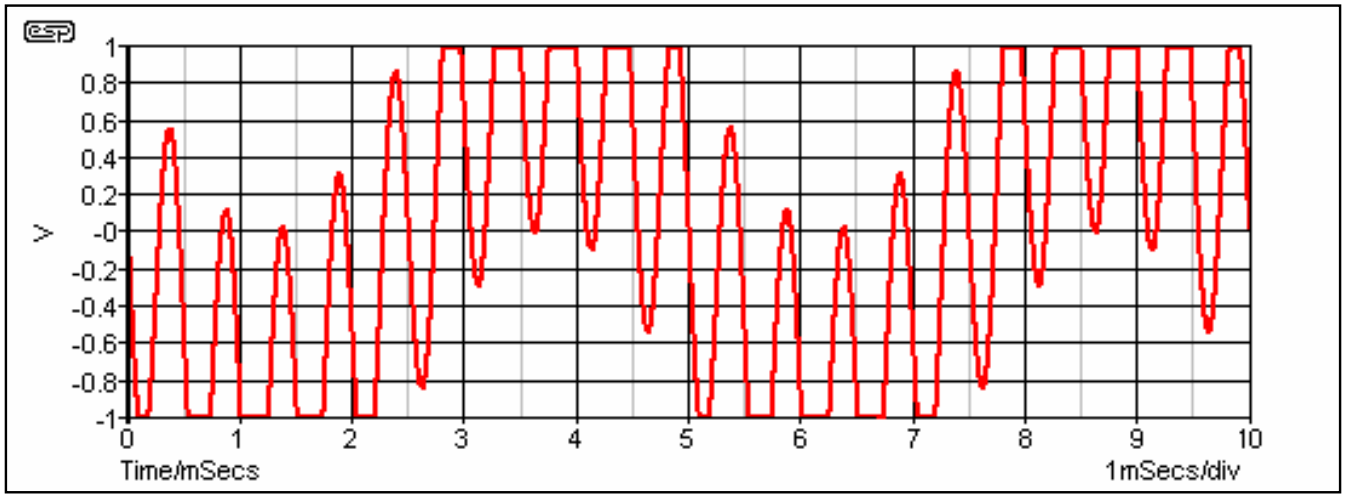

Figure 3B - Clipped Waveform From Underpowered Amplifier

The result of feeding a 2V input signal into an amplifier that is capable of reproducing 1V is shown in Figure 3B. The waveform in Fig 3B is *exactly* the same as that in Figure 3A, except the amplifier has limited the peak amplitude to ±1V, so causing the signal to be clipped. It is not immediately apparent, but both the low and high frequencies are distorted by the clipping action, and it is obvious that a significant part of the signal detail is no longer available as it has been 'clipped' off.

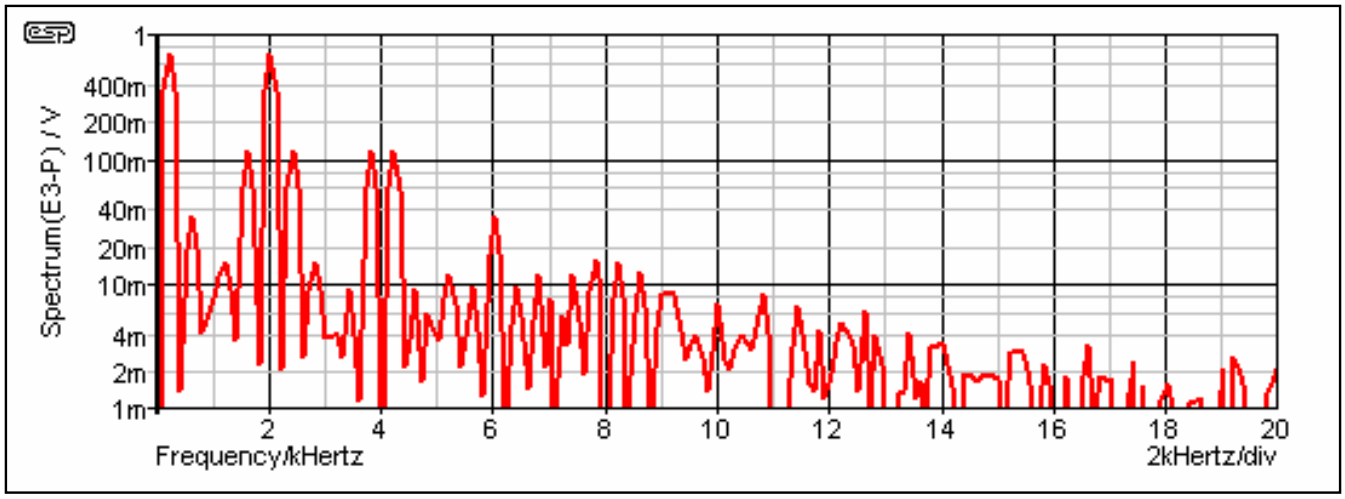

Figure 3C - Spectrum of Clipped Waveform

It is quite obvious that some of the signal has gone missing because of clipping. Not so obvious is that additional new frequencies are created, and this is shown in Figure 3C. This is a spectrum of the clipped waveform. The normal (unclipped) spectrum simply shows two peaks - one at 200Hz and another at 2kHz, with both being exactly 1V in amplitude.

Figure 3C shows that there is a multiplicity of 'new' frequencies. The original frequencies are each reduced to 714mV, and new frequencies are added. We have simple distortion, adding 600Hz to the signal, as well as sum and difference frequencies. These add 1.8kHz and 2.2kHz (at over 10% distortion level), as well as 3.8kHz and 4.2kHz. 6kHz is added (the third harmonic of 2kHz at the same level as the new 600Hz signal), plus 7.8kHz and 8.2kHz. All of these signals are above 10mV in amplitude (1% distortion referred to 1V), but there are a great many more new

frequencies below that level. The end result is a very harsh noise - it no longer qualifies as wanted sound (or music).

While it may seem that a bi-amped system gives you 'something for nothing' in the power department, this is not really the case. Four 100 Watt amps (2 x stereo 100W / channel) are going to be about the same price as (or perhaps more than) two 400 Watt amps (1 x stereo 400W / channel), but they will not be as highly stressed by high voltages, will probably run cooler, and each only has to handle a more limited frequency range. (For more good ideas on this concept, see Summary, below.). An electronic crossover is also needed, and this adds to the total cost of the system. Of course, the low frequency passive crossover isn't needed, so this offsets the overall cost somewhat. While you never get something for nothing, biamping probably comes as close as you'll get.

1.6 - High Frequency Energy Content

The basic principles described above also apply to the way high frequency signals are superimposed upon the low and middle signals. The main difference is in the energy (power) of the respective frequency bands. There is normally a relatively high amount of energy in the midrange band (see A Short Dissertation on Crossover Frequencies) as well as in the low frequency band. However, as the frequency increases beyond the upper fundamental frequencies of most musical instruments, the amount of energy falls off. Typically this will occur from about 800Hz and up (but will vary widely depending upon the type of program material), and the energy content will be seen to drop at a rate of about 3dB per octave (and more rapidly again above about 5kHz).

Since with a 3-way system the midrange to tweeter crossover frequency will be at perhaps 2500Hz or so, we can expect that the energy content of the high frequency band will be 9dB to 12dB down compared with the low and mid ranges. If we translate that back to our original 100 Watt amplifiers, this equates to somewhere between 7 and 12 Watts (peak) - giving an average power of around 1 Watt.

Because the high frequency energy content is such a low value (about 1/10th that of the midrange band), there is not a lot to be gained by using another electronic crossover network to separate this from the midrange signals. If the goal is to obtain the absolute maximum SPL (such as for sound reinforcement) it will be well worth the effort, but for hi-fi the law of diminishing returns indicates that it is not generally worthwhile. However, for optimum clarity, there is no comparison. An electronic crossover is not affected by driver impedance, and is (comparatively) infinitely stable.

One area where it is certainly better to use the additional electronic crossover and more amps for the tweeters, is where the sensitivities of the midrange driver and tweeter are more than 2 or 3dB different. In this case, using a separate amp will allow the levels to be matched far more easily, and will eliminate the use of resistive pads in the crossover network. There is also the potential for

a useful reduction in intermodulation distortion, although with good quality modern amplifiers this is normally very low.

1.7 - Intermodulation Distortion

Intermodulation distortion in an amplifier is a form of distortion created when two different frequencies are being amplified simultaneously. The effects of intermod are most noticeable when one of the frequencies is much lower than the other, and the high frequency signal is actually modulated by the low frequency. This is quite different from the signals simply adding as they are supposed to. The effect (musically speaking) is that the sound is muddied, and the highs lose their transparency. Individual instruments become difficult to separate as their harmonics all start to blend into a 'wall of sound' (have another look at Figure 3B - this is intermodulation distortion at its worst).

As described above, intermodulation distortion is not harmonically related, so its effect is worse than simple harmonic distortion. Transient Intermodulation Distortion (TIM or TID) is (supposedly) created when fast transients exceed the amplifier's ability to change its output voltage fast enough. Although uncommon in modern amplifiers, TIM is still theoretically possible, although it is very rare to find any programme material that will cause *any* reasonably competent amplifier any stress.

These effects can be hard to quantify, but by using two (or more) amplifiers, any problems will be greatly reduced.

By separating the low and mid+high frequencies from each other prior to the power amplifiers, we reduce (to a large degree) one of the major sources of intermodulation. This is a great benefit to the music lover, since the sound instantly becomes more open and cleaner.

+ So far we have identified two major plusses - effectively more power, meaning that transients are less likely to cause amplifier overload (clipping), and reduced intermodulation distortion. But wait, there's more .... (No, sorry, we're completely out of steak knives!)

1.8 - Passive Crossovers

For those who are unfamiliar with the setup of a three-way passive crossover, please refer to Figure 5, which shows (and the text explains) the connections. The diagram shown is for a "bi-wired" system, but includes the conventional connections.

When an amplifier reproduces the entire musical range, coils (inductors) and capacitors are used in the speaker cabinet to separate the high and low frequencies so that each may be supplied to the appropriate loudspeaker driver. A loudspeaker can be a difficult load for any amplifier, but

when additional inductance and capacitance enter the equation, this only makes matters worse. Add to this the fact that all passive crossovers introduce some degree of loss (in some cases as much as 3dB - which means that they are "stealing" half the available power), and one can see that getting rid of them cannot be such a bad thing.

Look at the impedance graphs for almost any speaker system, and it will be seen that there is almost always a dip in impedance (sometimes severe) at the crossover frequency. This is caused by the interactions of the loudspeakers and their inductor/capacitor networks, and in some cases can cause amplifiers considerable grief - especially at high power levels. Although few amps will fail, one can expect a reduction in effective output power as the protection circuits limit the maximum power available due to the loading of the crossover network.

These vague thoughts are brought into stark reality when one learns that the inductors and capacitors needed for the low frequency crossover are quite large values, which leads many speaker designers to compromise in the interests of economy. The inductors may have an iron or ferrite core - which improves its inductance, but ruins its linearity. So now the crossover behaves differently depending upon the amplitude of the signal. High value high quality capacitors are expensive, so again, bi-polar electrolytics are often used. It is often stated that these sound awful, although this is a somewhat contentious issue, but without any doubt their characteristics change with temperature and age. They also have rather mediocre accuracy against their claimed value (+20/-50% is typical), so a 10uF crossover cap may be 12uF, or as low as 5uF. This does not make for an accurate crossover network, and most reputable speaker manufacturers will not make this sort of compromise, at least not for their top-of-the-line models.

In addition, at high powers, the impedance of the voice coil rises because of the temperature rise in the voice coil. This is not stable, and varies widely with the music. So with loud passages, the voice coil temperature might rise significantly, which will severely impact the performance of the crossover - relying as it does on the load impedance being a constant. A loud bass solo followed by a relatively quiet but complex passage might create an interesting shift in the crossover frequency and phase response as the voice coil cools, which is unlikely to enhance the listening experience.

1.9 - Electronic Crossovers

In contrast, the electronic crossover uses active filters in the low-level signal path. These suffer none of the power "eating" problems of the passive variety, and are far more easily tuned to exactly match each other - both within the same unit (between low and mid+high), and from one unit to the next. Indeed, it is so easy to tune an electronic crossover that they could be (and often are) set up individually for the exact loudspeaker drivers installed in a given cabinet.

In the sound reinforcement industry, crossover frequencies may (or should) be changed to suit the type of music, or even to suit the acoustics of a particular venue.

There are no issues with the crossover frequency shifting, since it is stable and not at all reliant on the voice coil impedance. This will still change with the power level, but the effects are unlikely (certainly less likely) to be audible.

+ Now there are another two plusses to add to the list - elimination of the low frequency passive crossover, resplendent with its inherent losses, potentially poor linearity and crossover point inaccuracy (either as manufactured or with time, or both), and the reduction of the difficulty of the load presented to the power amplifier. Both of these result in more effective available power, ensuring that transients are preserved and overall linearity is improved markedly.

1.10 - Speaker Sensitivity

This rated a scanty mention above, but is a highly contentious issue and can cause (does cause?) many a fine speaker system to suffer from a relatively low overall sensitivity. When a speaker manufacturer chooses drivers for an enclosure, they should be the very best available for the intended final product. In many cases, although other characteristics may be ideal, the chosen drivers will have different sensitivities. This is generally solved by "padding", using resistive dividers to reduce the sensitivity of the more sensitive driver to match that of the least efficient. So if our hypothetical drivers (as described above) were to have the following efficiencies:

- Low 90dB / W @ 1m
- Mid 93dB / W @ 1m
- High 92dB / W @ 1m

It is immediately apparent that the midrange loudspeaker requires only half the power of the low frequency unit for the same output SPL. (It is 3dB more efficient, and 3dB equates to half (or double) the power.) This will never do for a quality unit, so it must be padded back by 3dB if the midrange is not to be prominent. Likewise, the efficiency of the tweeter is also too high, so this must be padded by 2dB to bring it into line with the others.

This represents a whole bunch of power being thrown away, simply dissipated as heat in resistors in the crossover network. But wait! Amplifier damping factor is a much quoted and highly sought after commodity. It mainly affects the low frequency drivers, but midrange loudspeakers are just as likely to have their own little resonances, too. Admittedly, these are much easier to control than the low frequency nasties, but it does seem to be such a shame to use all that expensive cable to ensure the best possible response and damping factor, and there it is - gone - filched by a couple of grotty little resistors.

Oh, and speaking of resistance. Remember the inductor for the low frequency crossover? Well the resistance of that is probably between 3 and 20 times greater than the resistance of your expensive cable. Don't assume that bi-wiring helps this either, because it doesn't (more on that a

little later).

With our bi-amplified model, we can simply adjust the relative gain of the amplifiers (and their power too, if maximum SPL is the goal) to bring everything back into balance. No power is lost as heat in redundant passive components, and we can ensure that the damping factor of both low and midrange drivers is not compromised by the crossover components. The low frequency loudspeaker in particular is driven directly by the power amplifier with only the speaker cable in between.

There are also some loudspeaker drivers that, for various reasons, will sound better if driven from a finite impedance. This may be to correct the Thiele-Small parameters, or (as has been suggested by one reader who referred me to a web site - in Russian!) to reduce driver intermodulation distortion. This is an area that I shall investigate when time permits, but I have been using this technique for many years, but for different reasons.

For more information on matching the amplifier power to the speakers, see Correcting Crossover Filter Amplitude Response, below.

\+ Add two more plusses. No padding is required to align the driver sensitivities, so we are not simply wasting power, and the damping factor is greatly improved for both the low and midrange loudspeakers (or can be individually set to the impedance that makes the speakers the happiest).

1.11 - Phase Response

This one is nearly as big a "killer" as the power gain - and from a musical point of view it may well be seen as even more important (I happen to think it is). The phase response of any crossover is quite predictable, as long as the source and load impedances are well defined and stable. In a passive crossover, this is rarely the case, and the results can be quite nasty. There is a phase transition around the crossover frequency, and with even-order crossovers (i.e. 12 and 24 dB/octave), there is actually a phase reversal between the low frequency and the mid+high frequency outputs. This can be seen if one examines the wiring of a speaker using an even-order crossover network, and it will be observed that the midrange driver is wired out-of-phase with the woofer. The same thing happens with the mid to high crossover, except that the tweeter is now back in phase with the low frequency driver.

It must be noted that the phase reversal is required only to ensure that the drivers are in phase at the crossover frequency. A couple of octaves each side, and with the inductive and capacitive load presented by a loudspeaker, the signals are out of phase to a greater or lesser degree. This can only be considered a completely unacceptable situation when you look at it, but there it is - alive and well in a great many speaker systems from the very beginnings of high fidelity right up to

the present day.

See Project 09 for a Linkwitz-Riley aligned 24dB/octave crossover that *is* phase coherent, and has the added benefit that there is exactly equal power at all times from the two drivers. A conventional crossover by way of comparison has a 3dB peak at the crossover frequency when the two outputs are summed.

I have made some amendments here, as I was previously caught out by "prior knowledge syndrome", a phenomenon that occurs when one has heard (and read) the "facts" so many times that one fails to check them properly. As it turns out, the so-called facts were wrong, and thus, so was I. With a resistive load, the phase response is as shown below, and the signals are 180 degrees out of phase at all times - not just at the crossover frequency. The problems arise because of the reactive nature of loudspeakers, which will mangle the phase response of almost any passive crossover. Many designs use complex networks in series and/or parallel with the drivers to attempt to get a net resistive load. This is not too difficult with the mid to high crossover, but is virtually impossible with the bass to mid+high crossover because of the very large resonances.

Figure 3 shows how the phase reversal in a 12dB/octave crossover comes about. At the crossover frequency, each waveform is subjected to a phase shift of 90 degrees. Since one is positive (called "leading" phase) and the other negative (lagging), the net result is that the two waveforms are 180 degrees apart - exactly out of phase. Notice that at frequencies significantly lower than the low-pass filter's cut-off frequency (defined as the -3dB frequency), there is little phase shift at all. The converse applies to the high-pass filter, so at significantly higher frequencies there is again little phase shift.

This gives rise to the phenomenon described above, where the driver phase reversal is needed to prevent massive cancellations at the crossover frequency. The cancellations will occur at other frequencies too, but are not audible because the level difference is so great.

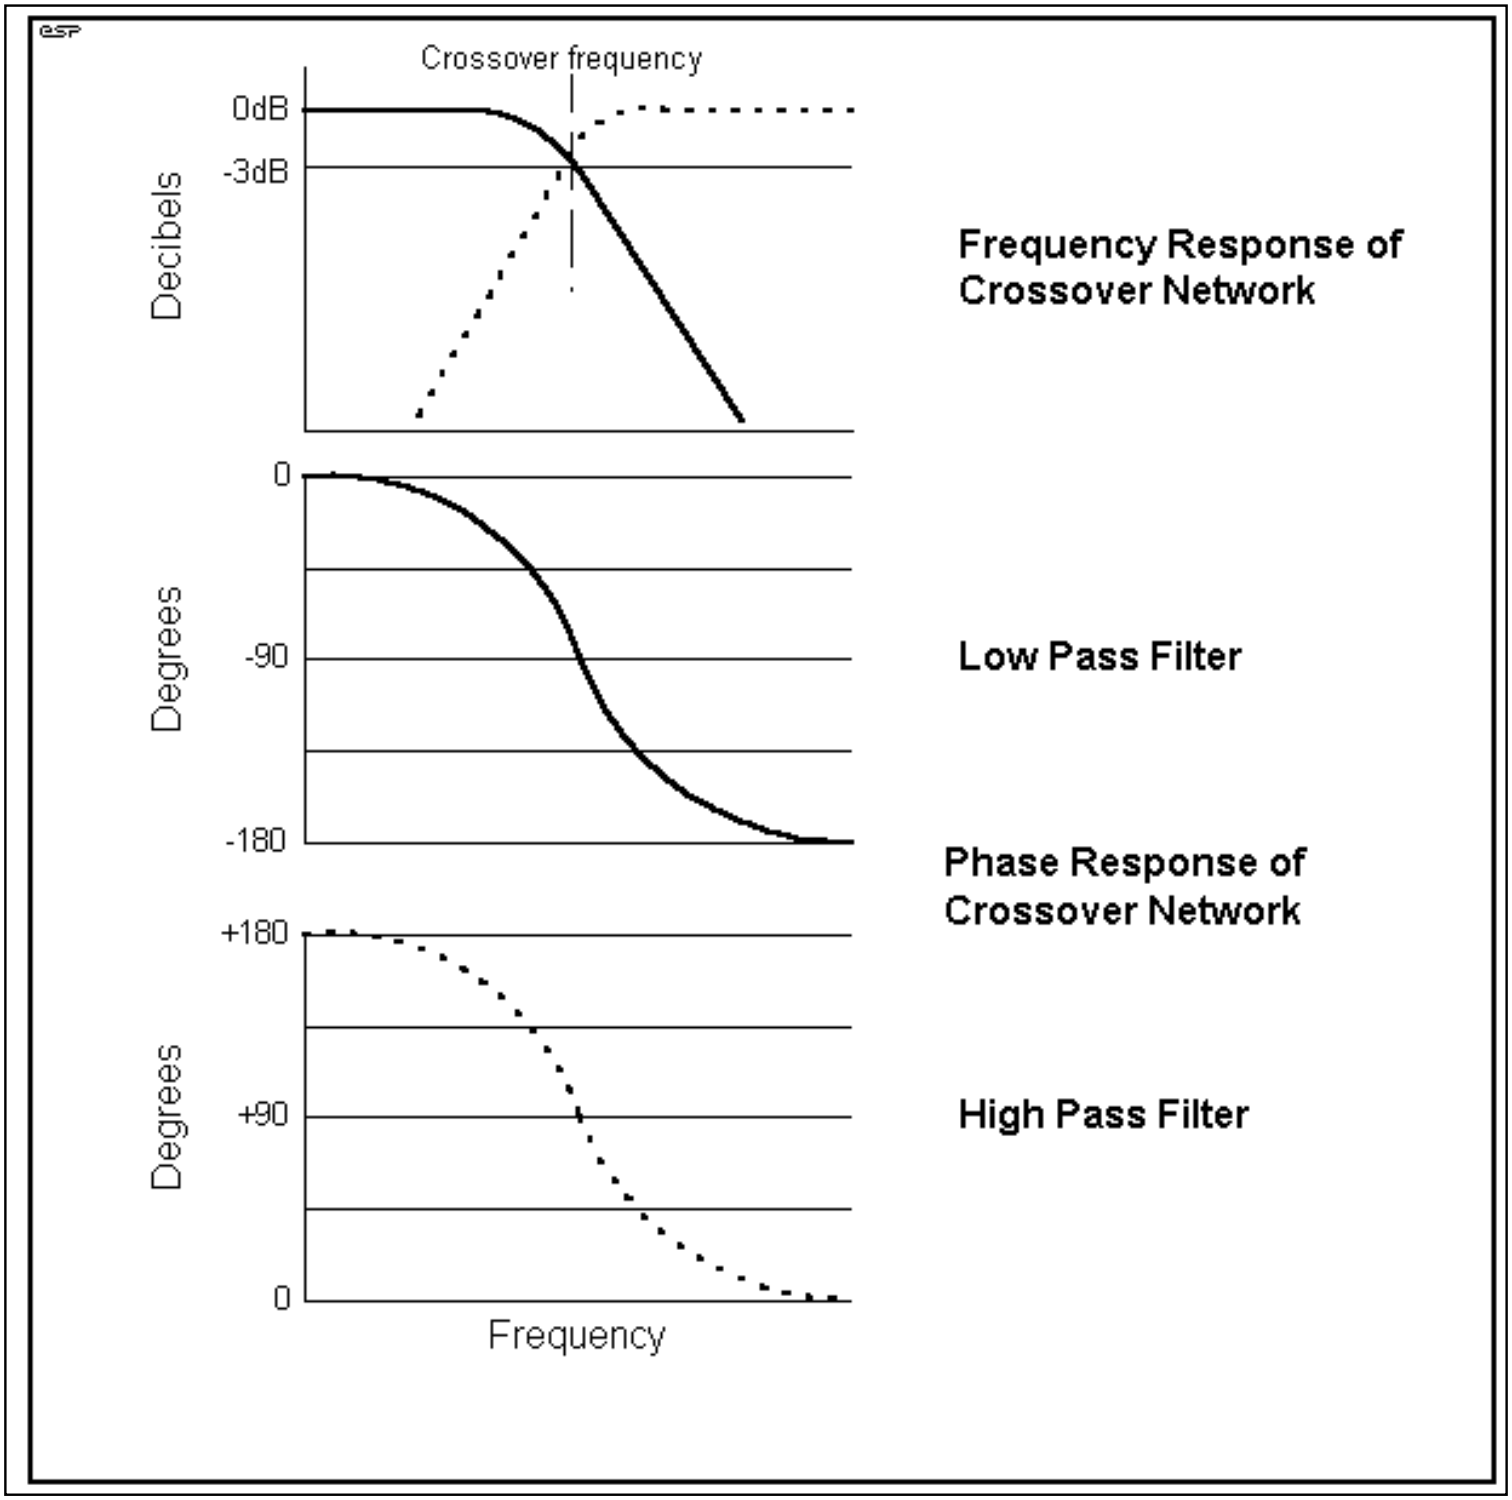

Figure 4 - Frequency And Phase Response of 12dB/Octave Crossover

It has been demonstrated by many workers in the field of acoustics that absolute phase is inaudible. Indeed, if this were not the case, then moving one's head 300mm closer or farther away from a sound source would give rise to a massive change in the perceived sound. As we all know, this is not the case. It has also been shown that some waveforms sound different if the phase is reversed, but the definitive word here is 'different' - there is no right or wrong involved. This topic is dealt with in greater detail elsewhere on the ESP site.

However, we are not talking about absolute phase but relative phase - the situation where the

phase of a signal is radiated from two different sources - *each with a different phase relationship from the other!* For this reason, many speaker manufacturers attempt to "time-align" the drivers so that the radiated signals are in the same physical plane - the idea being to combat additional phase distortion created by the loudspeaker drivers themselves. As the above shows, this is something of a lost battle - the crossover has already done plenty of damage to the phase response.

The only crossover which is relatively immune from the rapid phase transition around the crossover point as described above is a first order (6dB/octave) network, which is regrettably generally unsuitable for most loudspeakers because too much power is applied to the drivers outside their operating range. This can add considerable intermodulation distortion (this time loudspeaker induced), and is rarely an option in any system, especially between the low and mid +high frequencies. It may be an option with careful driver selection, but mostly this will only be applicable to the midrange to high frequency crossover (see below).

Although easily and cheaply built as an electronic filter, a passive third-order crossover is complex and expensive, and is more sensitive to variations in load impedance than the second-order filter.

No calculation is needed to demonstrate that if a speaker is pushed hard, its impedance will change - and this is completely aside from the reactive load presented. Most voice coils are wound using copper, and like all metals, copper has a positive coefficient of resistance. When you look at the specifications for most quality drivers, they will boast that they use a high temperature voice coil former - a good idea, since the voice coil can easily reach 150 degrees (Celsius) or more. This temperature change must cause a change in resistance, and any change will have an adverse effect on the alignment of the crossover, since impedance will change too.

Copper has a thermal coefficient of resistance such that its resistance increases by 0.39% per degree Celsius. Given a typical 6.6 ohm (DC) voice coil for an 8 ohm nominal speaker, at 150°C, the resistance will rise to over 10 ohms - naturally the impedance must be greater than this figure, so the loading on the crossover network is radically different from the design figure of 8 ohms.

At this point, the characteristics of the crossover are so far outside the design boundaries that any further calculation is futile.

1.12 - Phase-Coherent Electronic Crossover

It is possible to design a phase-coherent crossover (electronic, naturally), which exhibits none of the problem characteristics of the passive types. In an ideal world, the residual output (i.e. high frequencies below or low frequencies above the crossover point) would be in phase with the main output at any frequency in the spectrum. This ensures that there will be no cancellations or reinforcement of the signal as the outputs of the loudspeaker drivers re-combine in front of the cabinet. Regrettably, this is not the case with any passive crossover, and not all electronic crossovers exhibit this desirable characteristic either.

The author has designed and built such a unit however, and it's phase performance is exemplary. All output signals remain absolutely in phase for two octaves or more above and below the crossover frequencies. With a correctly time-aligned enclosure, phase and transient response are quite extraordinary.

It should be noted that the original phase-coherent crossover built by the author is now nearly 20 years old, and resides in a loudspeaker test amplifier (mono, tri-amped, with sweepable crossover frequencies, variable impedance - the lot) and is still in regular use.

See Project 09 for a Linkwitz-Riley aligned 24dB/octave crossover that *is* phase coherent. The question of phase coherency seems to have come of age, as it were. I have seen several designs advertised that are phase coherent, and more speaker designers are striving to achieve this goal. This is as it should be, and I am most pleased to see this happening at last. Although the filter whose graphs are shown in Fig 4 is phase coherent, it requires a polarity reversal to ensure correct phase response.

Advertisers, reviewers, manufacturers and the listening public do not seem to have seen the benefits of a phase-coherent system, and most available models of electronic crossovers seem to be electronic versions of ordinary passive crossovers. Although these units still provide many of the advantages listed in this article, phase-coherence is not necessarily included unless the manufacturer specifically states that this is a feature of the design.

\+ Phase Response - A big gain for the bi-amped system, since it can be driven from a phase-coherent crossover eliminating the rapid phase variations around the crossover frequency, and no phase reversals between drivers. Transients are cleaner and the sound is more open than can ever be achieved using passive crossovers.

1.13 - Bi-Wiring Facts And Myths (and More on Passive Crossovers)

Many speaker systems now cater for bi-wiring - running a separate speaker lead from the amplifier to the low and mid+high crossovers via separate terminals on the back of the enclosure. The benefits of this technique are said to be improved imaging due to the reduced interactions of the loudspeakers and their respective crossover networks, since the amplifier acts as an essentially zero impedance source for each section (the speaker cable now has no influence on crossover performance).

Some people equate bi-wiring as a cheaper method of achieving the same gains as one would with bi-amping. This is quite obviously not the case - there are gains to be had, but they are comparatively minor. This is not to say that the "minor" gains are not worth the effort, because as you will see this is not true at all.

For those who may not be sure of how bi-wiring really works, Figure 5 shows the setup. The broken line indicates where the connection would normally be made internally (i.e. inside the speaker cabinet). When bi-wiring is used, this connection is removed (usually with links on the connection panel), and a separate cable is run back to the amplifier.

This diagram also illustrates the composition of a 3-way crossover network. Low frequencies are fed to the woofer via a low-pass filter. The remaining signal is then fed through a high-pass filter to remove the bass energy. This is the mid+high component. To ensure that the midrange loudspeaker does not receive high frequencies as well (which it would otherwise proceed to mangle), a low-pass filter is used to filter out the high frequency component. Finally, to ensure that the tweeter is protected from the midrange signals, another high-pass filter is used.

The cutoff (i.e. crossover) frequencies for the two filter "groups" will typically be in the range of 300Hz to 800Hz for the low/mid+high section, and 2kHz to 6kHz for the mid/high section. Crossover frequency selection is discussed in a following section. (A Short Dissertation On Crossover Frequency Selection)

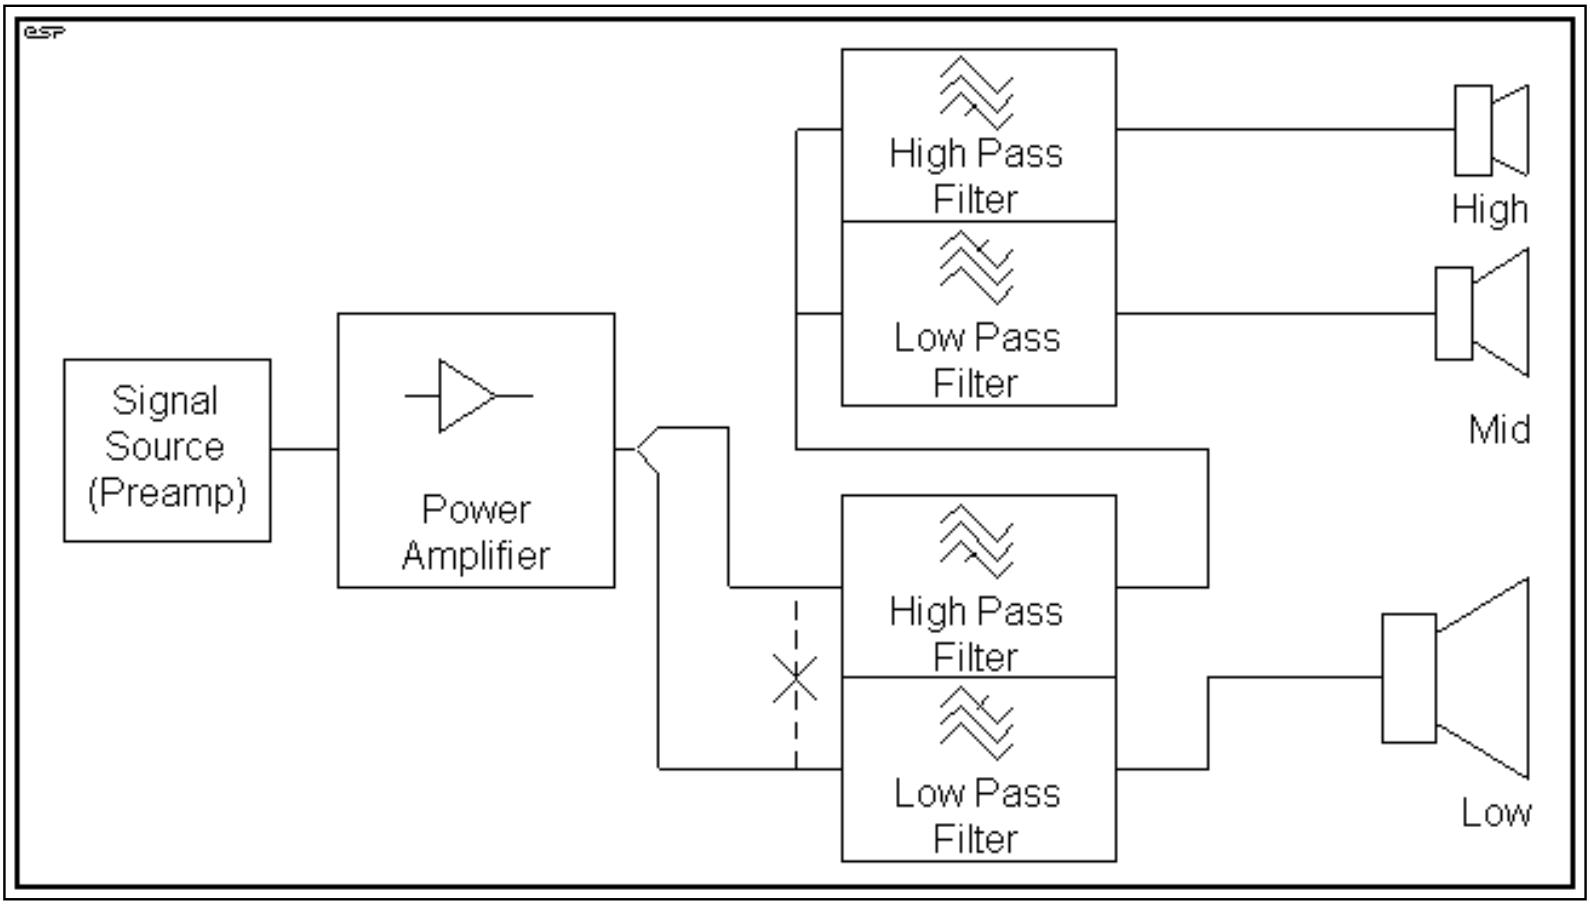

Figure 5 - Bi-Wiring Connections

As can be seen, the low frequency energy is now separated from the mid+high frequency energy in the cabling. The amplifier must still handle the full frequency range, but each section of the crossover has its own cable feed, which prevents some of the interactions between the crossover sections.

The overall effect is often (or so it has been said) a vast improvement, and largely because of the fundamental imperfections of passive crossover networks. These networks (regardless of their cost or complexity) have a few basic weaknesses which determine their overall performance. Basically, these are:

- Input impedance - a properly designed inductor / capacitor (L/C) filter relies on the input impedance (i.e. the impedance presented by the amplifier and speaker leads) to be zero ohms if the design crossover frequency is to be achieved. Any variation from this ideal will cause a small but measurable shift in the crossover's operating characteristics. When two such filters (low pass for the woofer and high pass for mid+high) are combined and share a common resistance (speaker leads) back to the source (the amplifier), interaction is inevitable, with the resulting final frequency and phase variations being unpredictable in real life.

- Load impedance - for any passive crossover to achieve its design frequency and phase response, the load must be purely resistive or wide variations in response are unavoidable. To combat this, many manufacturers design often highly complex impedance correction networks, placed across the loudspeaker in an attempt to make it "appear" resistive to the preceding filter. This task is by no means simple - a loudspeaker driver is a coil of wire (having resistance and inductance), connected to a moving mass (the diaphragm, cone, dome or whatever), all enclosed in a housing with its own resonances and reflections and coupled to the outside world via the air. This represents a highly complex electro-mechanical circuit, and presenting a pure resistance to the crossover can be approached, but never achieved (at least not over the desirable minimum of two octaves).

  In addition, these impedance correction circuits will invariably introduce additional losses, since they will generally consist of a combination of inductors, capacitors and resistors to achieve the desired result. Indeed, these networks can become more complex than the crossover itself in extreme cases, adding significantly to the final cost of the speaker system.

- Internal Impedance - as previously discussed, the coils (inductors) used in a crossover network must have resistance, since they are simply (hopefully!) an air-cored coil of copper wire. Being air-cored is the ideal, with no ferrous materials used at all. Using an iron (or any other magnetic material) core increases the inductance of the coil, so for the same value of inductance it will require fewer turns. Although this reduces internal resistance, it is at the expense of linearity and distortion, both of which are adversely affected by the use of magnetic materials.

  So, a good quality crossover inductor will have many turns of wire, which naturally has resistance. As discussed above, this should only be reduced by using a heavier gauge of wire - but compared to the cross-sectional area of your speaker cables, it is still going to be very thin! Again, power loss and variations from the ideal crossover frequency are the direct result. Naturally, speaker manufacturers are going to make the necessary frequency

corrections for the introduced resistance (in reality this is very small), but can do nothing to eliminate the power losses due to resistance. The crossover resistance also affects the damping factor presented to the loudspeaker by the amplifier - adversely of course.

- Variation of the Mechanical Components - The materials used for the manufacture of loudspeaker drivers are "real-world", which is to say they are imperfect. The roll surround of a woofer will not present the same impedance at all temperatures, and will change with age - as will all the other components. Of the fundamental ingredients which determine the overall characteristics of a loudspeaker, only the air is predictable over time (with the effects of greenhouse gasses, even this is debatable). But as we know, air varies its density and mass depending on altitude, barometric pressure, temperature and humidity, and even these variations will have some small effect on the overall characteristics of the driver. Since the response of the crossover network is dependent on all these mechanical factors as well as the electrical characteristics, it is small wonder that speaker systems seem to change their sound over time.

  Of the components which change over time, the loudspeaker itself is the greatest offender. Roll surrounds will stiffen (or start to decompose and "relax"), the cone will lose some of its stiffness and the spider (the section of the speaker which supports the voice coil) will also change. Damping materials in the speaker cabinet may settle or become more compacted as well, again changing the load presented to the crossover filter.

- Thermal Effects - So far, this discussion has taken into account only briefly the fact that the loudspeaker voice coil and inductance coil(s) in the crossover are generally of copper, and that its resistance will change with temperature. Particularly at high power levels, the self heating of these components cannot be neglected, so as the temperature increases, so too do the losses. There is also the small matter of the variation of load impedance presented to the crossover network as the loudspeaker voice coil heats up. Remember that the passive network relies on the load resistance (pure resistance is essential) remaining exactly the same at all times. Although these effects are measurable, it has neither been proven nor disproved that they are audible. I know of no speaker manufacturer who has included thermistors (thermal resistors) in a crossover network to maintain the exact design resistance at all voice coil temperatures. Indeed, the use of these devices would probably degrade the sound, since they are affected by self-heating (by the current flowing through them) which will vary with the signal.

  The use of oxygen free copper 'super' cable for speakers has many audiophiles convinced of the huge improvement (an argument I will not be drawn upon in this article, except for the note [1]below) - yet the variations in frequency response caused by the inductance, resistance and capacitance of the cable are barely perceptible (if at all) with the most sophisticated test equipment (other than ears). If these barely measurable effects are so apparent to listeners, why would the response variations of a crossover caused by temperature not be detectable? I believe that these changes are detectable, but since all (passive) speakers suffer from the same problem, this has simply been accepted as normal. These changes are also gradual, which allows time for our ears to adjust and compensate -

this is now delving into the area of psycho-acoustics, which I may examine in a future article - but not here and not now.

Again (this is starting to get tedious), an electronic crossover and separate power amplifiers will virtually eliminate the thermal effects other that a slight reduction of power as the loudspeaker voice coil heats. Even this can be corrected but the effort is not worth the gain, and due to additional circuit complexity will probably subtract more than it adds!

Many people have said that bi-wiring improved the sound quality, and although I have not used it myself (bi-amping being so far superior), I will reserve judgement until further notice. While there are some measurable differences, if sensibly sized cables are used the difference is unlikely to be audible unless the loudspeaker's crossover network has serious anomalies.

For more detailed information on the design of passive crossovers, and the many pitfalls involved, read the article Passive Crossover Design. While a mid to high passive crossover can be made reasonably economically and if well designed can sound very good (even excellent), there is often much to be gained by using a fully active system, where each driver has its own amplifier.

Note 1: It must be said that speaker cables in reality contribute little in the way of problems in hi-fi equipment. Much has been made of 'super' cables and the like, but in reality although measurable at audio frequencies, there is no proof that these effects are audible to the majority of listeners. The levels of performance variation caused by the cables are in fractions of a dB, so provided a sufficiently sized cable is used, it matters not whether it cost $2.50 / metre or ten times that amount - except to one's bank account, of course.

Note that the above may not necessarily be the case ... most speaker cables are benign, but some can easily cause a marginal amplifier to oscillate. In particular, be wary of those marketed as having a characteristic impedance of 8 ohms or others offering very low inductance. For more information on this topic, see Cable Impedance. There are solutions for these pointless (IMHO) constructions, but it's best to avoid them altogether. Any cable that is capable of making an amplifier unstable cannot offer an improvement, but can easily cause potentially serious problems.

To summarise this section, the complexity of a well designed passive crossover will be such that it will add significantly to the price of the speaker system, while still resolutely presenting the same old problems - power loss, interaction, imperfect impedance matching and rapid phase shifts around the crossover frequency. Variations of loudspeaker driver performance caused by ambient conditions (temperature and humidity for example) will affect all speaker systems (including bi-amped), but will only cause crossover frequency shifts with a passive network.

+ So now we can add a couple more plusses for bi-amplifying one's system - complete freedom from any interaction between the loudspeaker driver (and its environment) and the crossover network, and a potentially large cost saving for the now redundant complex passive crossover network.

  Add to this the benefit that many listeners already experience from bi-wiring - since a bi-amped system must be naturally be bi-wired since this is a fundamental part of its operation!

1.14 - Midrange to High Frequency Crossovers

So far I have only described the low to mid+high frequency crossover, because this is traditionally the most complex and power-hungry part of the network. There are potential gains to be had by tri-amping a system, but they become hard to justify when the added cost and complexity are considered.

The midrange to high frequency crossover still suffers from the same ailments as the low to mid +high, but they tend to be overshadowed by response aberrations created by the edges of the enclosure, grille cloth frames and other discontinuities. For this very reason, many manufacturers now use felt pads around the tweeter to reduce these effects. To some extent, the loudspeakers themselves will generally not be quite as difficult at higher frequencies, because the effects of cabinet resonances, cone mass and other mechanical factors are not as severe as at the low frequency end of the spectrum. This is admittedly a simplification, but the effects are more subtle unless the designer happens to be pushing loudspeakers beyond their limits.

Ferro-fluids are often introduced into the magnetic gap of mid and high frequency drivers, improving magnetic coupling and reducing resonances by way of the additional damping. This technique cannot be used on low frequency drivers, because the excursion of the voice coil is too great and the fluid would simply be flung from the gap as the cone moved.

Since the loudspeakers are actually more controlled at high frequencies, the complexity of the crossover is reduced. Some impedance correction is nearly always needed for the midrange driver (as its impedance will tend to rise with increasing frequency), but this is not especially arduous.

Likewise, padding may well be needed to make the driver sensitivities effectively equal, but especially in a bi-amped system this should only ever be done to reduce the sensitivity of a tweeter to match the midrange - never the other way around.

If one were to obtain drivers whose frequency response and power handling allowed it, a first-order 6dB/octave crossover network is ideal - good transient response (the best of all filter types, in fact), freedom from phase aberrations, no polarity reversal of drivers - the list goes on.

1.15 - Summary

During this article, I have given great account of the benefits of bi-amping, but nary a word about any negatives in the equation. There are some, of course, but they have actually been described already ...

- Two power amplifiers are required for each channel of a stereo system
- An electronic crossover is needed

An ideal solution would be to incorporate the power amplifiers and electronic crossover within the speaker cabinets themselves. This has been done by many manufacturers (including the author, many years ago), and is becoming quite common for high-end studio monitor speakers, especially some of the new "near-field" systems.

Even using conventional amplifiers and a separate electronic crossover network, real advantages are to be had. Imagine the best of all worlds - a really good transistor amp for the low end, providing tight and well controlled bass, and a valve (tube) amplifier for the midrange and high frequencies. With its soft overload characteristics and the renowned openness of a good valve amp, with none of the standard valve amp failings - woolly bass (generally due to the rather poor damping factor of valve amplifiers), and low frequency intermodulation distortion, caused primarily by the output transformer.

+ Another great benefit has revealed itself. Complete flexibility to choose amplifiers which are at their very best within a defined frequency range. Now the amp which all the reviewers said has "magnificent bass - but is disappointingly lacking at the top end", and the other one which is "glorious at the higher frequencies but suffers from lack of bass extension and tends towards woolliness" at low frequencies can find homes where they really excel!

1.16 - Adding up the Plusses

- Effectively (up to) twice the 'real' power of the amplifiers themselves
- Reduced intermodulation distortion
- Elimination of the low frequency passive crossover, its inherent losses, potentially poor linearity and crossover point inaccuracy
- Reduction of the difficulty of the load presented to the power amplifier
- No padding is required to align the driver sensitivities, so we are not simply wasting power
- The damping factor is greatly improved for both the low and midrange loudspeakers
- Complete freedom from any interaction between the loudspeaker driver (and its environment) and the crossover network
- Cost savings, since complex passive crossover networks an not needed
- Bi-wiring is included free!
- The flexibility to choose amplifiers which are at their best within a defined frequency range

- Ability to match amplifier power to the exact requirements of the drivers for maximum overall efficiency

I could go on (and on) here, but I shall resist the temptation. There is (IMHO) no reason to not use biamping wherever possible, from small (i.e. computer) speakers through to top of the line hi-fi. The benefits far outweigh the disadvantages in all cases.

I have seen many claims that loudspeaker manufacturers often go to extraordinary lengths to design the best possible crossover network for their products. I do not doubt that for many high-end systems, this is certainly the case. It must also be considered how much extra this costs, and we can be assured that many systems have a less than ideal network, simply to keep costs reasonable. Several times, I have seen reviews where expensive speakers use ferrite cored inductors for the low frequencies, and bipolar electrolytics are also common.

I do not consider these to be optimal or appropriate for a high quality system, and nor do many others. The truth is that cost considerations are nearly always made in any system, and much more so when the selling price becomes a consideration.

As I stated at the beginning, if you spend $25,000 or more for a pair of speakers, then we are into the "cost no object" area. Most people cannot afford such luxuries, and as a result they must settle for something they can afford. Only a very few systems will be as good as they can be, and you will pay dearly for it.

Biamping is not a simple tweak, and is not to be taken lightly. Make no mistake though, its application *will* improve almost any loudspeaker available, with very few exceptions.

There is one area where you may find that changing to a biamped system cases an apparent loss of bass response. This is rare, but in some cases the cabinet design may have been optimised for the woofer, including the resistance of the series inductor in the passive crossover. This is especially true for very well designed ported boxes. The result is that a biamped system is slightly over-damped by comparison, resulting in a loss of bass response.

There are two solutions for this ... either allow the system to 'break in' (which actually means that you get used to the new sound after a while), or increase the output impedance of the power amp. See the ESP articles index for more information on how to go about this. In general, the impedance variation is small, but it is certainly worth doing if you wish to get the best possible response from the system.

2.0 - Crossover Frequency Selection

It would be remiss of me to not mention a few salient points about the choice of crossover frequencies. This applies to all system types where fidelity is expected (or demanded) - high power music, sound reinforcement, or hi-fi.

It is not at all uncommon to see systems where the crossover frequency is set right in the middle of what I call the "intelligence band". This is the range of frequencies from 300Hz to 3600Hz, and is extremely important from a psycho-acoustic point of view.

It is no accident that this is the range of the telephone system (and has been for many years). If we are only to hear a limited range, then this band of frequencies is by far the most important. Just from this we can recognise a person's voice, which musical instrument is being played (even bass instruments!), and - more importantly - what is being said. It contains nearly all the "intelligence" of the sound, which is to say that if this band is "corrupted", intelligibility is greatly reduced.

So why do speaker manufacturers insist on placing their crossover frequencies within this band of frequencies? The public address (PA) systems used by many rock bands are a case in point - how often does one find that the vocals are completely unintelligible? Mind you, it may also be the case that the band's lyrics just don't make sense, but that's another story altogether.

Often this occurs because the system is so loud that the amplifiers are clipping badly, but even at lower levels it is quite common. Place a common-or-garden crossover filter right in the middle of the "intelligence band" and this is exactly what will (and does) happen. With phase aberrations and cancellations, this most important frequency range becomes muddied and indistinct causing loss of intelligibility - not only on voice, but instruments as well.

The effect is also noticeable with some hi-fi speaker systems, except that it usually less pronounced, and it is far less likely that the amplifier will be driven to clipping. Reviewers will often say of a speaker that the vocals seem veiled, or that there is noticeable colouration of either male or female vocals. These effects are often caused by the effects of phase shift around the crossover frequency, coupled with the fact that the crossover frequency falls right in the middle of the intelligence band.

Should a crossover be unavoidable in this region - due (for example) to available loudspeaker drivers - then the manufacturer must go to great lengths to ensure that "artefacts" created by the crossover are not audible. This often causes greater problems with amplifier loading at the crossover frequency, since impedance dips seem a common problem with many speakers. It will be found that these almost invariably occur at the crossover frequency.

2.1 - Ideal Crossover Frequencies

Since we have already discussed the "equal power" crossover frequency between low and mid+high frequencies, it should come as no surprise that the author prefers between 275Hz and 300Hz as the ideal frequency. This is outside the intelligence band (albeit only just), but as discussed, a phase-coherent crossover network and a bi-amped system will tend to be far more tolerant than conventional (passive) crossover networks.

One problem this technique does cause, is that the demands placed on the midrange driver are greater than will normally be the case. This is because the low frequency end of the midrange is now extended to around 300Hz rather than the more "conventional" frequency of 500 or 600Hz. Few (none that I know of) so-called "enclosed" (i.e. those with their own integral enclosure) midrange drivers are capable of reproducing 300Hz accurately - indeed, many are quite inadequate even at 600Hz!

Even ruling out this style of driver altogether still leaves relatively few speakers which are small enough to be considered a point source at 3kHz (one wavelength at this frequency is only 115mm - assuming "British Standard" air temperature, etc.), yet is capable of reproducing signals down to 300Hz accurately. Ideally one would want a driver whose radiating surface is no greater than 100mm diameter (this is already a significant compromise), having high compliance for low frequency reproduction, and a stiff cone structure to prevent cone break-up at the upper limits.

Bear in mind that a loudspeaker which is going to be used to reproduce frequencies down to 300Hz should ideally be capable of uncoloured reproduction for at least one octave (and preferably two octaves) above and below the crossover frequencies. This means that a suitable midrange driver must be capable of reproducing from 150Hz to 6kHz with good efficiency and without significant colouration. This is not an easy task for any loudspeaker.

Many otherwise fine midrange drivers do not provide a wide enough safety margin below their recommended minimum crossover frequency, which causes resonances and other

effects to colour the sound. Also affected will be phase response, which will start to suffer badly as the driver approaches resonance - this rather negates the advantages of using a phase-coherent crossover network!

2.2 - The Ideal Compromise

Yes, I know the heading is an oxymoron, but that is what we really have to find. We cannot go further into discussion at this point (at least not without naming names, and deciding on some suitable loudspeaker drivers), since the "ideal compromise" will be different for every loudspeaker combination available, with added problems incurred by the selected cabinet design and the maker's design goals (price - as always - being a major player in all these calculations).

Having examined some of the factors which affect the performance of a speaker system, it is apparent that there are few hard and fast rules which can be applied, since there are so many variables. What has been presented here is a guideline which - assuming that suitable drivers can be obtained - will have a standard of performance well above average. This web site has now been updated many times, as more information comes to hand, and as I get responses from readers who have similar (or wildly different - rare!) views from my own.

It is to be hoped that this information will at least provide some further discussion and feedback from readers who share my interest in "the ultimate loudspeaker" - however it is configured (even with passive crossovers, perhaps).

3.0 - Tri-Amping

I have had many enquiries about extending the bi-amp principle to tri-amping, and offer a few thoughts here. There are some points which must be made, largely to protect the tweeters in such a system, but also to ensure that the system as a whole is coherent, with no one component of the music receiving more or less attention than the others.

3.1 - DC Protection

With a bi-amped system, the tweeters are protected by the mid-high crossover. Once the loudspeaker is tri-amped, this protection is lost, since the capacitor which is used to determine the crossover frequency is no longer present.

With most 'solid-state' amps, this places the tweeter at great risk during the (generally short) switch-on and switch-off periods. As the supply voltage is applied (or removed), most amplifiers will create a DC transient (if such a thing is possible) as the circuitry starts to operate. This causes the all too common speaker thump.

This is mildly annoying when applied to the low frequency drivers, but is capable of destroying a tweeter if allowed to persist for more than a few milliseconds.

In the case of amplifier failure, the tweeter is almost certain to protect any speaker fuse by blowing first - not exactly the desired effect! The "Poly-Switches" now available might help, but I don't like the idea of a non-linear resistor in series with my speakers.

If the direct coupled approach is contemplated, I would suggest the following:

- Use a relay in series between the tweeter and the amp with a suitable muting circuit
- Include a fast acting DC sensor to disconnect the load if amplifier DC is detected

A suitable circuit is available - see Project 33 in my Project Pages, which can be easily be modified to protect tweeters, where its DC detection circuit can be made vary fast indeed.

3.2 - Choice of Capacitor

A humble capacitor will prevent DC from reaching the tweeter voice coil, but the selection is critical to ensure that the sound is not degraded.

Value - The capacitor will almost always have to be at least 20uF, which for an 8 Ohm tweeter, will create a 3dB high pass crossover at about 995Hz. Given that this additional crossover should be ideally 1.5 to 2 octaves from the "real" crossover frequency (even more if possible), the values likely to be needed in real life will tend to get quite large. The reason that the protection cap needs to be so large is that smaller values introduce phase shift, which is significant for all frequencies within 2 octaves of the crossover point.

An alternative (I hope your maths are good) is to use a modified high pass section in the electronic crossover, and then use the protection cap to provide the last pole of the filter. This will work (it will work very well), but the mathematical complexities will be such that I

expect few constructors to go this way.

A further disadvantage is that the electronic crossover cannot simply be swapped for a different type to allow comparisons, and with some filter types the approach will not work at all.

Type - When we contemplate high value caps (greater than 20uF) there is an immediate tendency to think about using a bipolar electrolytic. For this application, I do not recommend them, but sometimes you may have little choice. According to some, they are not recommend for any application, since they are (supposedly) sonically disgusting. I have not been able to measure distortion in a bipolar electro, but there are many who claim that they destroy the sound. I shall not continue this debate.

The ideal is to use polyester or polypropylene caps, since their stability is so vastly superior to bipolar electrolytics that there is no comparison. They also have a comparatively unlimited life, but bipolars gradually lose capacitance (and sometimes not so gradually), thus changing the crossover frequency (or disabling the tweeters completely when they eventually fail.

Good caps can cause some degree of financial hardship, but be assured, that is as nothing compared to the utter despair when smoke is seen escaping from your precious tweets.

If you are on a budget (decent caps at these values are expensive), one possibility is to use power-factor correction or induction motor start capacitors. These used to be oil-filled paper (some still are), and are much cheaper than "electronics shop" devices. I can vouch for the sound quality, as I use these to protect my tweeters - most are polyproplyene are of film and foil construction, although metallised film is probably used as well. The stability and power handling will certainly be superior to that of bipolar electrolytics, and the high frequency response can be corrected (if necessary) by bypassing with a high grade polyester. I would expect that a 1uF bypass would suffice in most cases.

These caps should normally be available from electrical supply outlets, since they are commonly used in electrical (i.e. mains house/ factory/ office) installations.

3.3 - Amplifier

The amplifiers for a triamped system will have a (possibly) profound effect on the final

sound quality. This is especially true of the tweeter amp, which will generally not require a lot of power (depending on crossover frequency). If we assume that the power drops off at 3dB/octave above 1kHz for "typical" music signals, we can do a quick calculation - this is not difficult (nor is it terribly accurate), but will give an idea of how much power will be needed for the tweeters. Note that this "formula" errs on the side of safety (i.e. the tweeter amp will have more power than is really needed), and this provides a good safety margin - a tweeter driver amplifier which is clipping is not likely to enhance the sound quality !

We might quickly re-examine the power of the low and mid amps first, assuming that we have selected the "equal power" low/mid frequency of about 300Hz. For a typical system for home use, 50 Watts for each will generally be enough (especially when you remember that biamping gives the approximate equivalent of double the actual power of the amps - i.e. 200 Watts).

So, for this example, given that we have arrived at using a 50 Watt amp for mid+high, we are now going to triamp, with a crossover frequency of (say) 3kHz. This is approximately 1.5 octaves (it's a little more, but it is not worth worrying about).

At 3dB/octave, and 1.5 octaves, this results in a power requirement for the tweeters of -3 x 1.5 = -4.5dB relative to the midrange amplifier. Reversing the dB (power) formula, it can be seen that the high frequency amp will need 0.35 of the midrange amp's power.

0.35 x 50 Watts = 17.7 Watts, so a 20 Watt amp will be quite sufficient.

3.4 - Class-A Amplifiers

For 20 Watts, we can look seriously at using a Class-A amplifier, something that most of us would die for, but is unrealistic for higher powers.

High power Class-A amps are seriously expensive to build or buy, and create a lot of heat. At the small power of 20 Watts however, they start to become much more attractive. They still create a lot of heat, but since this is proportional to their output power it becomes manageable at low powers.

A typical 20 Watt Class-A amp will dissipate about 100 Watts worst case, and although this is not insignificant, it can still be dealt with by conventional heatsinks and no fan cooling. This is not to say that the heatsinks will be small - they most certainly will not - but 50W per device (assuming transistors) is not too hard to get rid of.

At these powers, one might even consider a valve (vacuum tube) Class-A design, but I would not be inclined to this approach (personal opinion), however it may be that this could make musical magic. It you try it and love it, please make sure that you let me know - I shall include your comments on the Readers' Response page.

Schematic Diagram

Refer to the Project Pages for a design of a couple of transistor 15 to 20 Watt Class-A amplifiers designed for general use, but are ideal for driving tweeters. Includes the design and basic/generic construction details. As yet, I have not had time to test one of these circuits, so final specifications are not complete, but the DoZ is a fairly nice little amp.

Also, have a look at the (now old but still useful) design - 10 Watt Class-A Amplifier (By John Linsley Hood)

4.0 - Correcting Crossover Filter Amplitude Response

When an electronic crossover is used together with the respective amplifiers for each channel, there is always going to be a temptation to experiment with the levels of the filters or amplifiers to act as a sort of tone control. To extract the maximum benefit from bi- or tri-amping, this should not be done, since it will effectively do a few things (all undesirable)

- The crossover frequency will be modified
- The phase relationships between crossovers may no longer be valid
- The frequency response will have peaks or dips (or both) where it should be nice and flat

The optimum settings for the relative gains are dependent on only one thing - speaker sensitivity.

In order for this to make some degree of sense, we must return to our previous examples, and look at a few more diagrams. First, let's look at the ideal, where both speakers have a sensitivity of 90dB/m/W. In this case, the gains of the crossover sections (if gain controls are provided) should be exactly equal. Likewise, the sensitivity of the power amplifiers must also be equal.

In many cases, different amplifiers will be used, often with differing power ratings as well. This is where some measurements are needed, since both amps must have the same gain.

4.1 - Measuring Amplifier Gain

This is quite easy to do, but you do need a single frequency stable tone source - music is of no use, because it is too dynamic so levels are constantly changing. However you might consider the use of a test CD, which will have various frequencies at predictable levels. In many respects, this will be easier to use than any other method, since it requires only that the CD is inserted, rather than dragging oscillators or other signal sources about.

Unless the amplifier is a valve unit, it is not necessary to have a speaker load connected for these tests, or a suitably high-powered resistor can be used as a load if you want.

If a known level (say 100mV) is injected into the input of the amp you are going to use for bass (for example), you will measure an output voltage of about 2.5V at the amplifier output (this represents a fairly typical gain of 28dB). This must be identical for the amp being used for mid+high - assuming that the speakers have the same sensitivity. If the gains are not the same, you must install a volume control on the amplifier whose gain is the higher, and adjust until both amps produce exactly the same voltage at their outputs for 100mV input.

For the test frequency, use an oscillator at about 400Hz, or if you don't have an oscillator at all, you can use the attenuated output from a small power transformer. This will not be as good, but it will work. The frequency will be either 50Hz or 60Hz, depending on your local supply. (If you don't know how to use a transformer to do this, ask someone to help - you can easily damage the input stage of the amp (and the rest of it !) if the level is too high). Alternately, use a test CD as mentioned above.

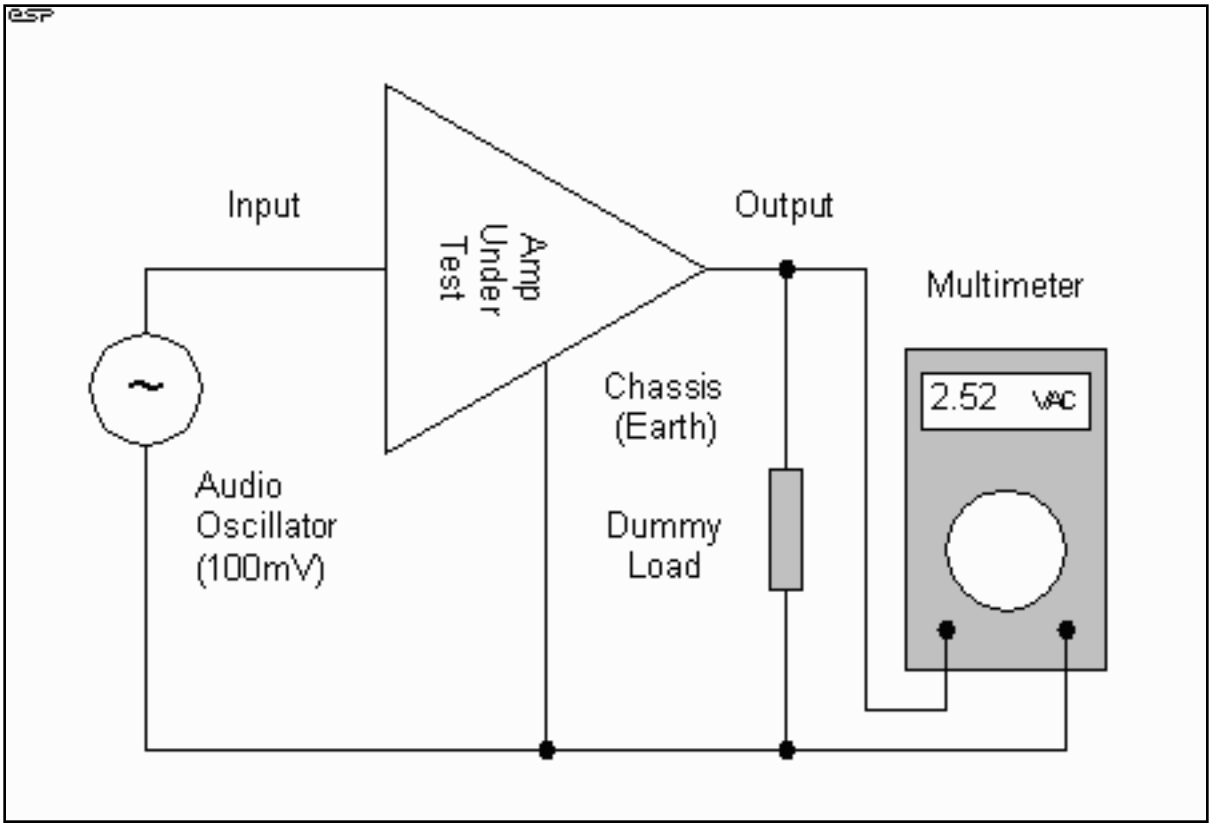

Figure 6 - Test Setup For Gain Measurement

The dummy load resistor should be equal to the speaker nominal impedance, and be rated at 5 to 10 Watts. Do not attempt to operate the amp at full power (especially if rated at more than 20W) into the load, or it will get very hot indeed. If you want to do this, then the resistor power rating should be at least double the expected amplifier output power. (Either that, or use lower power resistors and drop them in a bucket of water - it will not cause a short circuit, fear not).

The voltmeter used may be digital or analogue - as long as it can read the test frequency accurately.

4.2 - Speakers With Different Sensitivities

This is where things start to get a bit tricky. You will need to be able to calculate the required gain to suit the speaker sensitivities - not hard, but you might find that the scientific mode on the Windows calculator is useful (unless you already have a full scientific calc, of course).

Depending upon the crossover frequency, you might need to use a higher powered amp for the bass end, if its speaker has a lower sensitivity. For the purposes of the exercise, we will assume that the midrange (plus high frequency) speakers have a sensitivity of

90dB / W @1m as before. But the woofers have a sensitivity of 88dB / W @1m so we need to calculate the power and gain differences (assuming that the "equal power distribution" frequency of about 300Hz is being used - you want to use a different frequency? If you follow these procedures, you will become an expert at this stuff - guaranteed - because you will have to determine the relative power levels for the crossover frequency you are using - and I'm not going to help !

First, we will calculate the gain difference. Assume that the mid+high amp has a gain of 28dB, so the bass amp needs a gain of 30dB (the speaker is 2dB less efficient, so we just add the 2dB to the 28dB of the mid+high amp).

We will use the same 100mV input signal, so:

Gain = antilog (dB / 20) = antilog (30 / 20) = antilog (1.5) = 31.623

Since we started with 100mV (0.1V), the output voltage must be 3.16V from the output of the amp. That wasn't so hard. Now we need to determine the power output of the bass amp, if it is to exactly match the mid+high amp. Let's assume that we will use a 50W amplifier for the mid+high (with 28dB of gain).

P2 = antilog (dB / 10) * P1 (where P1 is the known power, and P2 is the unknown (higher) power)

P2 = antilog (2 / 10) * 50 = antilog (0.2) * 50 = 1.585 * 50 = 79.25W

Note that with the power calculation, the value of 10 is used, rather than 20 for voltage or current calculations.

We have now discovered that an 80W amplifier is needed with a gain of 31.6 (30dB), to exactly match the amp power and speaker efficiency of the mid+high combination.

Ah. So you have measured the amps, and have an output voltage, but cannot relate him to decibels. Fear not, another formula is at your disposal:

dB = 20 * log (V1 / V2) **(where V1 is the higher (i.e. output) voltage and V2 is the smaller)**

So if you measure an output of 2.32V at the output of the amp with an input of 100mV, its gain is

dB = 20 * log (2.32 / 0.1) = 20 * log (23.2) = 20 * 1.365 = 27.3dB

Note that in all calculations I have rounded the values to 3 decimal places, but when you do the calculations, retain all decimal places available for best accuracy. The difference is not great, but there is no need to introduce inaccuracies for no good reason.

4.3 - The Effect of Amplitude Inaccuracies

To see what happens when the gain is not correct, we need to look at the crossover curves again. Refer to Figure 4 again. This is the optimal frequency response of the crossover/amplifier/speaker combination, with the resulting output being virtually flat (there is a slight rise at the crossover frequency which can be corrected using Linkwitz Riley alignment, where the crossover point is 6dB down - see Project 09)

Have a look at what happens when the amplitude of one filter is different from what it should be. This is shown in Figure 7, and it is clear that the crossover frequency is shifted. What is not so clear is the final frequency response, and in the case of any crossover filter that is not phase-coherent, the adverse effects of the relative phase relationships. These are extremely difficult to quantify, but may be apparent in listening tests. The problem is that if you are unaware of the problems that can be created by modifying gain indiscriminately, it will be very hard indeed to determine why the system just doesn't sound right.

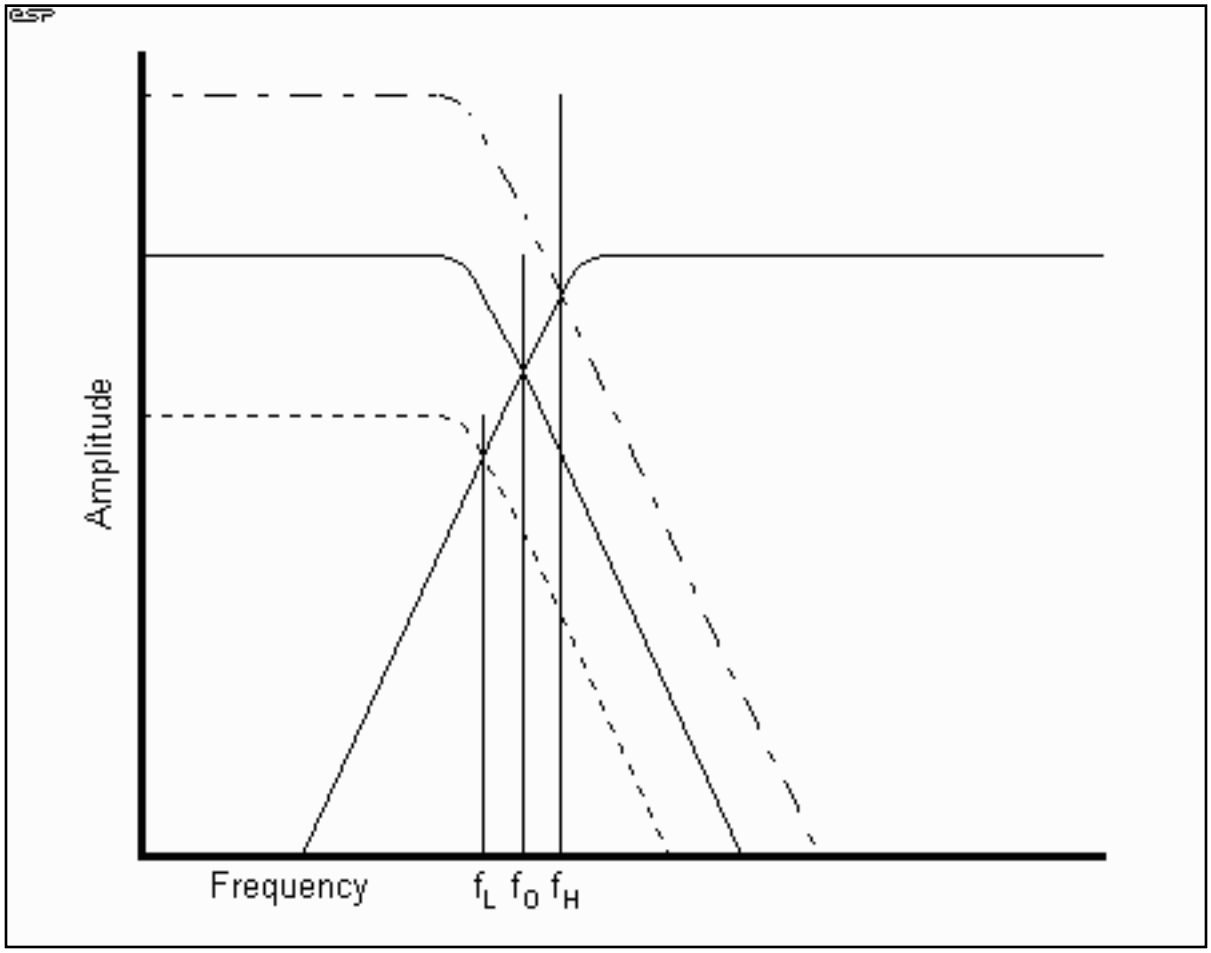

Figure 7 - The Effect of Changing Gain on Crossover Frequency

It is very obvious from Figure 7 that the crossover frequency has changed. At normal gain, the crossover is 295Hz, but if the gain is increased as shown, the crossover frequency shifts up to 500Hz. If the gain is reduced, the effective crossover frequency is now about 150Hz. Naturally, the same thing happens if we change the mid+high gain.

This is not just the output of the filter we are looking at, but rather the final output from the speakers - as shown above, it will often be necessary to change the gain of amplifiers to match the efficiency of the loudspeaker drivers used. This does not alter the crossover frequency as you might expect, but brings it back into proper alignment. In fact, if the gain is *not* changed, then you will get a result similar to that shown, by effectively amplifying one frequency band more than it should be for the correct tonal balance.

4.4 - What Does All This *Really* Mean?

The crossover / amp / speaker combination has to have the correct gain structure if a flat response is desired, and any variations can be quite audible. The audibility varies with

the type of music, and depends a lot on your hearing. In some cases, a slight unbalance can sound better than a perfectly flat system, and can be used to compensate for room influences or personal preference. Some passively crossed loudspeakers have a L-Pad level control for the tweeter, although these are a lot less common that they once were. If available, this does the same thing as changing the amp gain in an active system.

With a phase-coherent crossover, I have found that the ability to use the crossover gain controls as a "tone control" seems to work fine, and there are no real anomalies that I have heard (apart from the obvious prominence of the louder frequency band). This is something I often do with my workshop system. This unit runs from my tri-amped, phase-coherent 3-way variable impedance test amplifier (that's a mouthful). I am forever fiddling with the gain structure, amp output impedance and crossover frequencies, and although not ideal (although it has come close with some of the loudspeaker drivers I have there), it nearly always manages to sound much better than it has any right to.

With a conventional passive crossover network, the correct amplitude matching of the loudspeaker drivers is very important, but is usually fixed and cannot be altered. Even with an active system, correct level matching is not just to ensure a flat response, but to ensure that there are no additional phase problems created by the variations. There will nearly always be phase problems with passive crossovers even where the design is very complex, and these errors must create problems in either frequency response or overall accuracy (these don't necessarily coincide, although in an ideal situation they would).

Amplifier loading is another issue that cannot be ignored. The load presented should be essentially resistive (again in this mythical ideal situation), but in reality this is rare. Using electronic crossovers and separate power amplifiers alleviates the issue somewhat, especially for the mid+high section, but the variable load posed by a typical bass reflex type enclosure is always going to cause amplifiers (minor) problems. Reducing these problems by eliminating a crossover network (or part thereof) can go a long way towards improving the load seen by the amp, and potentially reducing amplifier intermodulation distortion (in particular). The reduction is largely brought about by making the amp work over a more limited frequency range than normal.

In short, there is no reason for a DIY enthusiast to avoid biamping, since the costs involved are very much lower if you make the crossover and power amplifiers. In addition, it is possible to obtain results that are startlingly good, without the considerable difficulty and expense of tweaking a passive crossover network. The latter can easily cost a hundred dollars or more, and if it's not quite right one can easily spend another hundred dollars trying to get it to sound like it should. By comparison, an active crossover costs between nothing and a few cents to change. Need I say any more?

Last Updated 21 February 2006

Main Index

The devices described here *must not* be considered comprehensive, as I am sure that there are a great many additional counterfeit devices available that have either not been discovered yet, or whose purchasers are too embarrassed by being caught by the fraudsters, and are unwilling to admit that they were robbed.

I would like to thank those who have sent information, photos or links to other sites about fake devices. Your continued vigilance will help the fight against these practices. It is a fight that we cannot win, but at least by knowing what to look for, and where the problems have been found, there is at least some hope that we can make it harder for the criminals involved.

Counterfeits Index

The following is a list of faked components identified so far. As noted above, there will be many, many more - these are the ones that people have advised me they have found. You can be sure that *any* high priced component is a candidate for counterfeit fraud, just as the case with clothing, aircraft spares, DVD movies, etc., etc.

- MJ15003/4 Power Transistors
- Sanken 2SA1216 (and presumably the NPN type 2SC2922) - Other similar 'Sanken' devices are also affected
- 2SA1302 and 2SC3281 (Toshiba) Found *all over the world!* The ones seen are all marked Toshiba.
- OP-07 Opamps

- 2N2773 Power Transistors (probable)
- NTE37 and NTE37 (I am told these are equivalent to 2SC2581 and 2SA1106) - not confirmed, but highly suspect
- LM3915 LED VU Meter
- Toshiba 2SA1943 (and presumably 2SC5200) - this had to happen, and was only a matter of time.
- 2N3773 - Allegedly made by someone calling themselves 'MEV'
- MJL21193/4 ON Semi MJL21193/4 (branded Motorola) **Update - 21 Feb 2006**
- 2SA1386 and 2SC3519 Sanken (branded IEC)

... and just in case you thought that this was a conspiracy affecting hobbyists, I suggest a web search - the cost is in $millions, and is spread world-wide! Almost anything that can be faked is being faked. I'm sure everyone has received innumerable e-mails from spammers offering cheap watches, software, drugs, etc. Almost without exception, the goods are of poor quality, and many may not work at all (prescription drugs are a particularly worrying problem - many have zero active ingredients, placing people's health and lives at risk).

The Main Story ...

So, off you go to the local parts shop to buy some transistors (or indeed, other parts!). Having decided the devices that fit your needs (having selected any of a number of devices that are suitably rugged and powerful), you hand over a not insubstantial amount of cash and head home to build the masterpiece. Inexplicably, the expensive output transistors fail, but you know that their ratings are well within the design limits for the project you are building. This happens once, maybe twice, or perhaps more. You get discouraged, and shelve the project - having already spent quite a lot on all the parts needed.

Even worse, during testing, the transistors are (or seem to be) fine, only to fail later taking your expensive speakers with them. Now it is *really* serious.

So is the problem a bad design? Very probably not. Counterfeit power transistors are not only available (again!), they are rife in the industry. Don't bother re-reading that - you saw it correctly. Counterfeit power transistors !!

The first instance (that I know of) was in 1980, when MJ15003/4 transistors were sold under the brand name 'TIC'. These, and many similar counterfeits were in fact 2N3055

and MJ2955 aluminium cased devices, and the counterfeiters had removed the original markings and screen printed the fraudulent type numbers on the cases. Why? Because 2N3055 and MJ2955 devices are cheap, and genuine MJ15003 and MJ15004 transistors are not.

All over the world, people buy power transistors with amplifier kits or by themselves (for example to assemble any of the ESP designs), and they fail. One reader in New Zealand was caught with fake 2SA1302 & 2SC3281 devices, causing his P68 subwoofer amp to fail, and similar stories surface all the time.

Counterfeit transistors cost far more than their monetary value - loss of confidence, time, 'collateral damage', etc. are far worse. I hear these stories typically about once or twice a week, and the only difference is that a new target for the counterfeiters has been found.

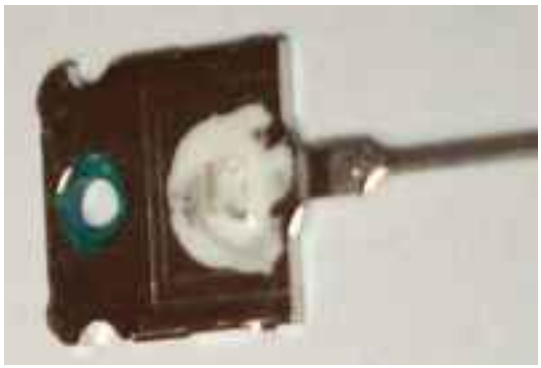
In most cases, I doubt that the supplier has deliberately supplied fake devices, but the fact remains that they have counterfeit stock and people have been affected. All suppliers should, nay **must** be advised immediately if you discover counterfeit devices. It is most unfortunate that so many suppliers have their heads buried so far in the sand (or see below) that they will not believe their customers. It may help to direct them to this page, but some are so far gone that they refuse to believe that counterfeiting even happens!

Supplier Reaction to Counterfeit Claims

For every e-mail I get on this topic, there will be hundreds of other people who don't

know about this page, and who think that the mistake must have been theirs - this is a sad situation indeed!

Fake MJ15003 - Typical



Fake 2SA1302 / 2SC3281

The photos above are indicative of what you will find inside a couple of typical fakes. The MJ15003 has two dies, each about 3 mm square, and simply wired in parallel. As can be seen, there is no heat distribution "coin" - they are simply bonded to the steel case. Motorola (or ON Semiconductor) has never made a power transistor in this way (to my knowledge, or that of anyone else I've spoken to about the fakes).

The situation with the 2SA/C devices is a little less obvious. The silicon die is just visible under a layer of silicone (the emitter and base leads came away with the epoxy, which is why you don't see them). The die is again 3mm square, and is bonded directly to the metal tab. In this case, the tab is of copper, so that part is acceptable. Unfortunately, I don't have an original device for comparison, so if anyone does (preferably a blown one - they are too expensive to sacrifice), I would appreciate a photo or even a description of the insides.

Vigilance

The only thing I can suggest is that you exercise extreme vigilance when purchasing semiconductors, and especially the premium devices. If they are normally expensive, then they are ripe for counterfeiting, since the potential gains for the criminals behind these rackets are very large indeed. Always beware if you see normally expensive devices being offered for sale much cheaper than normal. This is usually a good indicator that something is wrong - and in such cases, the supplier may know full well that he is selling sub-standard parts. This is a criminal act ('intent to defraud' or similar) in most countries, and should be reported to the police.

For many resellers, they are tempted by the low wholesale prices (and may not be

aware that fakes even exist). They see a way to maximise their own profits, . The backlash is that their customers will be bitterly disappointed, and will very likely take their custom elsewhere - a classic no-win situation.

Be more than careful with devices offered at auctions. Not all will be fakes, but you can almost guarantee that a fair proportion are counterfeit. I have had e-mails from a number of people who have purchased semiconductors at various on-line auctions, and the results were entirely predictable. The devices bought were fakes, and there is little or no recourse with an on-line seller who can happily disappear after unloading the goods.

Even some of the more established sellers will (inadvertently or otherwise) offer counterfeit components. Don't assume that semiconductors are the only parts that are affected - a great many polypropylene capacitors are nothing of the sort (they are polyester or mylar), and virtually anything that can be made to look like a more expensive part will be. Even though the individual gain may be small, if an unscrupulous dealer can make an extra ten cents on 10,000 parts, this represents a very worthwhile profit from their perspective.

Counterfeit components are not only those that are re-marked with a different manufacturer's logo and/or part number - no-one has been able to categorically deny that 'bad' batches of parts (where something went wrong in the manufacturing process) are destroyed. The most likely situation is that they are auctioned off as scrap, except the scrap metal merchants may well see a golden opportunity to make a lot more than the would by melting the parts down for their metal content.

Does this actually happen? I honestly don't know, but I would be much more surprised if it does not occur than if it can be shown that it is normal practice (in some countries at least).

To All Resellers - World Wide ...

If you discover that you have been supplied with fake components, come clean and admit your mistake. Otherwise, be willing to prove to your customers that you have never stocked counterfeit components. Please! This is not a big thing to ask, and will go a long way to showing that you value your customers and their custom. If not, you will be seen as the baddies, and rightfully so if you continue to defraud your customers!

All suppliers should be able (and willing) to provide the customer with an assurance that parts have been supplied by reputable wholesale outlets, preferably the manufacturer's

appointed distributor. This applies equally to independent distributors (brokers) who act for equipment manufacturers with 'distress' stock (i.e. stock that will not be used in production), and who supply devices from many different semiconductor suppliers. I suspect that these brokers are one of the main problems, because they will rarely (if ever) be in a position to supply the necessary paperwork to prove the device's authenticity.

This does not mean that no-one should ever use their services, but all end users and retail/ wholesale suppliers must be vigilant to make sure that no fakes are substituted for the real thing. No-one wants to be stuck with thousands of counterfeit components, so they tend to circulate world-wide until they all eventually blow up. The cost of counterfeits to everyone involved is high, and the sooner everyone is aware of the problem, the better.

When discovered, fakes should *always* be destroyed. This will help to prevent circulation, so that the overall impact is reduced. Unfortunately, no-one wants to do that because destruction represents a complete financial loss. Few suppliers are in a position (or will be willing) to suffer the loss - even if it was their own stupid fault for not checking the pedigree of the stock they purchase.

Introduction

Technical colleges, schools and universities - ESP can design and supply educational kits, specialising in analogue electronics projects. Many of the featured projects have been used as student projects at educational institutions all over the world, but specialised projects designed to supplement specific parts of the curriculum can be developed, and either complete kits or just the blank PCB and full instructions can be supplied.

This is a new service from ESP, and I would be delighted to quote for any customised schematics, PCBs or complete kits, for almost any analogue or simple logic based project. As may be seen from the extensive range of projects and articles on The Audio Pages, there are a great many possibilities.

There is a big difference between knowing and understanding, and only by working with things at their most exposed level (discrete circuitry) does a student gain true understanding. A great many projects use ICs - sometimes highly specialised - the student may know how to use that IC (or similar ICs), but gets no understanding of the basic principles. With the passing years, the basics are being lost, with many engineers being unable to even bias a transistor for linear operation.

Examples

For more information and full details, please refer to the projects index - as can be seen, there are projects for construction of ever popular audio amplifiers and preamps, simple mixers, test equipment and lighting applications.

ESP is in a unique position to be able to offer anything from a complete service to just a design and/or a PCB to suit, along with comprehensive documentation. There are very few educational kit suppliers, and most are targetted at complete beginners - ESP can supply educational services for complete beginners, right through to advanced levels.

Some good examples of educational kits are ...

- Transistor and FET Circuits - biasing, different topologies - common emitter, common collector, common base, cascode, compound pairs, darlington pairs, direct coupled circuits, etc. Essential basic techniques for linear operation.
- Voltage Regulators - IC and discrete designs, where the student can learn the basic principles of series and shunt regulation, error amplifiers, series pass transistors, low drop-out circuits, etc. All of these devices are available in IC form, but the inner workings are hidden from view, thus preventing a full understanding of the principles of operation.
- Switching Regulators - again, using both IC and discrete designs to ensure that the student has a complete understanding of the principles of boost and buck regulators, switchmode power supplies, feedback principles, stability and efficiency.
- Operational Amplifiers - IC and discrete circuits, demonstrating voltage and current offsets, biasing, stability, feedback techniques (voltage and current) and output impedance. Filters, oscillators, comparators, level shifting circuits, precision rectifiers, current sources and sinks - the range is almost endless
- Analogue Servo Systems - simple servos that show the importance of servo gain, dead-band setting, etc. Stability and accuracy issues can be seen first hand, and the solutions investigated. Excellent introduction to electro-mechanical systems in general.
- Rectification - using basic rectifier topologies to gain an appreciation for the benefits and disadvantages of different topologies (e.g. half wave, full wave, bridge, voltage doublers, voltage multipliers, etc.).
- Mains Control - phase control using TRIACs and SCRs, zero voltage switching, linear control of AC systems, motor speed controls (servo and open loop systems), etc.

The above is a small sample of the possibilities, and there are obviously many more.

One of the difficulties of educational kits is that they are usually designed with a "one size fits all" approach, and this limits their usefulness. It is also important that the circuits demonstrated should do *exactly* what was intended - they must work flawlessly if properly assembled, and have a wide tolerance for normal component variations.

Further Information

Should you feel that well designed projects to reinforce the theoretical aspects of the curriculum would be helpful, please do not hesitate to contact me with details of your requirements. Having taught electronics, I know how important it is for students to have hands-on practical experience. Although discrete circuitry may well be considered "old hat" by the students of today, they will have a far, far greater understanding of basic principles if they are exposed to them in a way that makes the subject not only interesting, but *fun*. In my experience, people learn faster and better if the subject is fun - it greatly improves attention and (more importantly, retention), since people's minds don't wander very far when they are having a good time.

To contact ESP with any enquiry, please go to the Contact ESP page for details. I look forward to helping you to improve the education of our future engineers and technicians.

Elliott Sound Products **The State of Manufacturing**

By Rod Elliott
(With additional material by Fred Newton and Mark Hammer,
as well as other material suggested by various readers)

Introduction

In one of the sorriest news items I have heard for some time, it was revealed that job losses in the manufacturing sector were the highest of any industry in Australia. Australia is not alone in this, as major companies and corporations rush to Asia to get the lowest prices they can for manufactured goods.

This push is partly because everyone wants their consumer goods to be cheap, and the labour content is the thing that (allegedly) pushes up the price. Cheap goods are not necessarily sold cheap, of course - profit maximisation is another reason to seek the lowest labour rates you can find, while selling the product at the same price.

By way of a direct example, a recent story in the newspaper ... A major Australian airline is getting uniforms made overseas and it saves them $1M / year - supposedly. The effect of this locally is that some 300 people will lose their jobs, so at even the most basic wage, that works out to around $6M in lost wages, plus flow-on effects. Sounds like a real bargain to me :-(

This same airline is now talking about outsourcing their aircraft *maintenance*! Suggested locations are New Zealand, China and Indonesia. I shall leave it to the reader to see the many flaws in this idea, but the world's safest airline is unlikely to remain that way if this lunacy is allowed to continue. It is incomprehensible that anyone could be so bloody stupid to think that this is a good idea.

Is Anyone Thinking?

It seems that none of the major corporations, and even less our governments, are looking to the future - what happens when a country has little or no manufacturing

capability left? This is already happening, and I'm sure that everyone who reads this will have knowledge of a factory (large or small) that has been shut down because the product(s) are being made elsewhere.

So, when we have closed all but a few small-time manufacturers, when the machinery has been sold off (or scrapped!), when everything is being made in the "Far East", where is our independence? What happens if there is a major crisis, and goods (for whatever reason) cannot be obtained? Worse, what will we do when (not if, when!) the cheap labour that we currently enjoy says "Sorry, but we are forced to increase our rates. All rates are now double." The chances are that they will double again soon, and we have absolutely no choice.

There is no competition, since we no longer have any factories capable of making the products, we no longer have the machinery needed to rebuild the factories, and we no longer even have the factories to make new machinery.

Greed

The 'Captains of Industry' (and that is meant as an insult), the stock holders and we, the consumers, are basically greedy - despite what was claimed in the '80s, greed is NOT good - it is selfish and self destructive. In the rush to be cheaper than everyone else, or to have higher profits than everyone else, or maximise profitability and 'shareholder value', most of the Western countries have blithely thrown out the baby with the bathwater.

This is serious. It will get worse. The electronics industry in Australia is decimated, ruined by incompetence and stupidity. Most other manufacturing is in the same position - the clothing and footwear manufacturing industries have been beaten to death, steelworks and shipbuilding yards have closed, and more disappear every day. Both governments and industry alike are to blame for this - and most Western countries are either the same, or heading down the same path of destruction.

Australia (like almost every other country) is still blessed with a few small 'boutique' manufacturers making whatever they can, and usually doing it well - despite government. Is it any different in the US? Europe? It may not be as bad in some other places, but it is certainly unlikely to get better. Very few governments are smart enough to be able to see the inevitable, and the major corporations are just as bad, if not worse. Would these boutique manufacturers be able to fill the void if the cost of all imported goods suddenly doubled? No, of course they couldn't, because they don't have the

machinery, the space or the capital, and even worse, they would be unable to find people to use the machines even if they did have them.

A Definition of Manufacture

It is time for all countries to look at manufacturing differently - manufacture is creation, it is a noble activity, taking raw materials and making something that wasn't there before. The whole concept of 'blue collar' work is wrong - it is not something to be looked down upon and disdained, it should be glorified and revered (Ok, that may be stretching the limits a little, but you get the idea :-)

We all need things to be made. Very few people could make their own car or washing machine, even if they had the tools. Only a relatively small number of people can make their own clothes - even with a sewing machine. The skills that we are losing are irreplaceable - it's not the tools or the materials that make manufacture what it is, it is skill. The ability to use a machine to make something is not 'manual labour' or 'production work' - it is a skill. The fewer factories we have, the fewer skilled people are employed, and the lower the demand for training - this is a self-fulfilling prophesy, and eventually there will be virtually no technical colleges teaching manufacturing skills, because there is no available employment in the industry, so there will be even less demand for the training.

It is the lack of skilled workers more than anything else that will be our undoing. There will be no-one left who has the knowledge of a production environment, the ability to use the machinery, or the logistics of a manufacturing plant.

Cascade Effect

The rot spreads much further afield though - if no-one is making anything, then the engineering suppliers (as well as metals and plastics suppliers) disappear as well. These are the people who would normally stock the raw materials, tools, drill bits, and other strange looking tools that most people have never even seen or heard of, that make manufacture possible (even on a small boutique scale). As these essential suppliers disappear, then it becomes more difficult for anyone to even contemplate starting a small manufacturing business. Large businesses grow from small ones, and these days they don't stand a chance.

The process continues all down the line (as always), and until we wake up to ourselves

and start encouraging manufacture, the situation will become critical - or more critical than it already is.

Large hardware (and electronics supply) stores used to stock things that people would need every so often - in other words, the stock would sit and gather dust until someone needed it. The bean counters don't like that - stock has to keep moving or it's dead. The remaining stuff that is useful on a daily basis is retained because it makes money - it keeps moving, but where does that leave anyone who needs a 19mm twist drill? Out in the cold, is where (and yes, this is a recent attempted purchase on my part - fortunately, a 3/4" drill bit is 19.05mm so I could use that - 3 hardware stores later I found one!).

Needless to say, if one is in need of lathe tools, or a local aluminium anodiser, then you are seriously out of luck. This is stuff that should be available, and if there was a vestige of manufacturing left (other than kitchens and bathrooms - they are everywhere, and don't really count - sorry) then these items/ services would be available.

Years ago, I could get aluminium cut and bent to the shape I needed, then anodised ready for installation of the components that made it into an amplifier. I still can, but I will have to travel a great deal further, have much less choice, and will pay considerably more (allowing for inflation) than I did before, simply because the demand no longer exists - because the manufacturers who used these supplier's services have gone!

This is not about me, or anything I may be doing. This is a general malaise that has struck down a vast number of manufacturers, both small and large.

The DIY Fraternity

Since my pages are devoted to hobbyists and DIY enthusiasts, it is worth mentioning that the DIY fraternity is capable of making a big difference - why buy something that was made somewhere else, uses proprietary parts that you can't get, is designed so that you can't even get it apart without the inside knowledge of the maker, when you can build it yourself.

Add to that the satisfaction of having made it, and the fact that you have acquired new skills and knowledge (which sadly will not help you get a job). The net result is a win - for you because you have something that you made, for the suppliers you deal with because you and your ilk help keep them in business, and for the country, because that is money that has stayed put, and not gone somewhere else across the sea.

This applies to every field of DIY - from wood turning, cabinet making, electronics, knitting - you name it. It is all local content, saves you money, and gives great personal satisfaction. If enough people do it, the difference to the economy and the community can be enormous. The only losers are the large corporations and their off-shore manufacturing plants.

Locally Made - Not Likely

It is time that governments realised what their policies are doing to local industry, and encouraged people to make things, by supporting the local product (not that there is any), and by offering incentives and even inducements ... "We need 5,000 WhatNots - locally manufactured products will be preferred, even if the price is higher."

The taxpayer obviously pays for this, but look at the advantages to the taxpayer - the more industry there is, the more money flows through the economy, and everyone benefits. There is always a flow-on effect, and it is high time that the direction of the flow is reversed.

An example is a small local manufacturer who made parts for commuter trains (this is a true story, but the actual items are not named). Despite assurances from government that local suppliers were preferred, he lost the contract to China. They saved less than AU$1 on each item, which was probably worth an average of about AU$200, and that only got the items landed in Australia - the customer still had to collect them at their own expense (the local supplier's cost included shipment to the works where the trains were built). The local manufacturer is now out of business, with the loss of half a dozen jobs and several lifetimes of accumulated knowledge. This is insignificant in the greater scheme of things, until you understand that it is happening every day - every day a small manufacturer (or several) will go out of business. Lost jobs, lost opportunities, and I'm lost for words!

Meanwhile, governments like to tell us about the 'level playing field' they have created by removing tariffs, and opening our markets to competition. Yes, the markets are open, but the playing field is not at all level. Subsidised transport (etc., etc.) is just one area where other countries can undercut the local product. This so-called 'level playing field has seen the demise of more farmers and manufacturers than ever before - somehow, I don't consider that to be level in any possible interpretation of the word.

Interdependence

We all depend on each other, and your business could not survive without other support businesses - but we are being stripped of one of our most important assets - independence, not from each other, but from the rest of the world. We need trade, but as support, not wholesale replacement of our own capabilities. In times of crisis, we all need to be able to do things on our own, since our major supplier may be the country in trouble (or in extreme crisis, even our enemy).

The oil situation is a perfect example - not everyone has oil to extract, of course, but the outcome is just as predictable with any commodity, whether manufactured or not. If war were to be declared against the country where your car/ fridge/ hi-fi/ dishwasher (etc.) was made, how would you get parts? Would you be considered a traitor for owning something made by 'the enemy'. If no-one in your country made the item in question, what would anyone be able to do without local manufacture? Go without? That is not something we are used to in our society, and it would cause much complaining - and very likely, those who would complain the loudest would be the ones who allowed it to happen in the first place!

Standards

The insistence on 'standards' has ruined a great many small manufacturers too. Not because their products are inferior, but because they have not achieved the required ISO stamp of mediocrity. The standards to a large extent regulate the way you do business, but not how well (or otherwise) your product performs, its build quality or longevity.

This is not to say that standards should not exist - they do help to keep the large corporations (marginally) honest. The small businessman needs integrity to stay in business, not standards. The way the business is operated (provided it is legal, of course) is of no concern - if the employees are happy, the goods are of high quality and the customers are happy, then what possible additional benefit can ISO9000 compliance produce? It certainly won't make the products any better, but it is likely to make them cost more.

Safety standards are another matter, and are in place in just about every country in the world. Daily newspapers and consumer magazines have legions of product recalls - very often because the product was sold without having been tested against the safety standards, or is defective. ISO9000 should prevent that from happening, but it doesn't.

One must also consider the integrity of the overseas supplier. Fake watches, clothing, transistors, aircraft parts and many, many more abound. Is a supplier who may be party to making fake products going to *really* care that the UL, CE or Australian Standard tests have all been properly conducted? Of course not. If they are found to breach the standards of any country, no-one can do a damn thing about it. The factory just changes its name and continues on as if nothing has happened. Countless safety breaches and non-compliance with applicable standards can be found on the Net, and they will get worse, not better.

Safety and the Environment

I have been advised recently (from someone who was working is Asia) that there is another side to outsourcing to developing nations. While I've also seen it myself, that particular penny hadn't dropped when this article was first written.

Most 'western' societies have very strict OH&S (Occupational Health and Safety) standards, and employers are expected to provide a safe working environment for all employees (including sub-contractors). Breaches cost companies dearly, both in bad publicity and financially - heavy fines are imposed for breaches, especially if someone is injured or killed in the workplace.

Likewise, companies that produce waste are expected to dispose of it in an approved manner, and this area is tightly regulated. Breaches can be very costly, since here too heavy fines are imposed for breaches, and the publicity can be particularly damaging. Anything that is even slightly toxic must be handled, stored and disposed of in a manner that is set down in the law. For example, spray painting booths must not allow any 'significant' solvent or particulate matter to escape, and there are very strict regulations that dictate exactly how the solvents and particles shall be filtered, and any waste disposed of.

Naturally, we also have minimum wage standards, compulsory superannuation contributions for employees (only so the government won't have to pay pensions in our latter years, but that's another story), etc. These are all burdens on local industry, but they are necessary to ensure a reasonable living standard, and to prevent screwing up the planet any more than is deemed necessary at the time.

Many of the 'cheap labour' countries do not have *any* of these schemes in place. OH&S is up to the individual - basically "you get hurt and can't work, you don't get paid". Superannuation? You must be kidding. Waste disposal? The recent massive toxic waste

spill(s) in China tell us what we need to know about that. In short, all the things we take for granted are missing. The workers are paid a pittance by our standards, but to them, it's very good money. Why would the employers make life any harder for themselves by employing best practices for OH&S, superannuation or environmentally friendly waste disposal?

Let's face facts here - most of the western corporations would quite happily dispense with these 'unwarranted exploits of their profitability' if they possibly could. Our governments have *imposed* these things upon them, very few are voluntary. Wages and conditions have been fought for over a long period by unions, and although it must be admitted that some union claims are outrageous, many of the benefits we now enjoy were the result of prolonged battles between unions and employers. No employer wants to pay any more than absolutely necessary, and every government or union demand is seen as a threat.

Since our scumbag government recently castrated our labour laws, we have seen a rash of unscrupulous employers 'offering' current employees their own jobs at a reduced wage - or risk the jobs going offshore. This is simply blackmail, and we have lost a significant number of manufacturing jobs recently to cheaper overseas alternatives. Unions in general have nipped such tactics in the bud in the past, but it is getting harder for employees to negotiate a fair deal - and this with the government's assistance!

This is not to say that all union claims (or their own blackmail tactics) ultimately benefit the workers - far from it. Nor are all government impositions well thought out - think of the European Union's 'ROHS' directive (restriction of hazardous substances), and the lead-free solder debacle!

Ultimately (and this is really the whole point), when a critical mass of jobs has gone overseas, the original countries (Oz, US, UK, Europe, etc.), will also lack the critical mass of purchasers. At around that time, the economy simply implodes.

I know the above is a bit of an over-simplification, but the net result is that economies *will* implode, and it will happen sooner rather than later if governments don't act. The signs are already present ... record numbers of bankruptcies, huge debt per head of population, more and more jobs disappearing overseas, and even migrant workers brought in to 'solve' the skills shortage. Why do we have a skills shortage? Might it be that people can see the writing on the wall for manufacturing anyway? Perhaps because the government has done *nothing whatsoever* to encourage apprentice employment? Maybe the consumer society in which we live considers 'manual labour' to be beneath

us? All of the above.

To an extent, we might say that the (major) retailers are true villains in this, but we are also to blame (we believe their advertising drivel, after all). Promote the consumer society, push the latest 'must have' models, squeeze the local manufacturers until they are no longer *capable* of bleeding, and sell, sell, sell (at all costs). Buyers must be convinced that the CD player or TV they bought last year is *so* passé that it must be replaced at once, lest they be seen as 'last week' types.

The time will come when the buyers become sufficiently scarce, and the competition for the lowest price sufficiently fierce - regardless of how insanely low it might be - then the retailers will implode too (it has happened to several here already). As soon as people feel scared for their job security (what job security??), they slow down their spending. All we need is the critical mass ...

Consumerism

This article is not about promotion of consumerism (rampant or otherwise), planned obsolescence and new models every three months. That is the 'model' pushed by large corporations, endorsed by governments and suffered by everyone else. Consumerism is the very thing that has created many of the manufacturing woes we see, and is putting repair people out of business as well. Why would you get something repaired for $150, when you can buy a new one for not much more - or perhaps considerably less?

What happens to all the old ones - whatever they may be? In some cases they will be recycled, but re-use is vastly kinder to our environment. Re-use means using the parts to make something else, or making the product work again so someone less fortunate than ourselves can have one. The economics of this don't make sense any more, because the goods we buy are made to be made - in other words, they are built with the intention that they will not be repaired. The manufacturing process is much more difficult if you have to consider the poor service person who will have to work on it later, so that too is history.

The ever increasing levels of complexity are inevitable, since we expect a new appliance to work at least as well as the old one (not necessarily the case, of course), and new techniques can improve efficiency and the environment is all the better for that. But even if efficiency is improved, if the expected life is reduced, then the net gain will very likely be negative - it will always take far more materials and energy to build a new one than to repair the old, so the alleged economy is false.

As an example, a 10 year old product is still working, and is maybe 70% efficient. Used (say) twice per week for perhaps one hour or so, it uses 1kWh* of electricity per usage. The 'new improved' model has an expected life of perhaps five years, but is now 80% efficient, so uses 0.88kWh per use to perform the same work. 0.12kWh per use is saved (0.24kWh per week), but by the time it has failed, a bit less than 63kWh has been saved compared to the old 'inefficient' model.

* 1KWh - 1000 watts per hour. A 1000W heater operated for 1 hour uses 1kWh of electricity

Since we do not know the exact figure for the energy usage to make the new product, it is difficult to make a fully informed decision, but a reasonable guess is probably not far off the mark. If we guessed that 100kWh of energy were used to make the product (not too unrealistic), there is a net loss of 47kWh for the new model versus the old - it would have to last almost 8 years just to break even. This is not an improvement. The efficiency is completely false, and also fails to take into consideration the energy that was used to make the old one in the first place.

To give you an idea, the iron and steel manufacturing sector is the largest energy consuming industry in the world. As an whole, it uses some 10 - 15% of the total industrial energy consumption. To exchange an old (steel) product for a new one, it will need to last for a very long time, or be extremely efficient before there is a net gain. At present, it takes 350kWh per tonne to smelt steel, which may not seem like a great deal (0.35kWh per kilogram). If an appliance is built using only 10kg of steel, there is 3.5kWh just for the initial production of the base metal. It hasn't even been formed, rolled, cut to the required size or shipped yet.

When all other processes are added in the production of a typical appliance, the energy costs mount up very quickly, since energy is used in every process of manufacture - from the reduction of raw materials into the base material (be it steel, aluminium, glass or plastic), then the rework to shape, mould, paint and pack the product. Then there is distribution, delivery to your home, and disposal of the old unit.

Perhaps manufacturers should be forced to provide not only an energy efficiency rating for new products, but should also indicate the total energy consumption required to build it. This may not directly influence the consumer's decision, but it should, since we all pay for the emissions of power generating plants, by way of greenhouse gases and depletion of the world's resources.

This is not a new topic, but it is more relevant now than ever before. New is 'good' - even

if we have to somehow convince ourselves that it really isn't as bad as we first thought. We are bombarded with advertisements for the latest and greatest product in every category - we MUST have this new improved model (or what exactly will happen? Oh, we may be thought unfashionable ... well deary me! - Hardly a heinous crime in my books

Am I cynical? Of course I am - and you should be too. There is a great deal to be cynical about - we all know that our governments lie to us when it suits them, and look at the large corporations that have collapsed because their web of lies and deceit finally unravelled. Are the remaining ones honest and caring, looking after their customers and employees as they should? I don't have to answer that, because you already know.

The European Union has introduced laws for recycling, but there is already some evidence that these are flawed. Certainly the idea is good, but the idea is in the execution and compliance with the laws. We will have to wait to see if any of this actually works.

The Future

Unless there is a turnaround by big business and governments, the situation will just get worse and worse. The attitude of "why should I make it here, when (somewhere else) can make it for less" has to go. Not that anyone would want to deny the Asian countries their income, but not at the expense of our own independence.

If other countries want to manufacture products, then that is how it should be, but not at the expense of loosing our own ability to make the same thing. It may well be more expensive, but if the quality is equivalent or higher, then a great many people will buy the local product as a gesture of 'patriotism'. Of course, there can still be problems with this. Current labelling laws in Australia are seriously defective (especially in the food sector), and allow importers and retailers to gloss over the truth.

Most countries have had, at some stage or another, a protective tariff on imported goods. This was seen as restrictive, and disadvantaged the consumer who was forced to pay more. All true. In the process, the local manufacturer was able to compete, the protective tariff entered government coffers, and other forms of taxation could have been reduced (I think I must be dreaming now :-)

The fact is that local manufacturing capability is vital, not just to the economy, but for national security. If all (or most) manufacturing is done by a few countries overseas,

what chance does anyone have of surviving a crisis? With no local skills, factories or machinery, where will we turn next when the current major manufacturing countries decide to increase their rates - knowing that we have no choice whatsoever?

Supply and demand is about competition - a monopoly is never a good thing, since there is no-one to compete with, so the monopoly can do whatever it pleases, at whatever rates it feels like charging. We are very close to that situation for many of the products we take for granted - we can no longer make them ourselves, so rely on others to make them for us, blindly (stupidly) assuming that everything will stay the same, and they will be cheap and available forever.

This is not the way real life is - it never was like that, and it certainly is not about to change.

We will pay for the short-sighted and stupid actions of companies and governments, that much is assured. When will it happen? My guess is about 10 years (somewhere around 2010-2015), unless action is taken now. Real, genuine action, not a few half-arsed politicians paying lip-service!

Thanks to a friend in the US, who does consultancy for manufacturers, I can add his perspective to this discussion. Fred Newton supplied this very revealing insight into the real economics involved when manufacturing is moved off shore or across the border.

My Thoughts on The State of Manufacturing (By Fred Newton)

In the US, the actual 'touch labour' portion or the percentage of 'Total Cost to build' of most consumer goods averages in the 17-20 % range. As an example let's take one of the popular brands of computers that is currently being marketed on a global basis. With an average delivered C.T.B. (cost to build at the factory level), price of US $350-$400. The portion of this that is actual touch labour is about $23.00. This is 5.75- 6.5 % of the shipped cost. The remaining cost is distributed between overhead, materials, and warranty, with materials on this specific product generally having the higher remaining percentage.

Now let's relocate this to a eastern rim country where the $23.00 decreases by $18.00 to an equivalent US$4.85 C.T.B. and the touch labour percentage of the new C.T.B. changes to 1.28 - 1.4% of the shipped cost. The new shipped cost is US$332 - $377.00.

Digging deeper into these numbers shows an average decrease in actual C.T.B. of 3.47% to 5.1%. Not a big number by itself, but there are other MAJOR costs that have not been discussed here so far. (Sorry for the economics lessons, but this dissertation is VERY important to all of us on a global basis!)

An average plant relocation from the US to an Eastern Rim country or to Mexico is in the $Hundred of Millions range. One recent plant relocation cost was well over US$200M. So if we begin to look closely at these large, no - *huge*, relocation costs we quickly begin to wonder where the profit is going to come from! At a marginal increase in profit from the slightly decreased labour cost it will require the relocating company to build and sell more than 11 million units to pay off the cost of the relocation, and start making a profit.

Now without going a lot deeper into this in numbers, it will take the company an average of 2-3 years of full production just to break even, and then only if the volume of products at the same quality level exists. If you add into the equation the required learning curve for the new location assemblers the 2-3 years changes into 3-4 very quickly. So where is the profit?

New Mass Market

In most countries around the world for a product to be sold there a certain percentage of that product is required to be manufactured there. With many of the more highly industrialised countries having had the current technology products available to them for the past twenty or more years, these markets are becoming saturated. The forecasted annual percentage of sales is MUCH lower in these replacement markets than for countries like China and Mexico where less than 1% of the population owns any of the modern products they are now manufacturing.

So ... to reduce all of this down to one line, the companies are relocating their products to the new MASS markets, and couldn't really give a damn about the livelihood of the country and its work force that allowed them to grow large enough to be Globally positioned as they are today!

This feeding frenzy is solely for the primary stakeholders within each of the organisations. Enron and the glut of centralised wealth that STILL exist within its senior staff members is a perfect example of lack of any sort of feeling for anyone other than themselves.

The real sad story here is that this is only the start of a vicious cycle! The economy

within these new countries will surely improve with the boost of the economies from these new jobs.

As the new (near poverty) workers get enough income to have purchasing power for more than the bare essentials, they will start demanding, (sound familiar?) a larger portion of the pie! There go the big new profit margins!

The corporations will then start looking for fresh masses to take advantage of. Guess where they will find them? Right back in the old locations where they were in the beginning! These economies will have been depleted from the relocation of their livelihood in the past, but this time it will most likely be the second generation workers of the original employees that supported the growth and development of these remaining companies originally. The first generation will have died off in the meantime.

I think the bottom line from my prospective is that the primary international Corporations are all short term gain oriented, with little or no long term growth and gain goals.

Now, I said at the beginning of this section that this was the US perspective, but it's not - it applies equally to all of the industrialised countries, all driven by greed, and the shareholders wanting more, more, more.

When are corporations going to realise that the shareholders are primarily gamblers ... they don't care about the company, its employees or its customers, only themselves. It is high time that management digs in its heels, and simply says "No!" to the ever increasing demands of the wealthy gamblers, who will buy and sell stock on the same day if it makes them a profit. Does anyone really think that this effects the way a company should do business? It is illogical in the extreme when a corporation sacks or retrenches a thousand workers, and the share price goes up. This is not business, it is just gambling, but gambling at the expense of the very people who made the corporation in the first place. A business without workers is a non-business, just like a worker with no job is a non worker.

There is supposed to be a mutual trust between the employer and employees, and in a few companies this still exists. For the vast majority, the worker is merely a pawn in a big game that no-one seems to really understand.

The smaller shareholders will eventually do well, if (and only if) they allow a well run company to do what it knows how to do best ... make its core business work, for the ultimate benefit of the employees, and following as a natural progression, the customers

and everyone else (such as the shareholders).

For the gamblers, they can feel free to visit their local bookmaker and gamble properly, rather than manipulate the odds in the stock market - let the people who actually create goods and products or supply services (i.e. The ones who actually make the economy work) get on with their jobs and lives.

As soon as any corporation stops looking to the future (not next week or next month, but a year - 5 years ahead), it immediately loses focus, and in the blind rush to try to keep up with the competition's share price, dishonest and illegal practices become common - until the whole thing falls in a pile - Enron, Worldcom, HIH Insurance are just three where the greed and corruption was exposed, and where the companies either folded or were disgraced. The loss of jobs, business confidence and the pain of the small investor are inestimable.

Why does a company try to insist on 30% growth per annum? 50%? To what end? Surely, the idea of business is to provide people with their needs - jobs, products, security. They don't care about these things any more, and look at the state of the world. Big business corrupts government if it suits it to do so, and we are able to see a pattern emerge, where the rich are very, very rich indeed, and the poor are exploited because they can't afford to fight back.

This is not an ethical way to run a business, a country or a planet - I think that it's high time that we all say that enough really is enough. Everyone has a right to a share of the pie, and making sure that the share is more evenly divided than at present is a good start.

No-one, absolutely no-one, is so smart, so good at what they do or so indispensable as to be actually worth 10 or 100 times (or even 1,000 times) what you or I would be paid for our job. Why should a worker, who knows his/her job and does it well, be paid $10/ hour, while someone else gets perhaps $100/ hr and another $1,000/ hr - in the same company? For some others, they wouldn't get out of bed for less than $10,000, let alone actually do any work. Are these people really that important, clever or hard-working?

No-one will deny that a CEO of a large corporation has a stressful and difficult job, just as no-one will deny that just about every job these days is stressful and difficult. There is not a person on this planet who is a thousand times smarter or better at his/her job than you or I, or who works a thousand times harder or a thousand times faster. There is obviously no reason that these people should be paid a thousand times more, nor 100 times more. Even at the other extreme, do you know anyone who is really (only) 10

times better, smarter or faster than you are?

No? I didn't think so.

Mark Hammer from Canada provided this additional insight, and has made some good observations that explain the malaise we see. His comments refer mainly to the actions of the stock market, and its effects on the small investor - these are the people who are often (financially) hurt badly by the "buy, buy, sell, sell!" antics of the gamblers, and the corporate attempts to satisfy what I believe is entirely the wrong sector of the market.

Economic "Rationalism" (by Mark Hammer)

The manoeuvrers that the corporate sector and their economist henchmen carry out are generally all in the name of good intentions. I work in government here, right in the same building as the ministry of finance, the treasury board and scads of economists, in the long shadow of parliament, and in the den of lawyers. They're all good people, but the majority have it wrong when it comes to the relationship between economy, economists and statesmanship. A thriving economy is certainly a worthy goal of a nation, but economic policy is not isomorphic with statesmanship.

So, these busy little beavers toil away on policies and negotiations designed to help 'the economy', often neglecting other things that matter. They believe they are doing the right thing, certainly cast no doubt in the minds of the corporate sector as to whether *they* are doing the right thing, and everyone sleeps soundly at night believing in what they believe in.

Western industrialised societies rest heavily these days on a number of things. One is certainly rampant consumerism and the mistaken equivalence between consumerism and 'progress' (''Hey, **my** phone has 10 brand new ways to annoy me, provoke rudeness on my part, require installation of new transmission lines, require teeny tiny fingertips, and generate embarrassing ring tones on the bus''). Another is certainly the disposable income of working adolescents (though this varies between North America and Europe). A third is the concomitant rise of retirement as a social institution and the stock market (and day trader) as the handmaiden and partner of retirement.

The stock market has always been there, and many people have tucked a little into the market for a few extra dollars. What has changed in the past 50 years is the concurrent increase in the duration/ length of the retirement period for many, the increasing duration

of what one might call the 'preparatory' years prior to establishing oneself (including college, university, and the usual adolescent tendency to try to escape the rat race entirely, until it becomes all too obvious that this is *not* going to work out in the long term). The net result is that a generally smaller portion of one's life is spent earning a decent wage.

The need to amass a personal net worth (current and future) which can provide for a retirement at the socially expected age leads many to either invest much more heavily and nervously than similar persons might have done in 1960 (when retiring at 65 or 67 was considered within the bounds of normal), or to be part of a work-related pension plan which is under pressure to deliver promised benefits. Indeed, retirement plans, pension funds, and personal nest eggs for the purposes of retirement make up a much larger chunk of the stock market than they might have many years ago. A lot of this money is related to retirement in opaque ways. For instance, when a bank issues guaranteed investment certificates, chances are that many of the owners of those GICs have purchased them expressly for retirement income purposes. The pressure on this money to perform is immense.

Correspondingly, the pressure on the organisations invested in to perform is similarly intense. I like to refer to this as 'nervous money'.

So what happens to 'nervous money'? Well, for one thing, to retain investors who are anxious about generating the kind of ROI (Return On Investment) that will keep them in the consumer style to which they have become accustomed - even after they don't work for a living any more - the profit margins have to be robust ... and the BS thick and savoury. My sense is that companies and boards of directors, elect to move, globalise, restructure, merge, buy out, down size, and do lots of economically and spiritually disruptive things in the name of retaining their investors.

Sometimes these moves are intended to increase profits, and sometimes they are simply intended to create the impression of the potential for profit (the stock market being mostly make-up, girdles, and falsies :-).

Whatever the case, if so many of these investors were not people who look at their money and see 25 years of their post-retirement life, it would be a different story. You will note that a good many of the folks who got stung by Enron were, in fact, stung for their retirement savings. I.e., they stuck with Enron and believed the BS because their need for retirement income urged them to. (This is not 'blame the victim' here, just trying to provide an aetiology of the current malaise).

The long and the short of it is that many of the things you mention are, to my mind, either direct consequences of nervous money or the spin-off to helpless victims (e.g., small non-public companies) who get caught in the wake of larger public organisations doing the kinds of things that nervous money does, like move out of country. Of course the countries where nervous money moves to are generally *not* replete with folks who are looking to invest their wages in retirement funds and pension plans because they actually don't *have* retirement as a social institution there - one would expect the financial planner business in many so called "third world" countries is rather slow - or certainly don't have early retirement as some kind of droit de seigneur.

I live in a town that has two major employers, civil service and telecommunications. Nortel, JDS Uniphase, and Alcatel are all situated here, as are Corel, Cognos and several other software places. Every day on the news, they list how local stocks are doing - something I don't remember hearing on the news as a youth. Do people actually know what the products of these organisations are?

Sometimes I'm not so sure. There are many days when you'd swear that their major business line was their stock. That companies can show huge leaps in stock value simply because the losses this quarter were not quite as bad as the same quarter last year (something which still baffles me) underscores the notion that folks care more about the stock than about what the company actually *does*.

Now I believe with all my heart that there ARE conscientious brokers who caution their clients to be patient, to accept the slow burn as opposed to being dazzled by risky high yield investments, to invest in companies that are more ethical, that give their commitment to local industry and don't simply chase money whichever border it happens to cross in its drive to evade taxes or fair wages. They're out there, but not everyone uses them.

What sorts of reasoning do the folks who invest multi-billion dollar teacher retirement funds apply? I have money in one of these, and I honestly couldn't tell you. I imagine the same goes for a lot of pension funds.

I suspect many folks who do public sector work 'for the good of humanity' would be quite surprised to know what their pension fund is doing and the kinds of corporate moves that may or may not have been provoked in an effort to hang onto that investment money. Has General Motors or John Deere closed plants locally and moved them south in order to show a higher profit margin or otherwise retain my TIAA-CREF contributions?

I certainly don't blame folks for wanting to retire, and I don't blame them for wanting to retire without being poor. That being said, however, if there are trickle-down effects of the kind of investment patterns that result from the way that social trends impact upon industry and the economy via the stock market and the nervousness of money, then I think people ought to take a moment to think through the choices they make, know more about the impact of their choices, and make some decisions. It's a *long* way from deciding to retire at 62, to the availability of decent potentiometers locally, to the living conditions of someone in a developing nation. But they ARE linked, even if by a great many intermediate stages, and one should consider one's values and the social repercussion of personal choices before making them. Yes, it's only one person, but one more person doing something is a lot different from one *less* person doing it.

Mark said that he often wonders is people know what the companies around them (or in which they have investments - knowingly or otherwise) actually make or do, and I am convinced that for the most part, the answer is "no". The same applies to the stock market, where investors (gamblers), know only that the company may have something to do with 'technology' - what they do with that information is based primarily on whether technology stocks are deemed 'good' or 'bad' on any given day.

The above is only one example, of course - similar 'decisions' are made on stocks of chemical companies, cigarette manufacturers, drug companies (making 'quit smoking' drugs :-), or anything else in the market. The problem is not with the small investor, the ethical investment broker, or the company itself. The greatest problems are created by the 'get rich quick' gamblers, who will artificially move a market based on rumour, whim or God only knows what, and cause a cascade effect that effects everyone else.

The company whose stocks are affected will then try to take 'remedial' action, which as often as not, is ill informed, and aimed at the wrong people. People lose their jobs, retirement funds, or in extreme cases (but sadly on the increase) their lives - the loss is more than they can handle, and they commit suicide.

The gamblers are of little consequence, and their actions are destructive to the company, its employees and its customers - should they lose their fortune, no one will care. That their actions can cause - directly or indirectly - the downfall of an entire corporation is deplorable, and it is high time that all companies (and governments) started looking to those who matter - those who are involved for the long term, and ignore the antics of the high flyers - let *them* crash, not the company or the economy.

1.0 - Introduction

This article will help those who have built an amplifier that just blew up for no apparent reason. It will also help those who are planning to build an amplifier, either from the ESP projects pages or elsewhere. Contained herein are answers to questions such as "why can't I use the P3A amplifier at +/-56V, or a single board P68 at +/-70V". These questions are common, and it is always good to know why something is so.

While this topic is also covered in the Safe Operating Area article, there is less detail in this present version, making it somewhat easier to read - especially for novices. In this case, I have concentrated on the specific effects of phase, and once this is understood, I suggest that you tackle the full version above.

While it is generally understood that a typical loudspeaker has an impedance (as opposed to resistance), the implications of this are not widely understood. Many of the designs

featured on The Audio Pages appear to be over-engineered, and the number of output devices seems excessive for the claimed output power.

This is entirely true! ... and for a very good reason ...

2.0 - The Loudspeaker Load

The problem with real loudspeakers is that they refuse to act like nice, well behaved resistors, and the impedance changes from being resistive, inductive and capacitive, depending on the frequency. Let's look at a typical speaker, whose equivalent circuit and impedance response are shown in Figures 1 and 2.

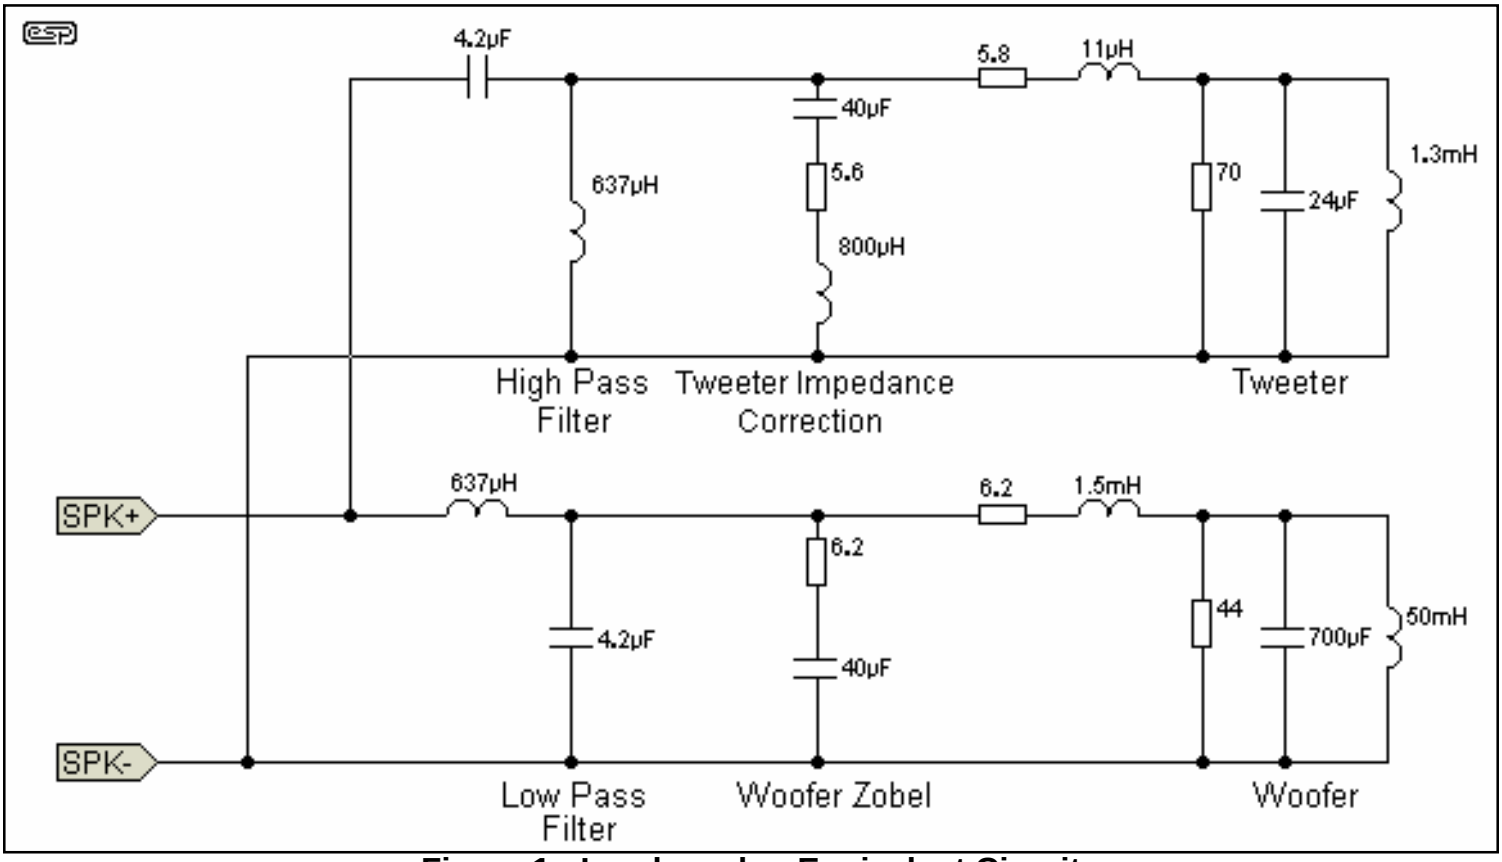

Figure 1 - Loudspeaker Equivalent Circuit

While it may look complex, it is simply a reasonable representation of a typical 2-way loudspeaker, having an impedance correction network to eliminate problems caused by the tweeter's resonance, and a basic Zobel across the woofer to damp the rising impedance cause by its voicecoil inductance. The crossover network is a conventional 12dB/octave parallel design.

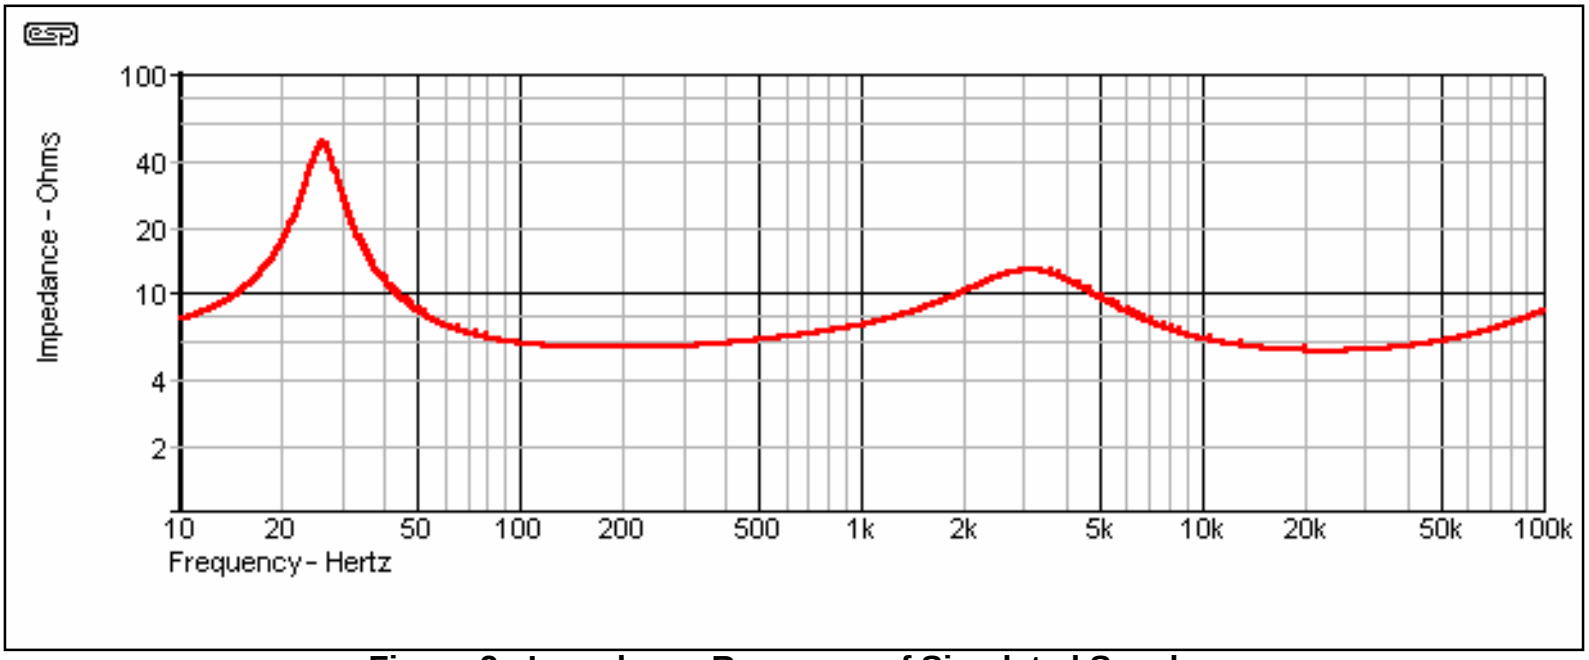

Figure 2 - Impedance Response of Simulated Speaker

Well below resonance, the system appears mildly inductive, with the inductive reactance component rising with frequency. At resonance, the load is purely resistive, and is at a relatively high value (typically from 20 to 50 ohms). Power at this frequency is very low - a 100W amplifier (8 ohms) will deliver less than 20W (19.6W to be exact) into an impedance of 40 ohms.

Above resonance, the load seen by the amplifier becomes capacitive, and impedance falls rapidly, eventually 'bottoming out' at some frequency (typically around 200Hz or so). This is the loudspeaker's 'nominal impedance' as quoted by the manufacturer. The impedance then starts to rise again as the voice coil inductance becomes significant. The crossover will almost always introduce further phase anomalies, and as you will see, any time the impedance changes, so too does the phase.

As long as the impedance is predominantly resistive, the amplifier has a relatively easy job, with voltage and current in phase, and amplifier dissipation is at the minimum possible for a given output power. The problems arise close to resonance - either above or below, where the load is highly reactive, or anywhere else where the impedance changes. Note that a vented enclosure has a second low frequency resonant peak, and the amplifier sees exactly the same reactive loading around the peak introduced by the vent tuning.

The worst case is that the amplifier sees either pure inductance or pure capacitance. Under those conditions, the voltage and current output from the amplifier are 180 degrees out of phase. Fortunately, this never happens with a loudspeaker.

2.1 - Phase Angle Vs. Transistor Dissipation

Although it may seem impossible (or at least highly unlikely), the voltage and current into anything other than a resistive load will not be in phase. Capacitive loads have a 'leading' phase, where the current waveform occurs first, followed by the voltage. Inductive loads have a 'lagging' phase shift, meaning that the current lags (is behind) the voltage.

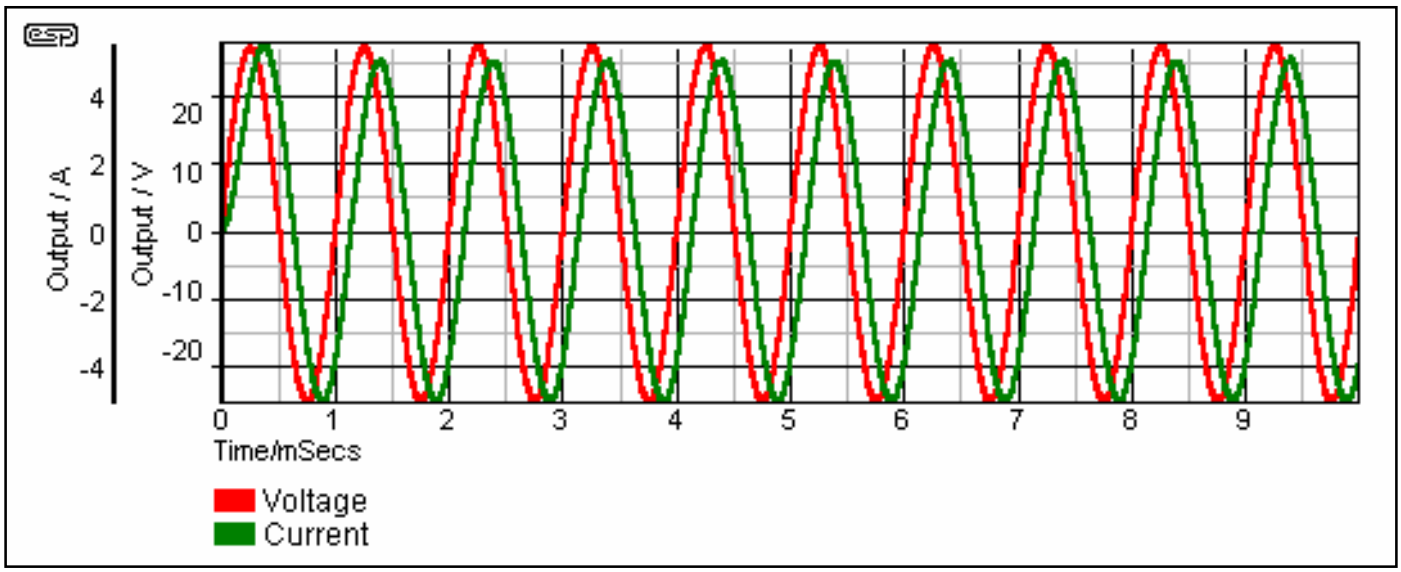

Figure 3 - Phase of Voltage Vs. Current With Reactive Load

As you can see, the voltage comes first, followed by the current (lagging power factor because of inductive load). In this case, the phase angle is a little over 45°, and was simulated by placing a 700uH inductor in series with the 4 Ohm load resistor. While not exactly the same as a loudspeaker load, it is good for simulations as it enables accurate determination of the peak transistor dissipation.

It must be understood that these conditions are steady state - the signal has to be present for a sustained period before the voltages and currents achieve their steady state values and relative phases. The actual time needed varies, based on the damping applied to the system, and many other factors, but in general, about 3 to 4 cycles will actually be enough. Normal music will easily be able to set up the necessary conditions for the voltage and current to be out of phase with any loudspeaker system. Let's have a look at the phase response of the speaker system shown in Fig 1.

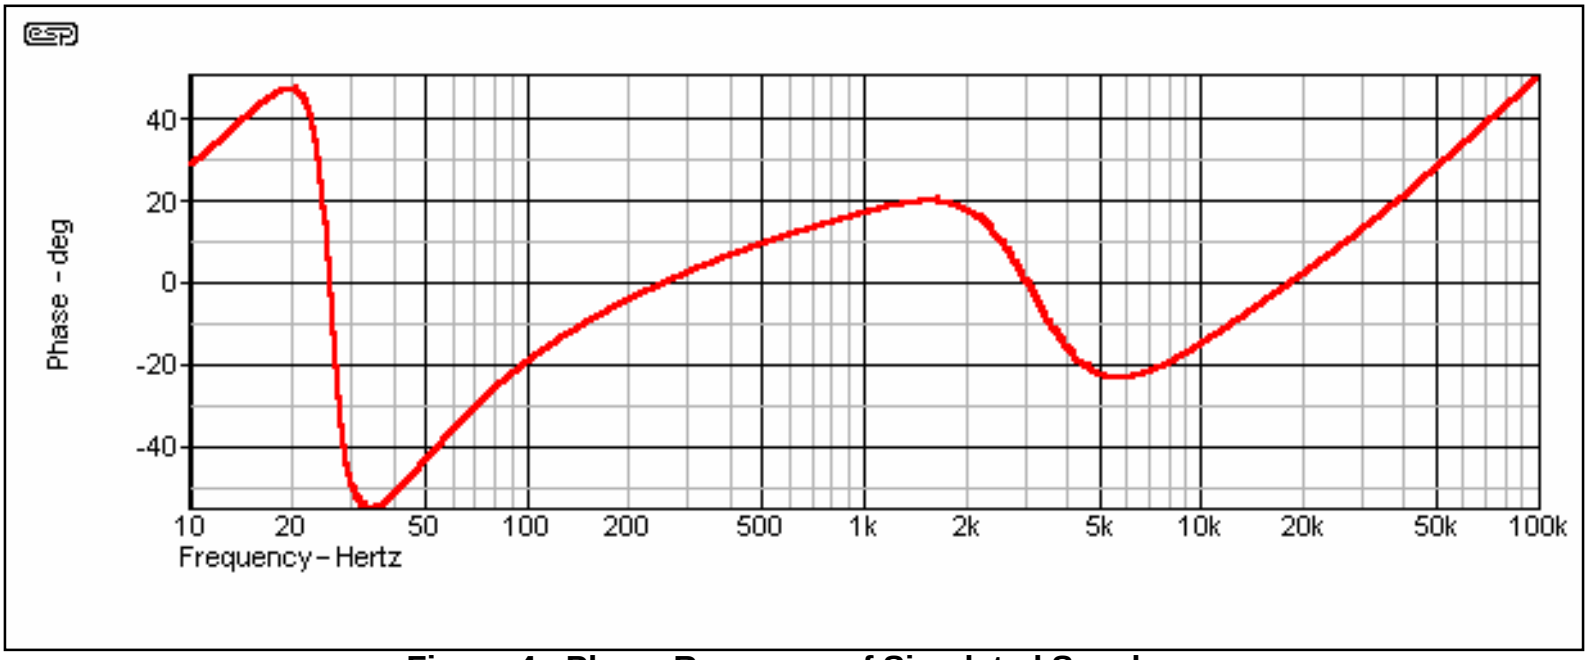

Figure 4 - Phase Response of Simulated Speaker

As you can see, the phase varies over approximately +/-50 degrees, and while this is fairly realistic, some speakers will exceed this. The majority (and especially mid-woofers as used in most 2-way systems) will have a phase response of +/-45 degrees or so, and some will be even less. It is worth noting just how little of the frequency range appears resistive - the phase angle over the majority of the frequency range is greater than 10° in one direction or the other.

Assume a 100W amplifier and a nominal 8 ohm load. Full power output is reached at a voltage of 40V peak (28.29V RMS). Maximum current is 40 / 8 = 5A peak or a little over 3.53A RMS. This is exactly the voltage and current at full power into a resistive load, and the peak transistor dissipation occurs at 1/2 the supply voltage.

At an instantaneous level 20V into 8 ohms, current is 2.5A, and transistor peak dissipation is 20 * 2.5 = 50W. If voltage and current are out of phase, the power delivered to the load is decreased, and the power dissipated by the transistor is increased.

Worst case (never achieved with any loudspeaker), is a 90 degree phase shift. This means that when the voltage across the transistors is at the minimum (turned fully on), the current is also at a minimum. That seems pretty good - zero dissipation can't be all bad. The problem is that the converse also applies, so when the voltage across the transistor is at the maximum, so is the current!

Assuming zero losses, that means that when the transistor has the full 40V supply across it, it is simultaneously supplying the peak current of 5A. Instantaneous dissipation is therefore 40 * 5 = 200W.

So, where it appeared that a 50W transistor was quite adequate, it is obvious that it will fail under these conditions. Add to this the fact that transistors have a SOA (Safe Operating Area) that limits the peak dissipation to the maximum rating or less (depending on voltage and current), and it is easily seen that more powerful transistors must be used.

Now, I stated earlier that the 'worst case' was never achieved in practice, and this is the only thing that saves us. In reality, the voice coil resistance is always in circuit, and this limits the maximum phase angle.

Looking back to Fig. 1, you can see that the voice coil resistance is not 8 ohms as you might expect, but 6.8 ohms. This resistance is the only factor that stands between your amplifier and a 100% reactive load, and the typical phase angle as a result is a little over 45 degrees. The speaker in Fig. 1 has a maximum phase angle of about 50° - not an unrealistic figure.

At 45 degrees, the transistor peak dissipation is doubled, compared to the case with a resistive load. This means that for our 100W 8 ohm amp, the transistor dissipation will be 100W instead of 50W - any increase of phase angle over 45 degrees increases the peak dissipated power vs. the power delivered to the load. It is fair to assume that the 'real life' worst case phase angle will be around 60 degrees, and will occur only near (above or below) resonance, or around the crossover frequency.

Table 1 shows the relationship between phase angle (the difference between voltage and current, measured in degrees), peak power dissipated in the amplifier and average power delivered to the load, normalised to 1W. The type of amplifier is unimportant - transistors, MOSFETs, valves or magic - all are affected equally.

Note that peak power is *not* the average power - these are entirely different things. Average power is used to determine the heatsink requirements, but peak power is the killer of bipolar junction transistors (BJTs) due to second breakdown. MOSFETs and valves will survive these momentary peaks without complaint - BJTs will not!

This table is for peak dissipation at the onset of clipping, and the situation is very different at worst case output level (¼ the maximum power, or ½ total voltage swing).

Phase Angle	**Power Factor**	**Power (Amp)**	**Power (Load)**
0	1.000	1	1
15	0.966	1.38	0.94
30	0.866	1.76	0.75
45	0.707	2	0.5

60	0.500	1.66	0.24
75	0.259	1.2	0.08
90	0.00	4	0

Table 1 - Power Factor, Normalised Amplifier/Load Dissipation Vs. Phase

Power Factor has been included, not so much because it is something you specifically need to know, but because some knowledge of it is likely to be useful. Power factor is determined by taking the cosine of the phase angle, and is essentially a 'figure of merit' for an AC load.

The 'magic' figure of 45° is worst case with typical systems, where the transistors must dissipate double the normal peak power, while the load only receives half the power it would normally get. Note that the amplifier peak dissipation *appears* to fall after 45 degrees - this is only because of the increased impedance presented because of the reactance. While these figures are reasonably accurate, it must be understood that the situation varies depending on output power and supply voltage - there are a great many variables, and it is not practical to try to cover them all.

The load power is interesting. Notice that at 90 degrees, there is zero power delivered to the load! There is voltage and current (referred to as VA with transformers), but no power, so no physical work is done - the speaker would be silent. This phenomenon is well known in the power industry, and is called power factor. The ideal case is a power factor of 1, where every volt and amp is converted into work - heat, light or rotation (for example).

Obviously, the worst case is a power factor of zero. Volts and amps are readily measured, yet no work is done, and the electricity meter remains still. The majority of real loads are somewhere in between, and the loudspeaker is no exception.

This is all the proof that is needed that a 90 degree phase shift never occurs with a loudspeaker load (i.e. the load is never pure inductance or capacitance). Although the sound output from a subwoofer at 20kHz is very low, this is due to many factors - none of which involves a power factor of zero. It is beyond the scope or intent of this article to discuss this further, so I won't.

The essential point here is that any power amplifier must have sufficient reserve power in the output (and to a lesser extent, the driver transistors as well) devices to handle the maximum possible dissipation. In real terms, this always means more output devices than you anticipated.

2.2 - Test Design

Let's assume that we want 100W into 4 ohms, based on the design of P3A. That means 20V RMS, or 28.2V peak. Assuming no losses, we shall use a power supply of +/-35V. Peak output transistor dissipation at 110W into a 4Ω resistive load is 70W, at an average of just under 23W (each transistor - 46W for the pair). This represents an easy load for the amp, and could easily lull one into a false sense of security.

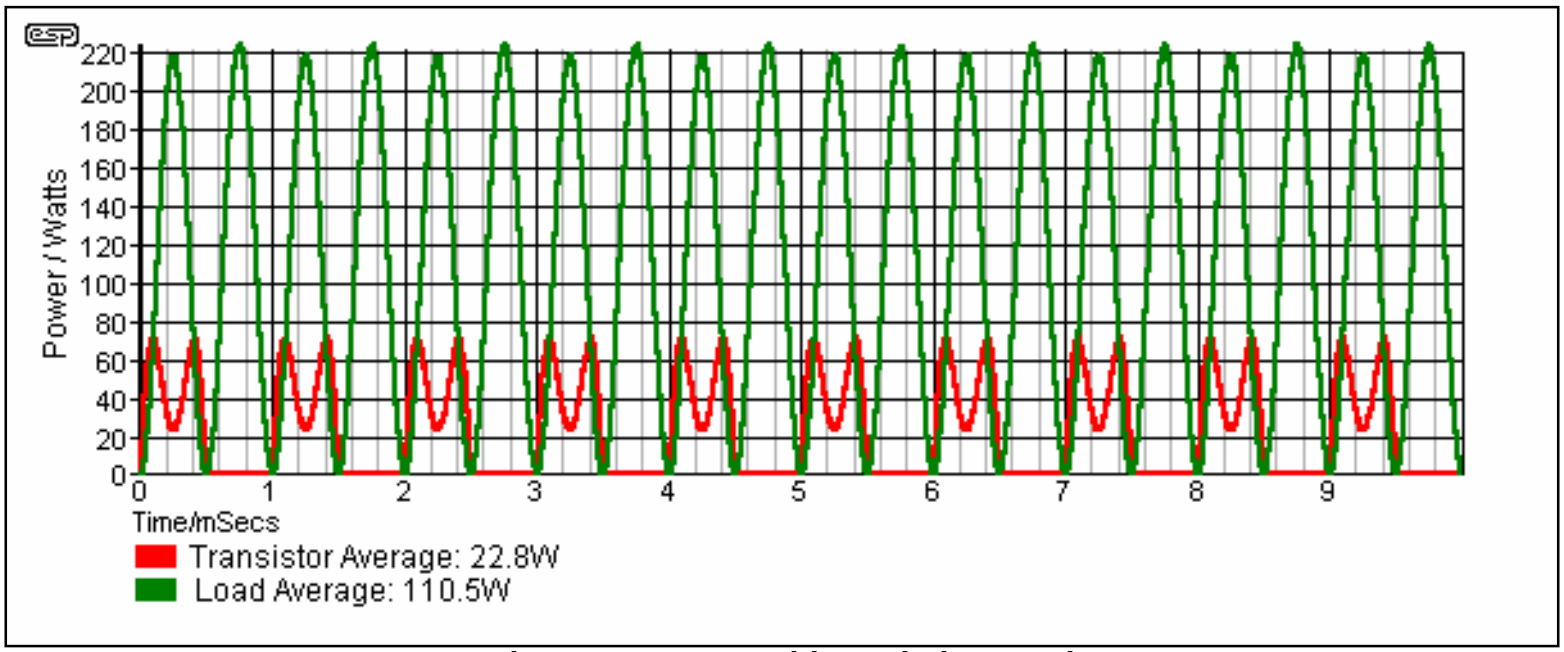

Figure 5 - Power With Resistive Load

Worst case power dissipation (resistive) is actually at around 0.707 of the maximum output voltage (½ power), or 14V RMS. Peak transistor dissipation is still 70W, but the average power increases to a little over 28W because of the way amplifiers work (this topic is covered in greater depth in the Amplifier Design article). This is not a large increase, but every Watt that needs to be disposed of means a greater load on the heatsink.

It is not unreasonable to design for a worst case phase angle of 45°, and as shown in the table above, power actually falls slightly above this. At 45° the peak dissipation is as shown in Figure 6 - this is where things can go pear-shaped in a hurry if you underestimate the operating conditions of a real-world amplifier. Transistor dissipation just before clipping is a bit over 120W (with an average of 28W). Any increase of the supply voltage will push the repetitive peak dissipation into the danger zone - especially when the power transistors are at an elevated temperature.

The above is based on a ±35V supply, but if you increase this to ±42V, at 4 Ohms reactive the peak dissipation will be over 200W ... the maximum rating for the transistors ... *at 25°C!*. Since it is highly unlikely (impossible, more like it) that the transistor die will be maintained at 25°C, the device must also be derated accordingly. Therefore, P3A cannot be used at 4 Ohms with a ±42V supply (something I have been claiming all along).

The bottom line is that to deliver 100W safely into 8 ohms, and allow 4 ohm operation, you need 400W of available transistor dissipation to ensure that the transistor SOA will not be exceeded at any time.

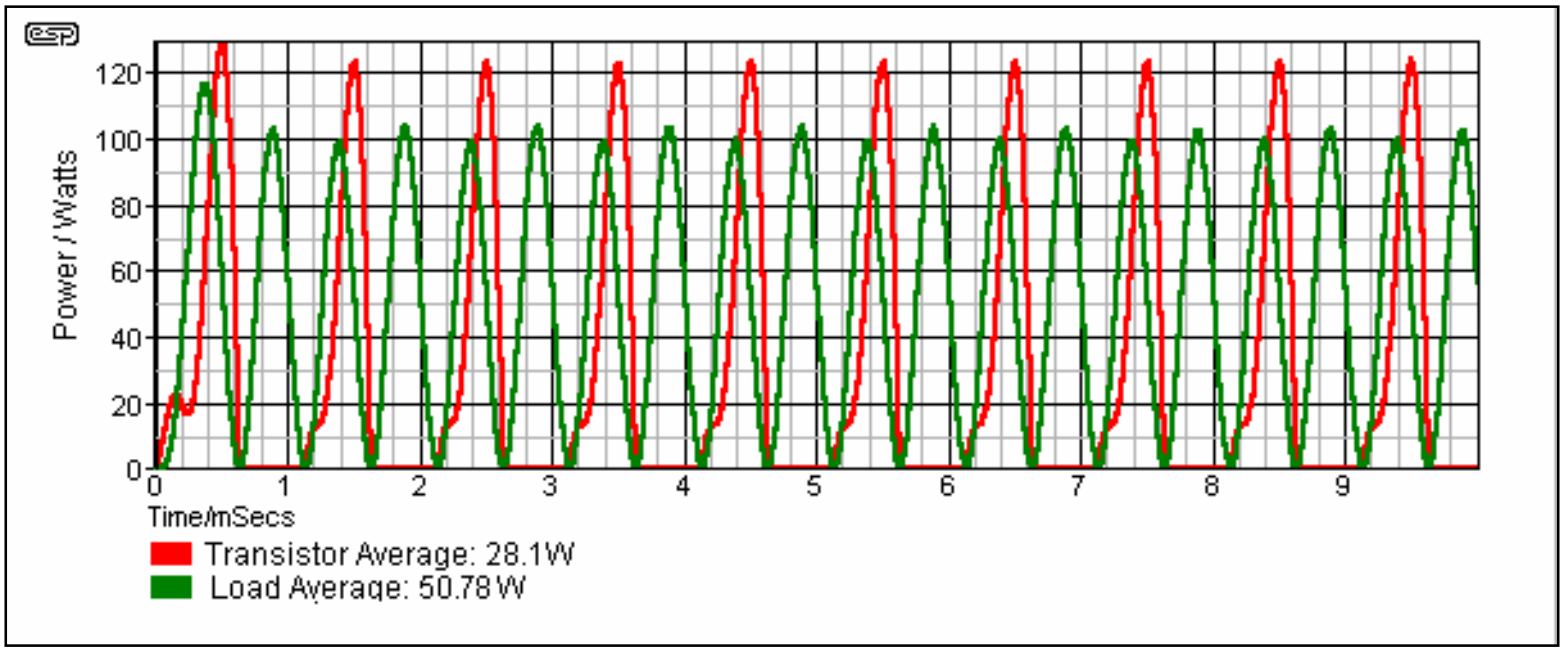

Figure 6 - Power With Reactive Load

Now you know why P3A (for example) is designed for operation at +/-35V, and the suggested upper limit (8 Ohms only) is +/-42V. When losses are taken into consideration, this is the absolute maximum recommended operating voltage. Under these conditions, using 200W output transistors, it is perfectly fine if the recommended supply is used, but is at risk if you go for the upper limit. The amp *might* be saved from destruction into 4 ohms (at the maximum voltage) by the fact that the supply voltage will collapse, and although this is common feature with many amplifiers, it is not recommended. Alternatively, you can always try your luck - it is amazing just what some people have managed to get away with, but this is not an approach that I am comfortable with.

It is quite obvious that the heatsink is of paramount importance, as is the transistor mounting. Maintaining the lowest possible thermal resistance keeps the transistors cool, and limits the amount of derating that must be applied. Other techniques that may be used include protection circuits, but these must also take the maximum operating temperature into account to be effective. It is widely believed that protection circuits contribute additional distortion and are 'audible', even when not activated. While this is possible with some designs, there is no doubt that aggressive protection most certainly *is* audible, as evidenced by many IC power amps - these must be kept below the protection threshold at all times.

3.0 - Conclusion

While this article has taken a somewhat simplistic approach to the issue, it is a reasonable description of reality. Real loudspeakers in enclosures will invariably make the amplifier's job harder than any resistive load, and even more so with a vented box. Few loudspeakers will present anything that looks even remotely like a resistive load, so amplifier dissipation will always be worse than simple analysis would indicate.

Of enclosures, the transmission line will usually present the easiest load to an amplifier, but unfortunately these are much larger than a conventional sealed or vented box. In all cases, a passive crossover network will also present additional phase shift. In some cases this can be extreme (usually due to poor design IMO).

At high frequencies, the amplitude is much lower than at low and mid frequencies, and even quite radical phase shifts do not cause undue amplifier stress.

The thing that saves some amplifiers is the power supply impedance, and careful design (hint - the cheapest alternative) ensures that there is enough power available for transients, but it will collapse sufficiently to allow for worst case conditions. This is not a good method to rely on.

Some commercial amplifiers use a tapped power transformer, and have settings for 8 and 4 ohms. The voltage is reduced for 4 ohm operation to make sure that the transistor SOA is not exceeded. Others take a more simplistic approach (many subwoofer amps fall into this category), where the transformer is simply too small for the job. If loaded heavily and driven hard, the supply voltage will collapse because of the under-rated transformer, and the amp will survive. Fortunately, music is dynamic, so the transformer will not have to suffer a sustained overload, and will usually live a long and happy life.

Remember, see the Safe Operating Area article for more detail on this topic.

All graphs shown were captured from SIMetrix circuit simulation software.

Introduction

There has been fierce debate for some time now about all sorts of problems that exist (or are supposed to exist) in amplifiers, speaker leads, interconnects, mains leads (power cords) and so on. Many of these are supposed to be so subtle that they cannot be measured by any known means, and the claims and counter claims can never be proven because of this.

The idea behind the Sound Impairment Monitor (SIM) is not new (I wish it were - I might be able to make my pages pay for themselves at last), but the application is unique. The thing that makes the SIM unique is that it has been specifically designed to be able to work with any amplifier that is reasonably sensibly behaved, and does not have massive phase shift at either frequency extreme within the audio spectrum. It is even possible to adapt the circuit to compensate for this, but the effort does not seem worthwhile (at least not for the time being). Having said that, some degree of compensation is essential to obtain satisfactory sensitivity to low level signals or small aberrations in the amplifier's linearity.

The important part of this is that if the sensitivity can be made high enough, then impairment may be seen at extremely low levels. I suggest that a well set up SIM should be able to show ...

- Distortion of waveform from any source. This could include alleged resonant (or microphonic) behaviour of amplifiers or other components
- The effect (or lack of effect) of so-called tuning, where an amplifier is claimed to contribute artefacts to the sound because of mechanical vibration
- The effect (or again, lack of effect) of different mains leads (power cords), interconnects or other

components within the SIM loop

The above is only a small sample, and I expect that many more will come to light if the principle is used in earnest. If (for example) a mains lead is claimed to improve bass response, then this must show up as a change in the amplifier's response. We do not generally percieve a dramatic (or even subtle) change in overall tonal balance without a corresponding electrical change (all other things being equal, of course). While this may possibly be elusive in static tests, it must be visible in a dynamic test under normal listening conditions, if the original signal can be subtracted from the amplified version to leave the smallest possible residual. The smallest change in performance will therefore be visible, since the input signal has not changed, but the output signal must. This will show up for phase or amplitude changes alike, since the subtraction process will be different from that when it was set up originally.

Let's face it - if the signal is exactly the same before and after a tweak, then the tweak in fact did nothing. If the signal is exactly (note: *exactly!*) the same, then we cannot possibly be hearing a difference. We might *think* there is a difference, but this in no way means that there *is* a difference - especially if the audio signal is unchanged. This last point is crucial to our understanding of the "mysterious" and "unexplained" differences between components.

In the same way, if any tweak causes the output of the SIM to change, then it did something. We don't know by looking at the signal if the "something" was good or bad - that's what we have ears for. What we do know is that what we are hearing is real, since we now have some physical evidence that we can analyse, disect and discuss until the reasons can be determined.

No amount of critical listening can reveal something that simply does not exist. Likewise, no amount of "superb specifications" will make an amplifier actually sound good in all cases. The goal is to isolate what small differences do exist, and to corelate these with what we hear. This is the goal of the SIM project, and with the use of a tool to allow us to see the effect of any change in amplifier topology, cables or damping that we may care to try, some plausible explanations will come to see the light of day.

In the meantime, we are all subject to our own prejudices and beliefs, "what we think we know *makes* a difference", and "what we think we know does *not* make a difference". For example, I believe that mains leads make no difference, while others believe the opposite. Now we can put it to the test, with an instrument that works in real time, with real music. Will differences in mains leads be revealed at last? I don't know, since I have not had the time I would like to experiment and perfect the external SIM.

System Description

The Sound Impairment Monitor concept is quite simple, and just subtracts the input signal from the output signal to indicate the difference between the two. An ideal amplifier will show a difference in amplitude only, and this is nulled using the Calibrate control. The resulting signal is the difference between the input and output of the amp, and will include any phase shift, frequency variation, or distortion. It is quite possible that the SIM could be implemented in the digital domain, using a DSP (Digital Signal Processor) to make the subtraction process more accurate.

The version I have developed is analogue, and requires the best opamp possible to get good results. The connection of the SIM is shown in Figure 1, and it includes a LED to indicate that something interesting (i.e. bad) is happening. An oscilloscope can be connected to allow us to see exactly what is causing the problem, and the SIM can be used with normal programme material. Indeed, this is the whole idea, since it avoids all the criticism of static (sine wave) tests. The SIM will be just as revealing (and in some cases more so) with so-called "static"

sinewave testing, since the exact distortion waveform will be quite visible. Square wave testing will also be very revealing. All amplifiers will show a difference between a fast rise-time square wave at the input versus output, but a modified (i.e. filtered to some agreed standard) square wave is still a very hard test on an amp, and may be helpful in identifying the problems that are supposedly audible, and isolating those that are not.

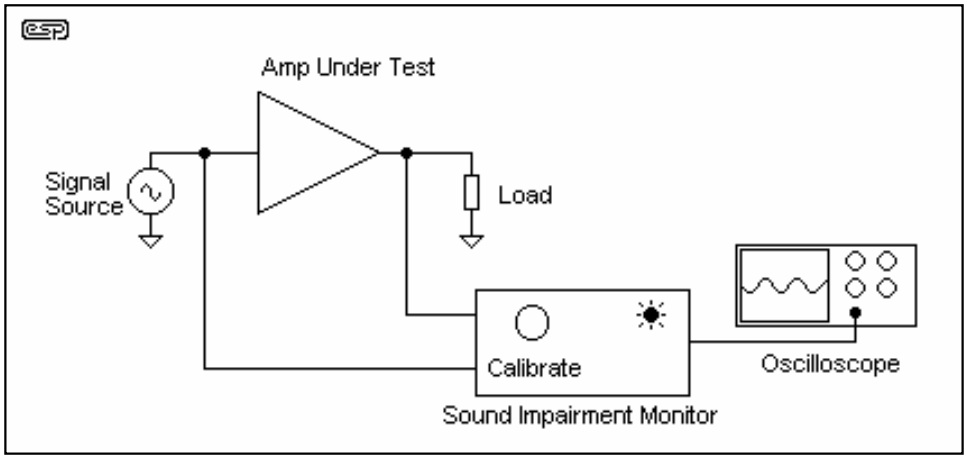

Figure 1 - Connecting The SIM To An Amplifier

When the SIM is connected, a normal signal (at a normal to low level) is applied. The calibration controls are set to ensure that the LED is not lit and the monitor amp should be almost completely quiet. Sensitivity (not shown) is increased, and calibration is readjusted until the highest possible sensitivity is obtained with the LED not illuminated. Some experimentation will be needed to ensure that small phase differences do not cause the SIM to indicate a problem that does not exist, but initial testing indicates that this may be an extraordinarily useful test for amplifiers.

With the monitor amplifier, we will be able to hear any difference between the original and amplified signal, and for the very few amps with distortion that is low enough, this should be mainly noise. There will always be some signal present, but it should not sound at all like music since we are interested only in distortion products. Note that distortion covers everything in this context - frequency and phase response, amplitude variations, and actual distortion.

Any distortion (regardless of origin) that arises as the level is increased or changes are made to leads or other components will cause the LED to light, and we can observe the difference between input and output on the oscilloscope. Figure 2 shows the waveform we will obtain if the amplifier clips and has some degree of overhang ("power rail sticking") - a sinewave is shown for clarity, but the same principle applies with music.

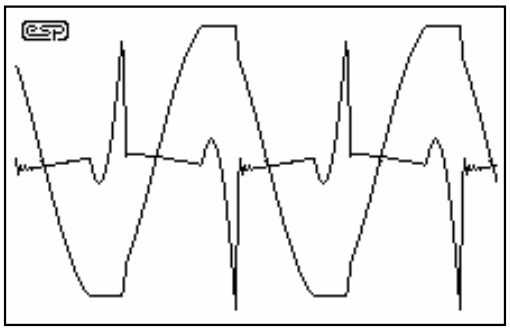

Figure 2 - An Amplifier With "Overhang" Clipping

Is this the perfect amplifier monitor? No. In some cases normal variations in input level will cause the LED to light, but the oscilloscope should show exactly what is happening. Any variation in the shape or sound (rather than the amplitude or volume) of the waveform indicates a problem, but it may not be possible with normal

programme material to see the exact mechanism that is the root cause.

It is potentially a much better test than the standard tests we have seen a thousand times (all looking pretty much the same as each other), but are still unable to reveal everything. Perhaps someone out there with DSP programming skills will be able to do a better job than a simple analogue circuit can achieve, but even as it stands, it is better than the current methods. By how much? This remains to be seen ....

Or heard. The output of the SIM really should be monitored with headphones or a loudspeaker, so not only do we see the difference on an oscilloscope, but we can listen to the difference signal. In a perfect amplifier we will hear silence - there will be no difference at all, but in the real world we will *always* be able to hear and see a residual signal.

Here is where listening is important! The residual signal may have a hard "gritty" edge with an amplifier and one set of speaker leads (for example). By substituting the leads, this may become a "smooth" signal, which although bearing no resemblance to the actual music, has no harsh overtones or other nastiness. We can safely assume that the difference is beneficial, that the second set of leads really does improve the sound.

We still don't know why, but armed with some evidence we have at least a fighting chance of finding out.

Initial Tests

I ran some tests on the SIM concept, with a normal signal and my 60W amp. The reaction to signal clipping was instant and highly visible. Even clipping that was of such magnitude and duration that I could not see it on the oscilloscope waveform of the amp's output showed up instantly, as will any other variation. Likewise, any signal that exceeds the amplifier's slew rate also shows up, but I had to deliberately slow the amp down by increasing the miller capacitance to see this.

If this amp had any form of protection, activation of the protection circuit would also show up as large spikes on the output waveform, so I am well satisfied that this is an extremely valid test. Unlike a clipping indicator, the SIM shows any deviation from the normal expected waveform, howsoever caused.

I found that phase shift at low frequencies (caused by the amp's input capacitor) made a good null very difficult, and after some experimentation I found that a high pass filter at the detector output tuned to about 700Hz eliminated the low frequency signal with no apparent loss of accuracy for signal impairment detection.

Next Steps - Involvement, Anyone?

I experimented with a square wave signal, and quite predictably the SIM went crazy, indicating every level change. The rise and fall time of my oscillator is very fast (it will give an excellent square wave at 100kHz), so this was entirely expected. The same will happen with almost any amp in the known universe, since few (if any) can reproduce a square wave perfectly, especially when the input signal is as fast as mine.

To be able to get an instant feel for an amp's ability to reproduce normal music, I suggest that for square wave testing with the SIM, a low pass filter be used, having a 6dB per octave rolloff from 1kHz. This will limit the harmonics to something passably sensible - it is still a severe test, and one that few amps will ace, because the SIM is so sensitive to any impairment to the signal - of amplitude or phase or any combination.

I am anxious to hear suggestions from anyone who might be interested in assisting with the development of a standard test method for amplifiers - one that will show the things we need to see, and reject those that are inaudible. The SIM is potentially the first real advance in amplifier testing methods for many years, and if properly

implemented could become a standard test that can be included in all reviews.

For example, if standardised, we could have an oscilloscope trace of the SIM filtered square wave performance for each amp tested and reviewed, and if left connected to the review amp (without the filtered square wave, of course), will enable the reviewer to ensure that no protection circuit is activated and there is no clipping during the listening test. I suspect that a few people might be surprised at the results, as I was when I was sure that the amp was not clipping with an applied music signal (according to the oscilloscope), yet the SIM showed quite plainly that it was.

One of the best things about the SIM is that it is relatively cheap to build, requires minimal calibration other than compensating for the gain (and in some cases phase) of the amp under test, and shows up imperfections that occur in music and in "real time" - not just steady tones. As mentioned above, it will also show that protection circuits have activated, and can display the instantaneous magnitude of the error signal on a LED bar graph, peak programme meter or monitor speaker.

If it appears that I am a little excited by my findings so far, this is only because I am! Can anyone imagine the jubilation if the SIM were to show that the perceived differences in various amplifiers showed up clearly, and in a way that could be easily analysed.

Not only amplifiers themselves, but speaker leads, interconnects, and even mains leads will all show a difference if it exists - we might be able to eliminate some of the fierce debate that currently exists if it can be shown that the effects are real (or equally that they are not). All of this with real music, connected to real speakers and in real time.

There is not a test methodology currently used that has this capability, so you bet I'm excited. I am even prepared to give this technology away to anyone who wants to try it. A project for the internal SIM is already published, and the external SIM will be published when completed.

External SIM

The idea of the external SIM is actually not new, having first been proposed by Peter Baxandall many years ago. The current design bears some similarity to the original, but there are important differences. The original Baxandall circuit is shown in Figure 3, but has a small problem in that the amplifier under test is expected to be inverting. This is very rare in modern designs, but in its time was relatively easy, since the amplifiers of the day were valve, and the polarity of the output transformer winding could simply be reversed. This is no longer possible.

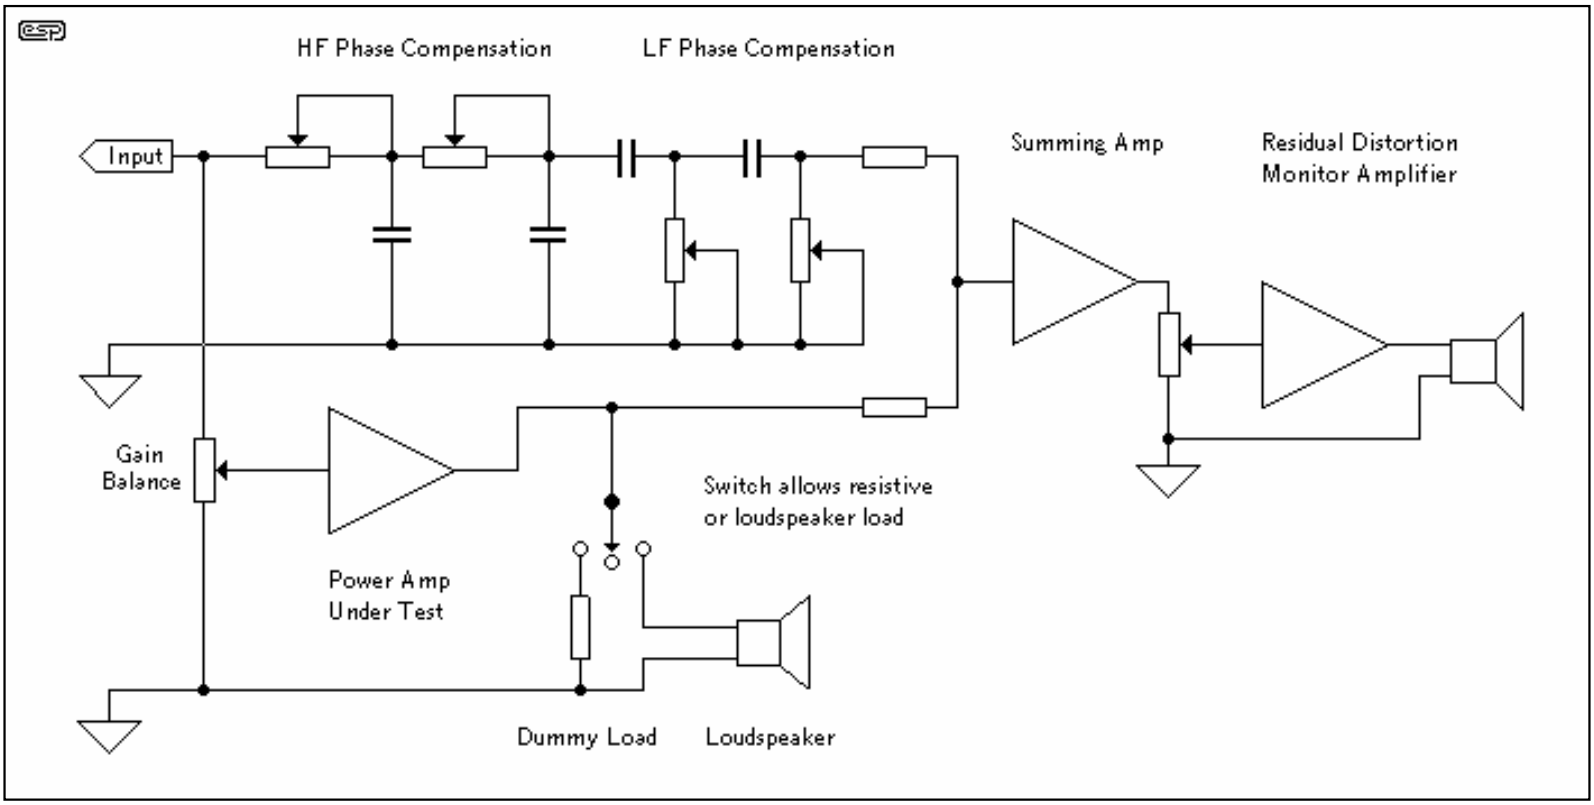

Figure 3 - The Original Baxandall Subtractive Test Set

Naturally enough, the term SIM was not applied to the original circuit, but name aside, I am puzzled as to why it never gained the popularity of "static" sine wave distortion testing (which is actually anything but static, a sine wave is a signal like any other, and stresses the amplifier in the same way as a music signal).

The original circuit proposed that gain and phase errors at high and low frequencies could be nulled by the compensation pots, and that the amplifier's gain would be equalised by adjusting the gain balance. Any residual signal would then be a direct representation of the distortion components in the amplifier. This residual may be monitored, and only the distortion components will be audible.

The Final New Design Criteria

Modern amplifiers will generally need minimal phase compensation, at least within the audio range. Because of this, the circuit can be simplified to some degree by reducing the phase nulling circuits to a single pole each. The external SIM is based on this principle, and with careful adjustment will allow very small differences to be heard (and seen on an oscilloscope).

To reduce the loading on the input source, the final SIM will use a high grade opamp to buffer and invert the signal before the phase compensation circuits. This has the added advantage that it will also allow a better match to the amplifier because of the very small phase differences it will introduce itself. To verify that the input buffer is not a contributor to the residual signal, I will be setting up a calibrate switch, allowing the amp under test to be bypassed entirely and replaced by a direct connection.

To minimise any loading on the input, a unity gain buffer will also be incorporated. This may change the sound to a small degree in itself, but will not affect the validity of any comparisons done on the test amplifier, as it will be in circuit all the time. To completely eliminate mains interference, the SIM will be battery powered, but will drive an external small power amp for monitoring. This connection will be balanced to eliminate earth loops and hum injection back into the SIM and the amp under test.

The 700Hz filter I mentioned above is an option I will have to think about very carefully. I do think it is a good

idea, but it should be able to be bypassed (or perhaps made variable).

As you can imagine, there is a lot of work to be done before the design is complete, and the basic criteria above are likely to change as I progress.

Internal SIM

The internal SIM is published as Project 57, and can be applied to any amplifier. It does require that the amp be modified, and it is very important that leads are kept short and all wiring is carefully done so as not to adversely affect the amplifier. There is little point in an instrument that will show you how badly the amplifier performs when the instrument is connected!

The internal SIM is only capable of showing differences that occur within the amplifier itself, although in some cases the speaker leads may affect the calibration. Again, it is possible to use a small headphone amp to allow the residual signal to be monitored. Now when you change the stock mains lead for a set of nice new SupaTune9000s, you will hear the difference in the amplifier itself, if indeed any difference exists.

Is the difference good or bad? This is for you to determine, but at least you will *know* there *is* a difference. This is the first principle of experimentation. There must be an observable change in an amplifiers output for any difference to be heard. This much is plain. What is not plain (using conventional test methods) is how this can be detcted. The SIM might well be the missing link, revealing all (well, some, at least) to those who really want to know.

1.0 Introduction

Safe Operating Area (SOA) for semiconductors is a little understood topic. Although the chart is generally provided in the data sheet, there is a great deal you need to know to be able to make proper use of it. Without a thorough understanding of the loudspeaker load, instantaneous voltage and currents, and what happens to transistors if the SOA is exceeded, it is easy to imagine that the supply voltage for an amplifier can be increased up to the maximum voltage allowed by the transistors used.

This is not the case at all, and this article discusses the problems faced in any amplifier design to create a reliable circuit that (ideally) can never place the power devices at risk. This is much easier said than

done, unfortunately.

2.0 Amplifier Power Demands

Most basic analysis of a power amplifier design is done (at least initially) using circuit simulation and basic theory. None of this is at all difficult, and is essentially a matter of current analysis through the amplifier into the load. For the sake of simplicity, a resistive load is generally used for all but the most rigorous analysis, and for low powered amplifiers, this is quite sufficient.

When you make (for example) a 20 Watt amplifier using discrete components, most of the power transistors available have so much reserve current and power available that few problems will be encountered. Even a 100W amp is not a problem if the impedance is known in advance, and reasonable care will give a reliable circuit.

The problem is that real life loads are neither predictable nor reasonable, with nominal* 8 ohm loads perhaps plunging to 3 ohms or less at some frequencies, and soaring to 50 ohms or more at loudspeaker driver resonance. Four ohm loads are no better, and 2 ohm loads are a nightmare for most amps.

One of the problems is that music is also unpredictable. Some music has a very low "crest factor" (the ratio, in dB, between the average and peak power), so relatively high power levels are present on a more or less constant basis. Other music has a high crest factor, with a peak to average ratio of up to 20dB (a power ratio of 100:1). Classical recordings are commonly thought to have a high crest factor, but this is not always the case, with some having as little as 6dB. Yes, this is uncommon, but it can (and does) happen).

"Modern" music (a term that has a different meaning to everyone ;-) is not immune from high crest factors, but they are less common than in unprocessed orchestral recordings (for example).

It is the combination of unpredictable loads, very different musical styles and power demands, different listening preferences and (we must never forget this one!) ... heat, that can spell doom for even the best designed amplifier, if it is used outside of the original design parameters.

* Nominal - in name only. As used in electronics, "nominal" refers to the expected voltage, power, impedance, etc., under "normal" (or sometimes ideal) conditions.

2.1 Amplifier Design Parameters

So, what are the factors that determine if an amp will be reliable or an owner's nightmare? There are quite a few, and as an example I will use the P3A 60/100W amp design from The Audio Pages projects section.

2.1.1 Output Power

The primary objective is to produce a design that has sufficient power to suit the needs of the owner - this

is a very difficult, because of the vast differences in loudspeaker efficiency, preferred listening level, and type of music. Nonetheless, 70W is not an unreasonable figure, and is well suited for many speaker systems. Smaller 2-way units are very popular because of their relatively high spousal acceptance factor, and they are convenient, reasonably priced and can give very good performance.

Such systems simply will not take the full continuous power of a 250W amplifier. The sales blurb may claim they are suited to amps of "20-200W", but this often assumes a "typical" crest factor of around 10dB (10:1), where the peak power will be 10 times the average, or in some cases even more.

This has everything to do with the amplifier design, as it sets a reasonable expectation of the power needed, and sets us towards an understanding of the load the amp is expected to drive. A quick analysis of any 2-way or 3-way speaker will show that the impedance is far from flat, it has peaks and dips at various frequencies, and will only show the nominal impedance at a few frequencies.

Again, for the purpose of explanation, I must choose a speaker system, and the one used for the remainder of this article is completely imaginary. It exists in simulation only, but has a reasonably close resemblance to many small/medium sized 2-way loudspeakers. The reason for a simulated speaker is simple ... the effects of the impedance variations are easily seen, and are actually very similar to a "real" speaker.

The primary requirement for obtaining power is voltage swing. This in turn is determined by the supply voltage, and the supply voltage and lowest impedance determines the maximum current.

2.1.2 Current

Using the (nominal) ±35V supply for P3A as the example, we must accept that even for an 8 ohm loudspeaker, the minimum impedance will be lower than claimed. Six ohms is a realistic figure (assuming a well engineered speaker), but it could be less. A 4 ohm speaker can be expected to have a minimum impedance of around 3 ohms.

Power transistors are assumed to be rated at 200W dissipation, and have adequate voltage and current capabilities (e.g. the recommended devices for the P3A amplifier).

For the 6 ohm case, peak current will be 5.8A, or 11.6A into 3 ohms. This is with a +/-35V supply, but the transformer voltage is always quoted at full (resistive) load, so typically with normal mains voltage, the supplies can be expected to be ±38V or so with no load. Large filter caps will hold this voltage for several milliseconds, so the maximum peak currents are probably closer to 6A and 12A for 8 and 4 ohm nominal loads (respectively).

2.1.3 Dissipation

Under ideal conditions, a transistor's power dissipation rating refers to the maximum average power that the device can handle, with the junction temperature at 25° C. At any temperature above 25°, the power is derated (reduced) linearly, until it reaches zero at around 150° C.

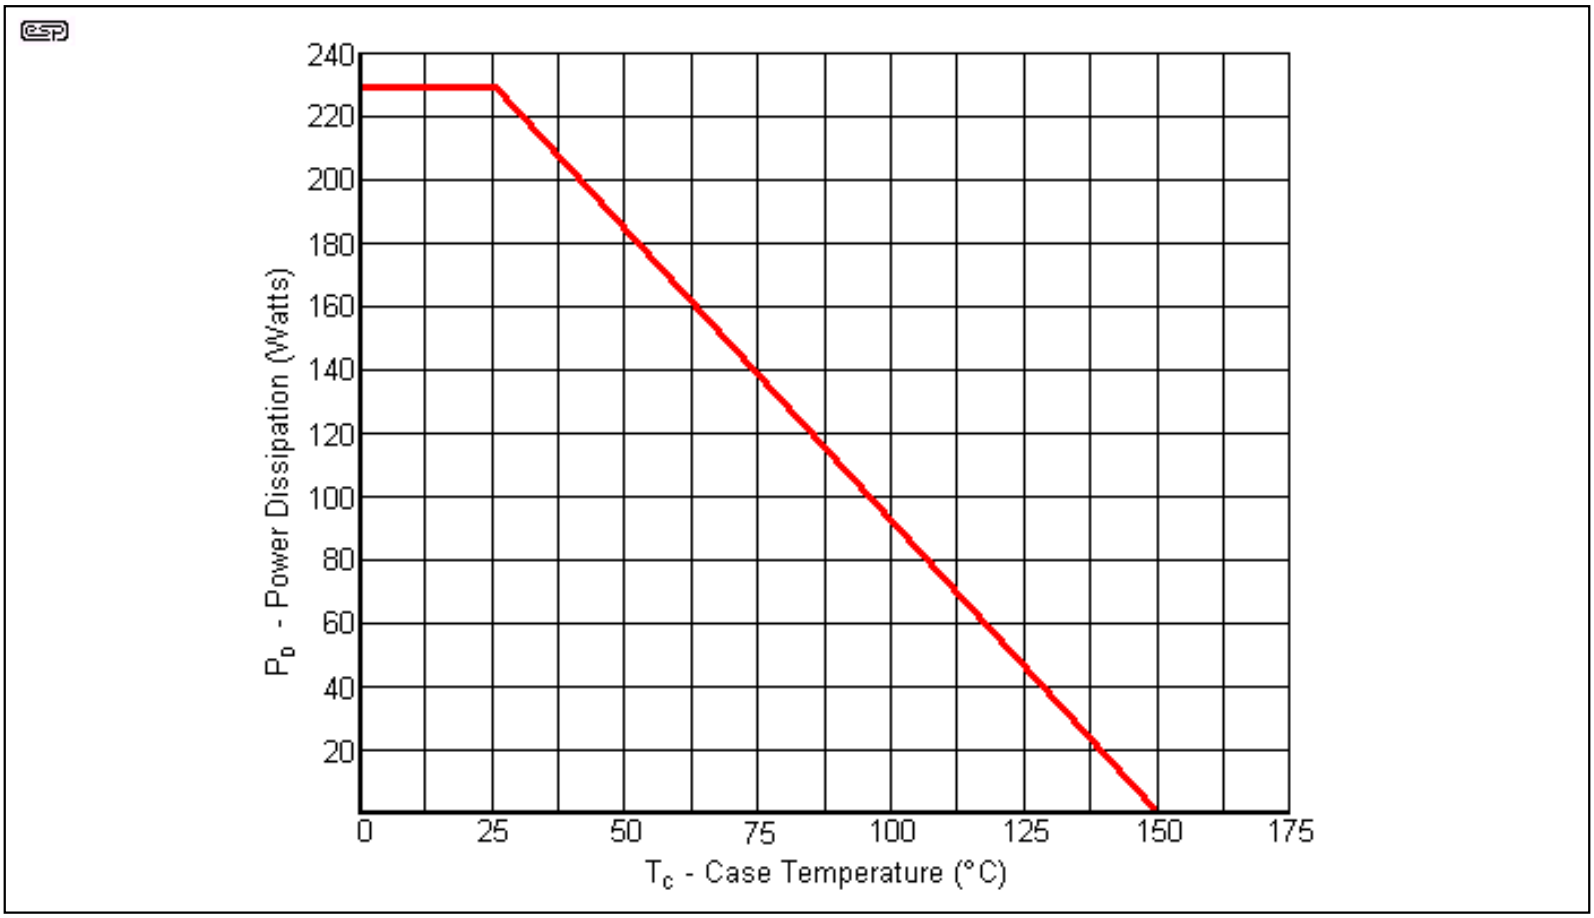

Figure 2.1 - Typical Power Derating Curve

Based on this, it is obvious that keeping the temperature down is critical, since elevated temperatures reduce the available dissipation, and reduce any safety margin that has been incorporated into the design. High temperatures also reduce device life, and the hotter a transistor runs, the expected life is reduced roughly exponentially.

To place the thermal issues into perspective, there is a calculation in the next section that shows average transistor dissipation to be about 40W (42.5W actually), when driving a 4 ohm reactive load at full power using ±35V supplies. For the sake of simplicity, we could assume about half that to be the continuous average with music at the highest level before clipping. 20W continuous does not sound like very much, but the thermal resistance from junction to air (per transistor) might be around 5.5° C/W ...

Rth(j-c) = 0.54°C/W (junction to case, assume 0.5°/W for simplicity)
Rth(c-h) = 1°C/W (case to heatsink - a very good figure, and difficult to achieve in practice)
Rth(h-a) = 4°C/W (heatsink to ambient, based on a 1°C/W heatsink and 4 transistors [two amps])

... so the temperature rise is 110°. Now, add the ambient temperature - say 25°C - but it could be a lot higher!. The die temperature is therefore 135°C, and from the above chart, that means that continuous allowable power dissipation is reduced to about 23W, so we are way too close to the thermal limit of the transistors - even a minor obstruction over the heatsink would be more than enough to tip the balance.

There is a lot more than just simple dissipation though. Figure 2.2 shows the power in a transistor driving a resistive load at the onset of clipping. As you can see, the power increases until the voltage reaches the halfway point between zero volts and full supply. After that, it goes down again - in a perfect amplifier,

dissipation will fall to almost zero at the clipping point. For Figure 2.2, the applied voltage was ±35V, with a 3 ohm resistive load.

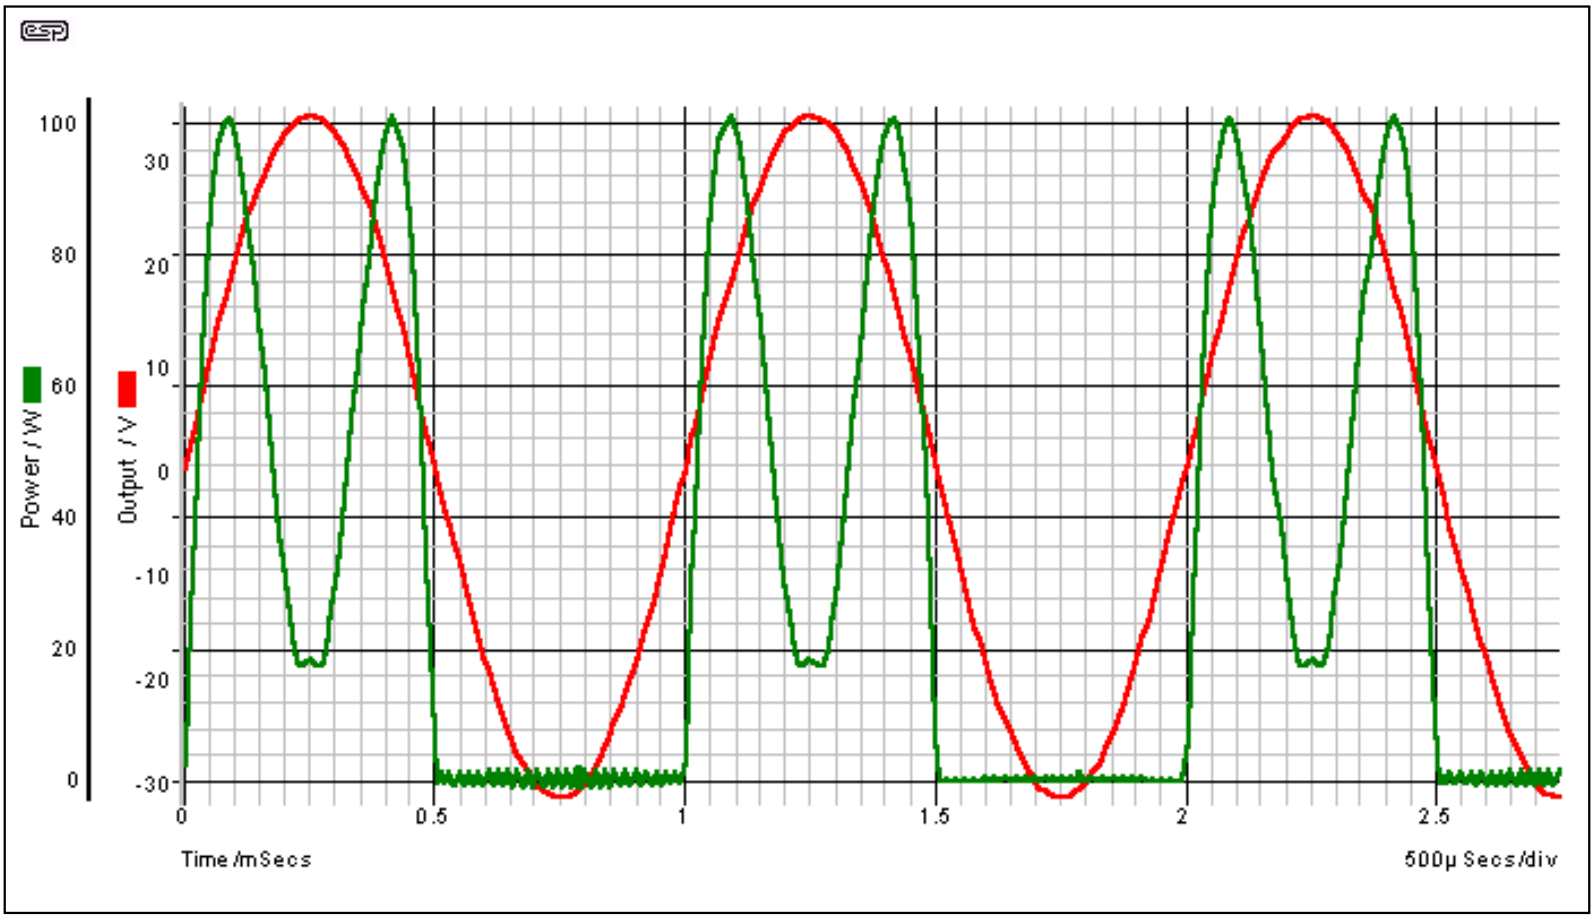

Figure 2.2 - Transistor Power Dissipation

The peak power is (using 6 ohms and 35V supplies) $(35/2)^2 / 6 = 51W$, or 102W for a 3 ohm load. Average dissipation is difficult to calculate because of the waveform, but my simulator tells me that it is 15 and 30 watts respectively. Note that for the simulations, zero quiescent current has been assumed - in real circuits, this just adds to the average dissipation.

2.2 Loudspeaker Loads

Where things rapidly get out of hand is with the loudspeaker load - it is not resistive (or even close to resistive) for 99% of all loudspeakers. The impedance and phase angle of a loudspeaker varies, and as phase angle changes from zero degrees (voltage vs. current), dissipation increases further.

For the 3 ohm case, a reactive load (at 45° phase angle) can be simulated by using a 477uH inductor in series with the 3 ohm load (for a frequency of 1kHz). With this combination, the peak transistor dissipation is 200W, with an average of almost 42.5W - note that the peak transistor power has doubled, and the average has increased by 1.414. Of particular interest is that the maximum power occurs at the voltage zero crossing point, when the maximum voltage is across the device. This is what causes transistors to fail, and the higher the voltage, the greater the risk.

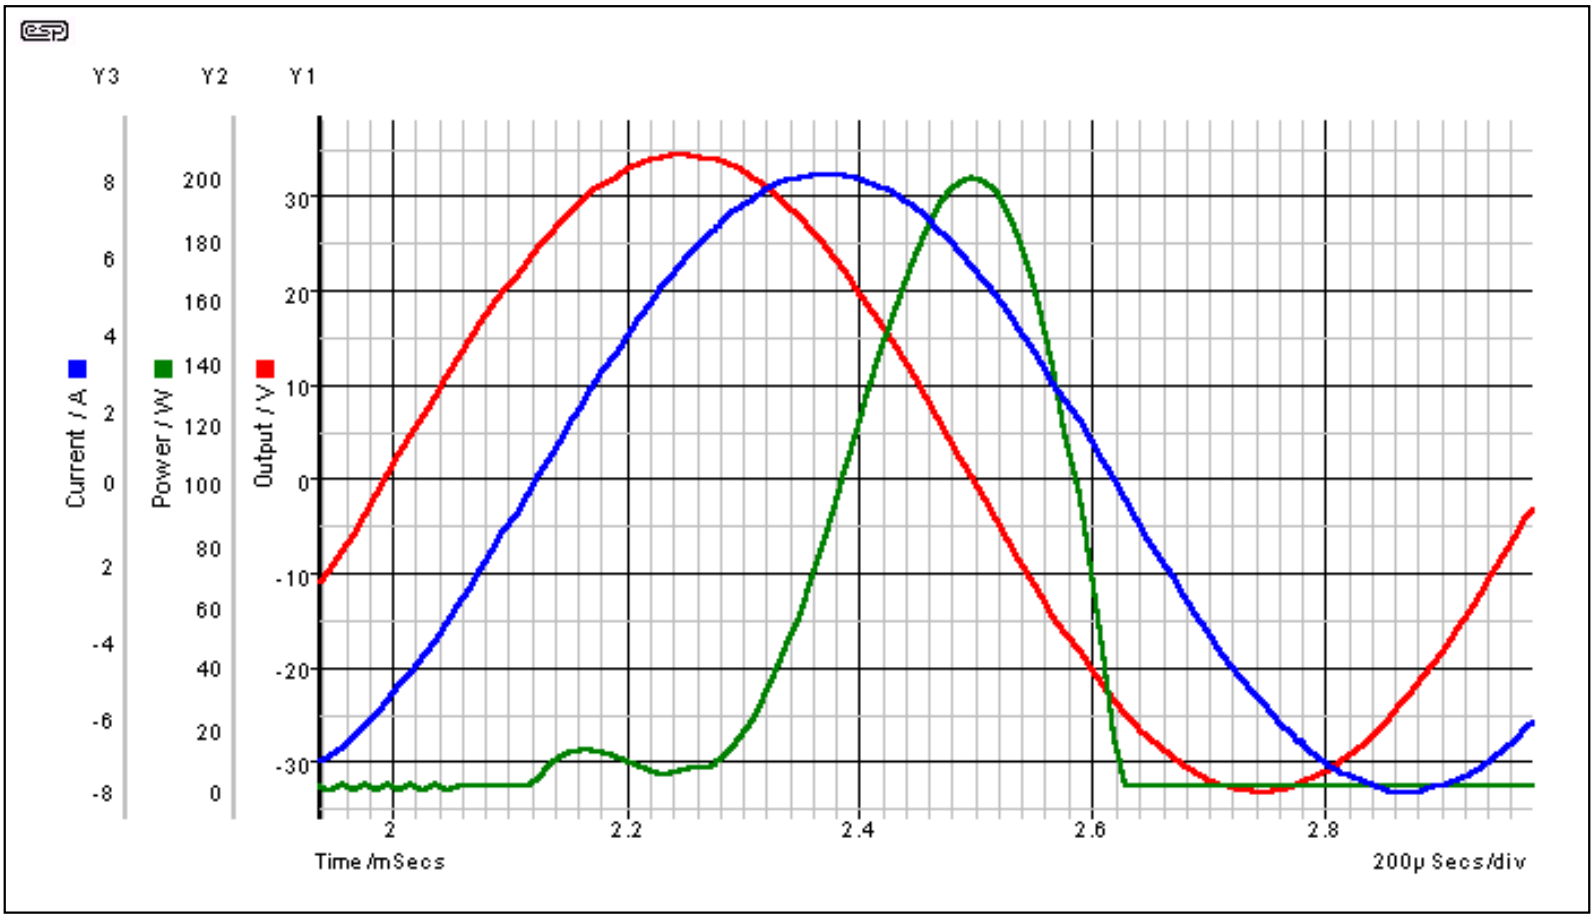

Figure 2.3 - Voltage, Current and Power Dissipation

While average power is well within the maximum ratings, the peak has reached the maximum device power, and we are now constrained by the SOA of the devices. Remember, this is with a supply voltage of +/-35V - higher voltages will create higher peak powers with real loudspeaker loads!

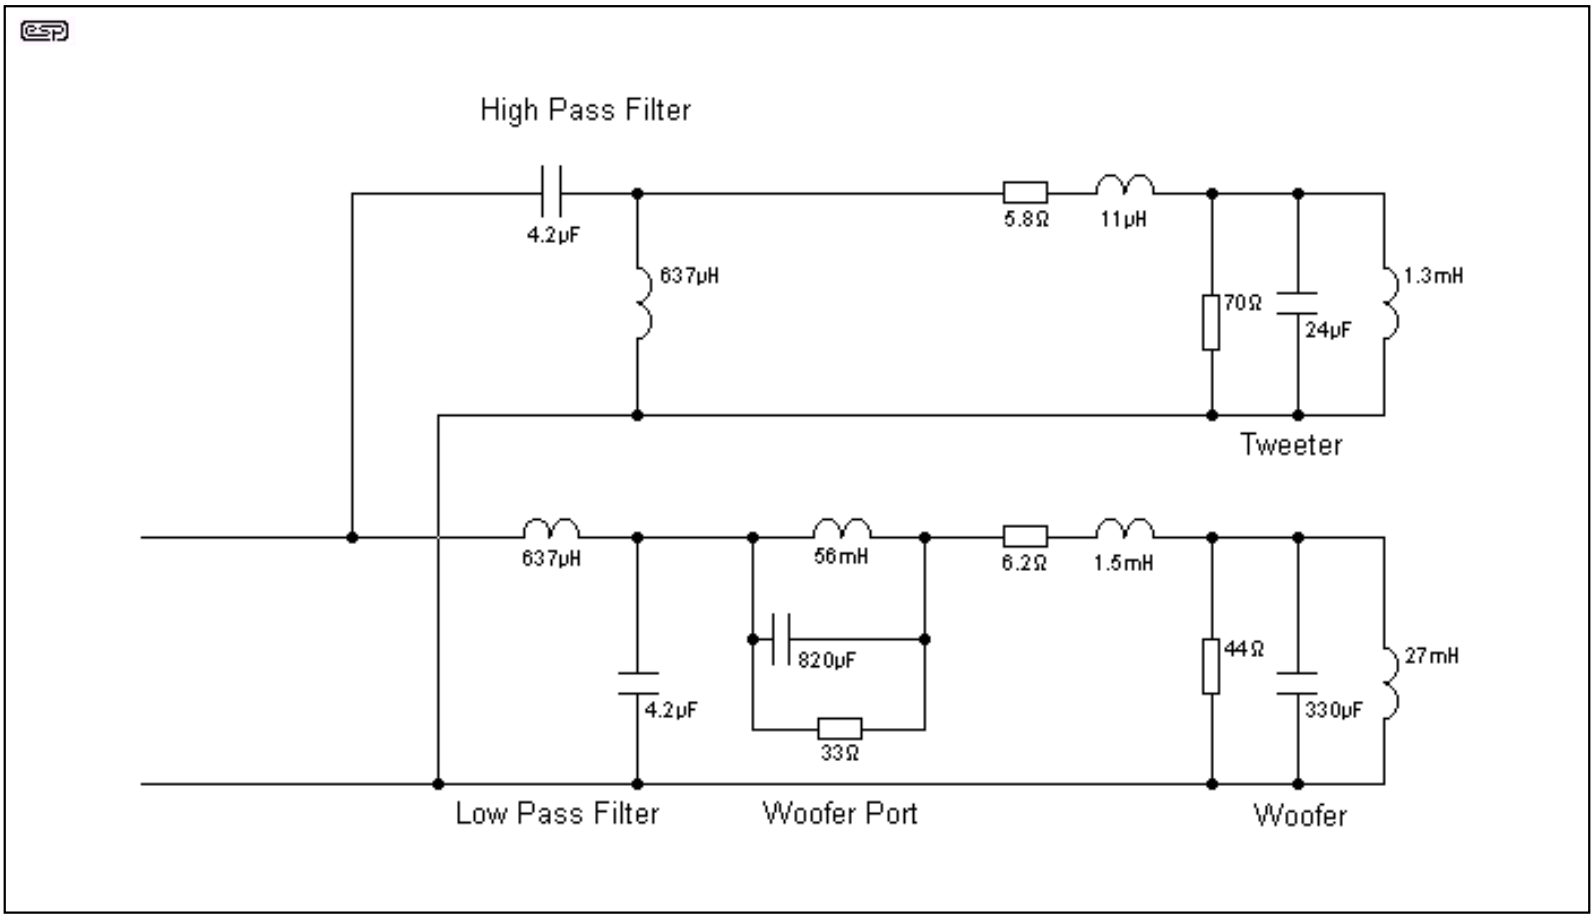

Figure 2.4 - Simulated Loudspeaker System

The combination of resistors, capacitors and inductors simulates the 2 drivers in the system, along with their crossover networks. For simplicity, no impedance correction networks have been included, and the loudspeaker is vented (note the double low frequency peaks shown in Fig. 2.5). This is a typical response, but remember that this is only the electrical response of the system - acoustically, it might be good, bad or indifferent (the electrical response gives clues, but cannot be used to predict the acoustical performance - I would expect it to be very ordinary however, based on the lack of impedance correction that is clearly visible looking at the phase angle and impedance curves).

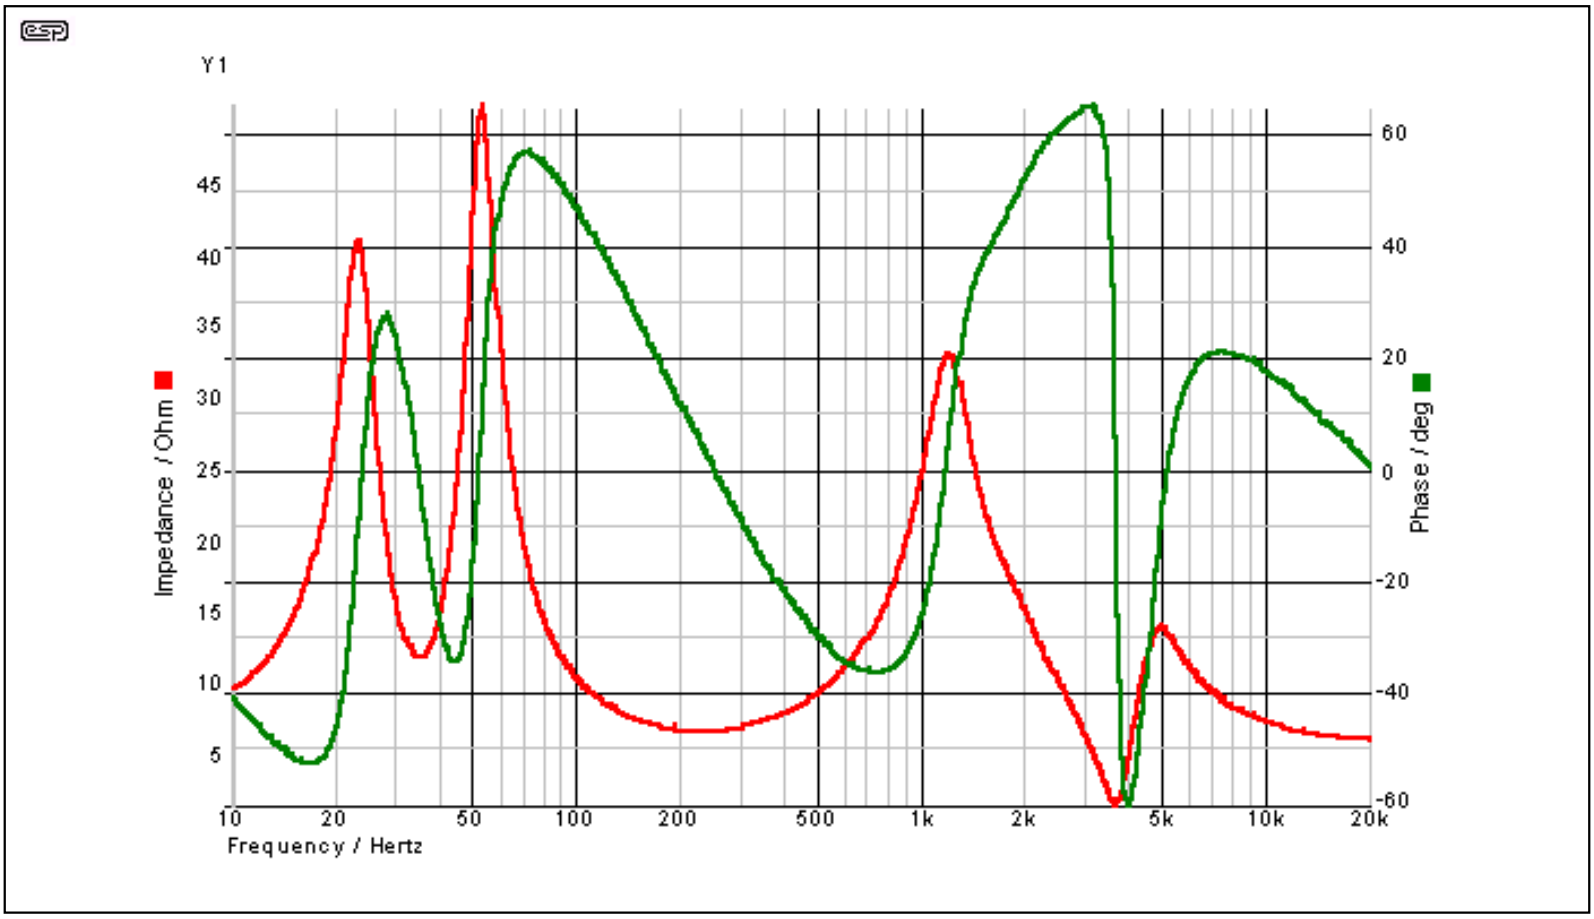

Figure 2.5 - Impedance and Phase Response Of Simulated Speaker

While the impedance is more or less as expected, the phase is another matter. At a phase angle of other than zero, the voltage and current are not simultaneous - the voltage may occur before the current (leading phase, capacitive load) or after the current (lagging phase, inductive load).

This is a major problem for amplifier designs, since at any phase other than zero, the power delivered to the load decreases, while the transistor dissipation increases. At 45°, peak transistor dissipation doubles, and power into the load is halved.

As the impedance rises with increasing frequency, the load appears as an inductor, and when it falls with increasing frequency, it is capacitive. Note how little time is spent at zero degrees phase shift! This means that at nearly all frequencies in the spectrum, the amplifier sees not a resistive load, but a reactive load. A significant number of frequencies are at or near 45° phase shift, so the amplifier is actually working nearly twice as hard as you thought it was.

3.0 Transistor Limitations

A bipolar junction transistor (BJT) has a negative temperature coefficient. As temperature rises, the junction voltage falls, and gain increases. Transistors are not perfect - there are always minute flaws in the fabrication, causing tiny variations in the characteristics of different parts of the transistor die.

Modern fabrication techniques have minimised these to a huge extent, but they still exist. Even the resistance of the conductive layers within the device becomes very significant at high currents, so perfect

current distribution cannot happen.

Now, there is a sequence of events than can (and does) occur within the transistor. If the instantaneous power dissipation is too high, parts of the transistor die will get hotter than others. This means that the junction voltage falls, and the gain increases - but only at the most sensitive part(s) of the die. If Vbe (base to emitter voltage) falls and gain increases - at one spot in the transistor - it will naturally take more of the current, which means it gets hotter, so it takes even more of the current (and so on). This can happen in a few milliseconds! That part of the transistor will quickly exceed the maximum permissible temperature, and the transistor will short-circuit internally.

All of this has happened in perhaps 10 milliseconds, and the case is not even warm. This phenomenon is called "second breakdown" (or secondary breakdown), and is the single greatest reason for transistor failure in a working circuit.

3.1 Second Breakdown

Data sheets usually have a full set of graphs and charts, showing the various device parameters as a function of voltage, current and frequency. In the design phase, all are important, but the most important of all are the two that are most often overlooked by hobbyists and experimenters - thermal derating and safe operating area.

From the data sheet for the MJL4381A, Fig. 3.1 shows the SOA curve for these devices. Non-repetitive peak currents of up to 30A are permissible for 10ms, but only for collector voltages up to 30V, and only with the junction temperature at 25 degrees. This is a peak power of 300W (the device rating is 230W), but it must be stressed that these conditions must not be allowed to continue beyond the time specified - 10ms is not very long!

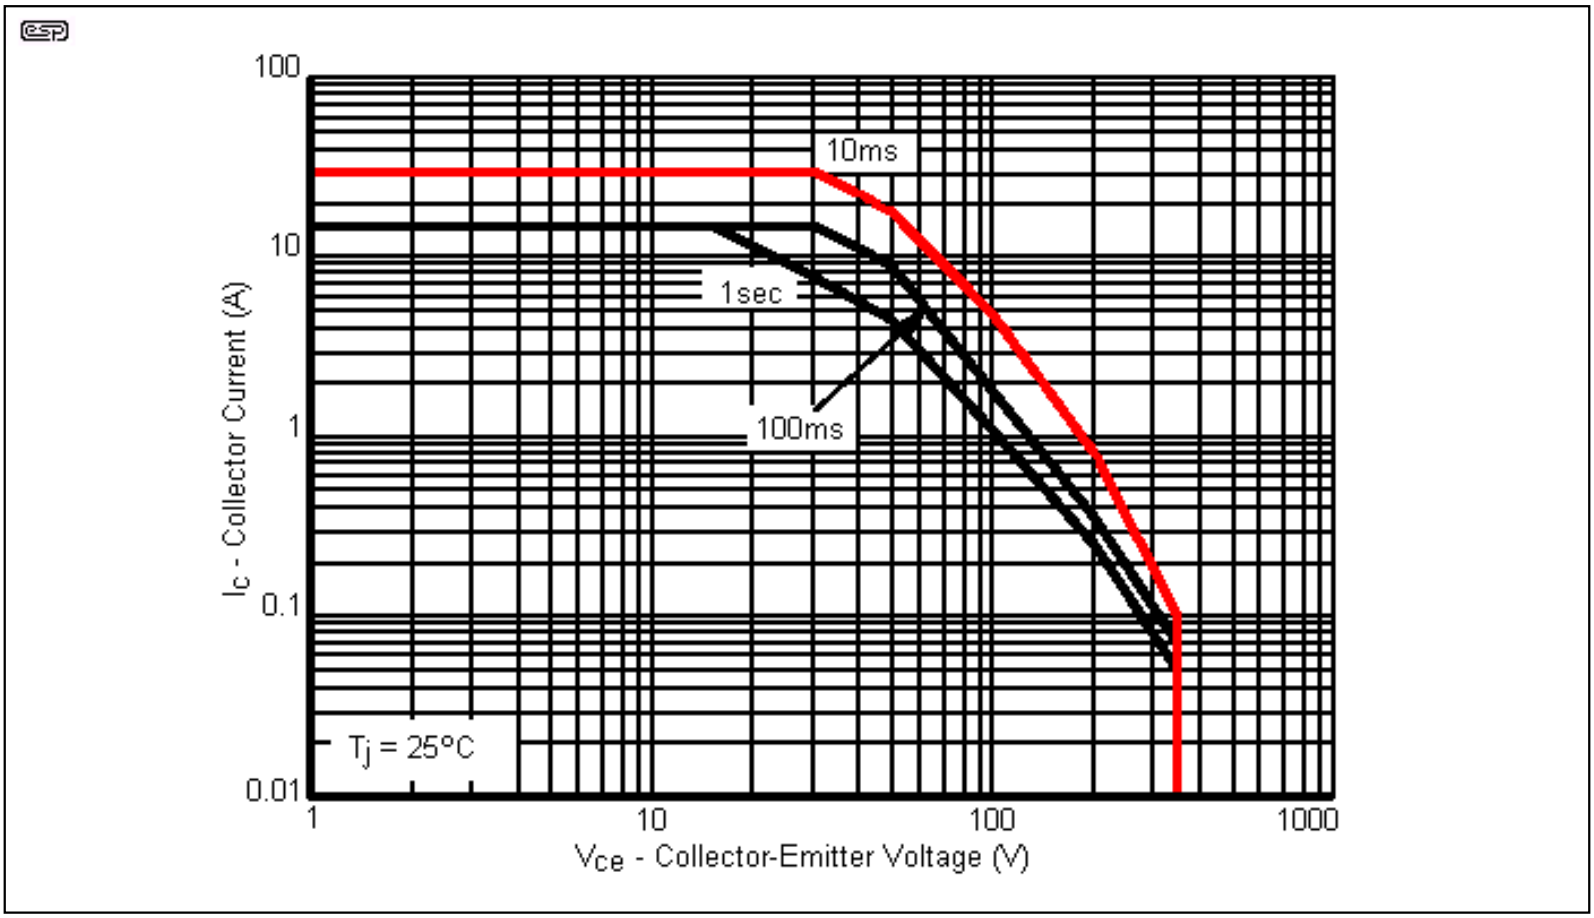

Figure 3.1 - SOA Curves for MJL4281A/4302A

If the time is extended, then the peak current is reduced for a given voltage, and for 1 second, the maximum rated current (15A) may only be drawn at collector-emitter voltages below 15V. This region is limited by the maximum rated current of the transistor, and will *never* allow continuous operation at maximum power (remember thermal derating? This is where it *must* be applied).

So far, all this looks pretty good if you look at it in conjunction with the demands outlined above, and it even *looks* as if it would be safe with 4 ohm loads at greater than rated ±35V. Appearances can be deceptive though! Remember that all peak currents and power dissipations referred to were for a junction temperature of 25 degrees - no transistor can maintain that temperature in real life, since there is thermal resistance between the die and case, and further thermal resistance between case and heatsink (see Heatsink Design for more information on thermal resistance and heatsinking of transistors).

The devices must be derated by 1.84° C/W above 25° (see Fig 2.1), which gives *zero* dissipation at 150° C. The thermal resistance from junction to ambient air (via the case, insulating washer and heatsink) can be expected to be around 1.5-2° C/W (for a *big* heatsink), so all dissipation limits quoted can be expected to be as little as 1/2 of those shown in the specifications.

That means that the 230W transistor is really capable of a dissipation of around 120W at typical (relatively high) operating temperatures. As a result, at ±35V with a 3 ohm resistive + 3 ohm reactive load (representing a typical 4 ohm speaker either side of resonance), the maximum limits will be exceeded!

Although this is completely true, in reality there are two things that will ensure that the amp remains functional (for many years) - the nature of music itself, and the collapse of the power supply under

sustained load. However, continuous operation at full power into a reactance that gives a 45° phase angle will cause the amp to fail, even with ±35V supply rails.

The variable nature of music, where the frequency and instantaneous amplitude are continually changing, means that potentially destructive signals do not last long enough to cause a problem, however increasing the supply voltage or reducing the load impedance further will almost certainly cause device failure.

Likwise, the bigger the heatsink, the better. The thermal resistances that cause the semiconductor die to operate at a much higher temperature than you may expect are the limiting parts of the equation - and they cannot be eliminated - at least not sensibly. It is generally considered uneconomical to provide a refrigeration system to keep the transistor temperature at low enough temperatures to avoid problems.

3.2 Device Parameters

Maximum Current: The emitter area determines the maximum current capability of the device, there are many design options for emitters, for audio transistors nearly all manufacturers use perforated emitter (also called mesh emitter) designs. The perforated emitter design also gives better gain linearity than a regular "interdigitised" emitter finger design (double or single comb). The other benefit for perforated emitter designs is silicon area utilisation, you can put a lot more emitter in a given piece of silicon with this design type for lower cost. One trade-off of the perforated design is switching, devices won't be as fast but we really don't need good switching capabilities for linear transistors and for audio this is a non issue. The bonding wire size depends on the current rating of course. Typical is around 15 mils (0.38mm) aluminium for audio high current devices.

Maximum Power Dissipation: Die size is the main parameter, ON Semi's Thermal Characterization Lab has done extensive studies and created some formulas for each package type so they can predict the thermal resistance (J-C) for any Die size in a given package. There are other factors besides die size that can affect the power dissipation, like solder line thickness, solder alloy, die thickness, etc. For good SOA performance good power dissipation is a must, thin die and very thin die attach solder are very important factors.

Second Breakdown: This is tough to determine and normally is determined by testing devices in a SOA tester by forcing power between collector and emitter and measuring the power dissipation time to secondary breakdown. Vertical structure of the device (collector and base thickness and resistivity) are important device design parameters, as well as die design geometry.

Current Gain: Emitter area determines the maximum current gain at high current levels of a device, too high peak hFE may result in lower BVCEO (Breakdown Voltage - collector to emitter, base open), higher hFE results in lower VCE(sat), VBE(on). As mentioned before, for good current gain linearity a perforated emitter design is best.

fT (Current Gain bandwidth Product): This is directly related to device gain and also to the device physical base width (wb). Most of the audio transistors in the industry have high fT (~30MHz), the trade-off is SOA performance with high voltage conditions. ON Semi Power Base Technology (which is unique in the market) has low/medium fT devices (8 to 12MHz) devices like the MJL21193/94 which have

excellent SOA above 100V, these devices have wider Bases and also some unique "base spreading resistor" design which make them extremely rugged, used by most high end audio manufacturers.

FBSOA (Forward Biased Safe Operating Area): Die size, power dissipation, die geometry and base width are some important parameters.

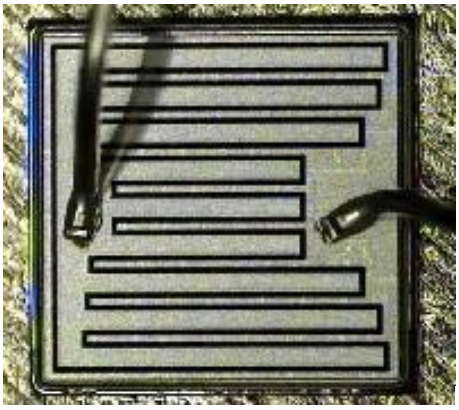
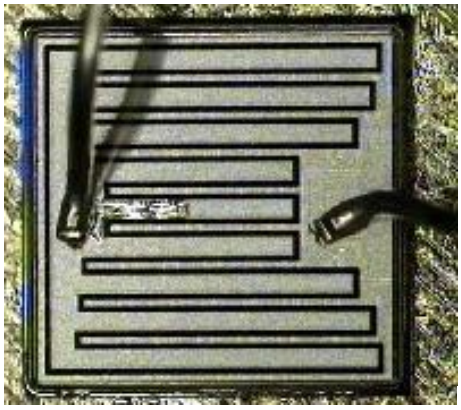
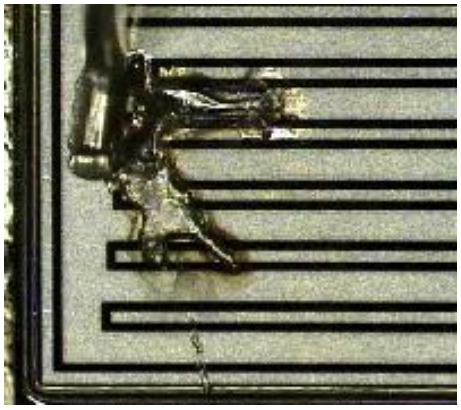
4.0 Destruction!

The following photos show a typical (functional) die, and two shots demonstrating destruction. The shiny sections are melted silicon! This is also a good example of the "interdigitised finger" type of emitter and base construction referred to above.







Figures 4.1, 2, 3 - Transistor Dies (click for full size image)

The functional die (left) shows clearly what a typical transistor looks like. The emitter and base sections are clearly visible, with the emitter having the thicker "fingers" for best current carrying ability. This is not one of the new ON Semi transistors - the photo is representative only.

The damage in the failed die is quite obvious (centre), and there is a section of melted silicon where the transistor failed. As is the case almost 100% of the time, the transistor is shorted. Open transistors normally are the result of a bonding wire failure after the short has caused excessive current. This failed die would (probably) show the base junction as intact in a resistance test.

A close-up view (right) with greater damage. A large section of the die has exploded from the failure point outwards, and molten silicon has been sprayed all over the die. This failure would almost certainly indicate a short on all terminals (provided bonding wires are intact).

It is a sobering thought that these failures would have taken place in a matter of milliseconds - once the second breakdown region has been reached, the transistor will enter a negative resistance state, and there is nothing that will prevent total failure once the process has started. (Negative resistance is probable, but not a certainty - it depends to some extent on the fabrication method.)

(The above photographs kindly provided by ON Semiconductor)

4.0 Protection Schemes

A great many protection systems have been used over the years, in the hope of protecting the transistors from damage under all conditions. Power opamp ICs have the most comprehensive protection, but often at the expense of sound quality. By necessity, the protection must operate while the transistors are still quite safe, so their maximum power is never available.

Discrete amplifiers usually employ a simplified system, that will afford protection from most mishaps. A completely foolproof system is usually quite complex, and considerable care is needed to ensure that it does not activate during normal operation. This also applies to simplified systems, and a great many that I have seen do not provide complete protection at all - some are incapable of protecting against short circuits, unless at the end of a length of speaker cable (i.e. the cable's resistance forms part of the protection).

A further problem is that a full protection system will switch the power transistors off very fast, and given that the loudspeaker load is reactive, a "flyback" voltage can be developed that can easily destroy the transistors anyway. Many amps use a pair of diodes from the output to each supply - they are designed to ensure that the output voltage can never exceed the supply rails (except by the diode voltage drop).

In nearly all cases, it is necessary to either use additional output transistors, or tailor the protection circuit to ensure that excessive fault currents are not possible. This invariably means that there will be regions of the signal waveform where the protection circuit will operate when it should not do so. It is thought by a great many people that protection circuits degrade sound quality, and from tests I have done, this is certainly the case if (when?) they operate on any normal loudspeaker load. The *only* way to avoid problems is to use more output devices than you planned to, and even this is no guarantee that the amplifier will survive every abuse that it will face in a typical domestic or professional application.

Few discrete protection circuits monitor the temperature of the output devices (or the average power level) and thus adjust to suit the conditions. This means that a hot amplifier has a lower level of protection than a cold one, and it is no surprise that amplifiers fail most when driven hard for long periods (commonly as a result of a speaker failure). Thermal tracking is "automatic" in IC power amplifiers, since all devices are on a common piece of silicon.

Probably the best protection of all is a monitor that will operate if the output transistor SOA is approached, and removes the input signal. This is unfortunately much more difficult than it may seem at first, and the signal switching circuit is another candidate for sound quality degradation. Relays cannot be used, as they are not fast enough - remember, faults lasting only one millisecond can be sufficient to cause failure.

Fuses are used in amplifiers to prevent fire and further damage - no fuse is fast enough to protect an amplifier against fault currents, unless it is so low in value that it will blow during normal use (and even that is very doubtful).

Some "high end" amplifiers (where cost is no object) use a vast number of transistors, and ensure that at no normal (or abnormal) load will they ever exceed perhaps 1/2 their maximum rating. For typical consumer amplifiers (and most professional amps as well) the cost is a primary consideration, and transistors are run to their limits - to do otherwise would make the amplifier uncompetitive in the market.

A typical protection circuit is shown in Figure 5.1 and it is representative of the majority of those in common use. By sensing the current through the emitter resistor, the circuit detects an over-current fault, and removes base drive from the Class-A driver. As the voltage across the output transistor(s) is reduced, the sensitivity of the protection circuit is also reduced, allowing the maximum current at lower collector-emitter voltages where second breakdown is not a problem.

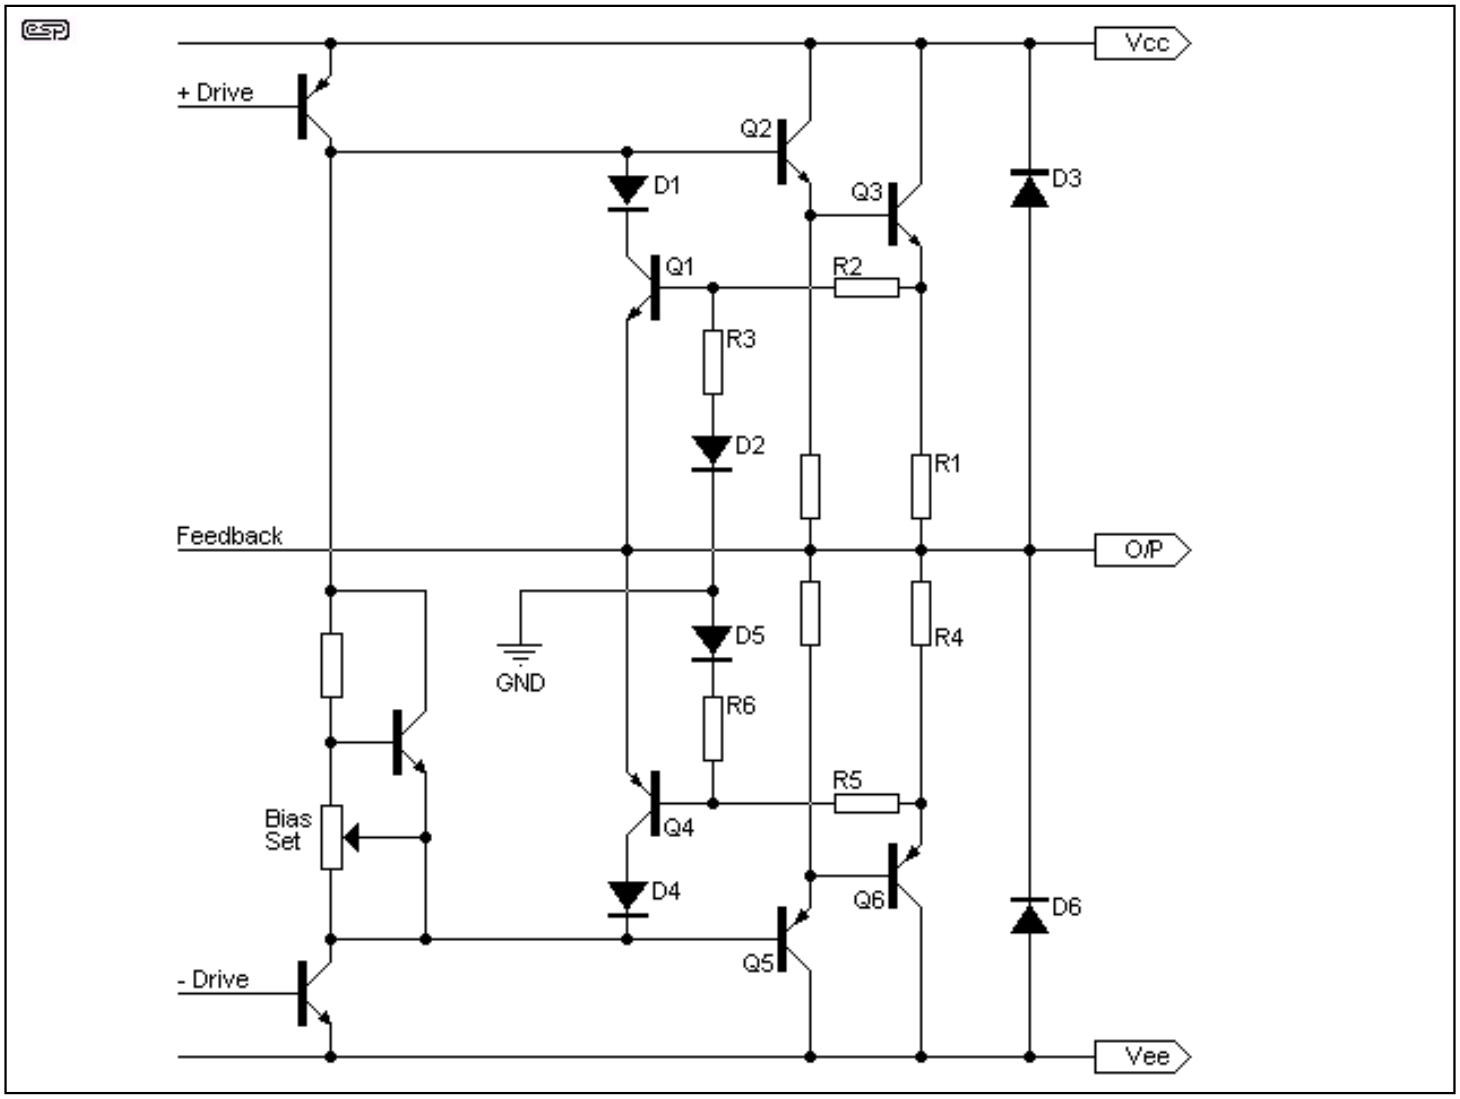


Figure 5.1 - Typical Output Protection Circuit

How does the circuit work? It is fairly straightforward to explain. Looking only at the upper section, R1 is used to sense the current through Q3, and if it exceeds about 0.65V, Q1 will turn on, "stealing" base current from Q2 (and thence Q3). D1 isolates the circuit from the drive circuit under normal operation. At zero volts output, the current through Q3 must be limited to below the danger level on the SOA curve. With a 35V supply, there are no major problems, but above that, the SOA is severly limited. For example, at 50V, the maximum current is 4A, so R1 must be chosen to provide 0.65V at (or below) 4A - remember that the SOA is limited further with increasing temperature, so 2A would be safer.

As the output voltage increases, R3 (via D2) shunts some of the current sense voltage to ground, reducing the effect, and allowing more current. The danger zone (and the cause of most of the problems) remains at 0V though - with a typical loudspeaker reactive load, a significant current is needed at 0V. Even with 35V supplies (as described above), we need as much as 6.5A when the output voltage is at

zero volts (see Fig 2.3). The problems caused by phase angle are such that it is almost impossible to design a current limit circuit that will allow maximum power, but still provide protection for shorted speaker leads, unless there are more output devices than appear to be required.

Note: At ±35V, an amplifier such as P3A is completely happy, and with high power (200W) transistors is operating within the SOA curve at all times and with any load (down to a typical 4 ohm nominal impedance). There is sufficient reserve power capacity to enable the amp to withstand full power into 4 ohm loads even at reasonably elevated temperatures.

However, once the supply voltage is increased, much of the reserve will be used up, making the amp liable to failure. This applies to any amplifier of similar ratings operating into typical loads - P3A has been used as an example, but the same constraints apply to any other design, used in the same way.

With careful component selection, circuits such as the above can work quite well. A good design will be conservative (and will therefore need additional output transistors), and will be reasonably effective in all cases. If the designer tries to get as close as possible to the transistor's ratings, the safety margin is reduced, and protection is less effective, Some legitimate signals will cause limiting, and other loads (especially at elevated temperatures) are likely to cause the transistors to exceed their ratings. There is a very good chance that the amp will survive regardless for many years, as the danger point may never be reached in some installations - others will destroy amp after amp, until one is found that can handle the abuse (or the abuse is removed).

6.0 Conclusion

It is obviously imperative to avoid second breakdown, and there are many ways that various designers have selected to do so. Protection circuits, Class-G (using two or more supply rails), variable supply voltages, and even switched supply voltages - these are common in many home theatre amps, and a switch is used to select the voltage to suit the load impedance.

There is also the "brute force" method, where there are so many power transistors that the cables will melt before any one transistor's ratings are exceeded, but this is uncommon except in high end amps where the added cost is not considered a problem. Many amps provide no protection at all, other than ensuring that dissipation limits are observed, but a shorted speaker lead (or a lower than recommended load impedance) can cause the amp to fail.

Regardless of the method used, it is important to ensure that the designers' recommendations are followed - good output transistors are expensive, and few of us can afford the luxury (??) of blowing up amplifiers for the hell of it. While a design that exceeds the transistor ratings may last for many years, there will eventually be a combination of circumstances that will cause failure. Parties are a prime cause of blown amps and speakers, and if they feature regularly in your activities, a cheap system (that can play loud, but very basic and with passable fidelity) is highly recommended. Its failure is not something you would cry over, and the main system remains intact always.

Finally, it is important to stress the importance of the SOA curve for any transistor used in an output

stage (including driver transistors). Any design that appears to be able to get more power from smaller transistors has almost certainly pushed the devices to (or beyond) their limits, and when driven hard into a difficult load, it will most probably fail - this is an expensive exercise if it takes the loudspeaker with it (not at all uncommon). Ultimately, a "worst case" design procedure assumes that the amp will be driven hard into a difficult load, and with undersized or barely adequate heatsinks. Such a design will survive - others will not.

When it comes to cable constructions, everything makes a difference. Most (but not all) of these differences are measurable. What is at issue is whether these differences are audible ... or not, when tested properly using a blind A-B test. Sighted tests are at best unreliable, and at worst cause people to believe things that are simply untrue. The vast majority of all cable claims have no basis in reality, and rely on the placebo effect.

Introduction

"I refuse to prove that I exist," says God, "for proof denies faith, and without faith, I am nothing."

> The Hitchhikers Guide to the Galaxy, Douglas Adams

The above could just as easily be re-phrased - for example ...

"I refuse to prove that my cables will make your system sound better", says the snake oil vendor, "for proof denies faith, and without faith, you will hear nothing."

The tenets of faith are an absolute requirement for many of the claims that are made for many (probably most) of the "esoteric" hi-fi additions that you will find everywhere on the web. There is no real information, technical, scientific or otherwise, and the only terms you will hear will be of a subjective nature - for example "solid, sparkling, sweet, musical" will be contrasted with "muffled, veiled, grainy, harsh" - the very selection of the words is designed to sway you to their position, preferably subconsciously.

The marketing is often very subtle, extremely persuasive, and there is no confusing techno-talk in there to confuse the non technical reader. While it may seem like Nirvana, the claims are nearly all completely false.

Faith (in the religious sense) is based on the premise that faith is God's proof that God's existence is truth and does not rely on facts. Indeed, if facts were available, then faith is

not required - so in a sense, faith can be seen to be based on an absence of evidence - a fiction.

Believers may also qualify faith as either representing truth or they will represent it as being above and beyond our understanding. Truth becomes a consequence of faith which is the believer's recognition of the absence of evidence. Truth is therefore defined according to a circular perception.

I am not about to dispute the religious beliefs of anyone - these are sacrosanct, and belong to the individual alone. When the same arguments are used for audio, this is a different matter. Audio (unlike religious beliefs) is based on science. Without the efforts of scientific work and studies over many years by a great many people, we would not have audio as we know it. Now, we have charlatans and thieves claiming that science is ruining audio, and that we have to get back to the basics to enable real enjoyment.

You need, *nay!* ***must have!*** the latest shiny rock on top of your CD player, lest the sound be harsh, grainy, and lacking bass authority, and without the latest cables at only US$200 per foot, you are missing out on half of the music. But ... you must believe, for the magic will surely be dissipated instantly should you attempt even the most rudimentary scientific test, or even request any technical information.

Now, consider the situation with watches. Has any ultra-high-priced watchmaker ever claimed that the "quality" of the time told by their watch is superior to that from "ordinary" watches, or that the "sense" of the time has greater depth and more "chi"? Maybe they just haven't thought of that angle yet, but I expect that this is unlikely. The simple fact is that these pieces of jewellery are finely crafted and superbly executed timekeepers, but are usually no better or worse that "lesser" brands that do exactly the same job.

The situation with cables is no different - you may *choose* to pay outlandish prices to get something that looks amazing, and demonstrates to everyone how much money you have, but it will not make a magical difference to the sound, there will be few (if any) real differences in the electrical characteristics, and it will sound much the same as "lesser" cables, selling at perhaps 100th of the price.

If image is important to you, and you can afford it, then that is your choice - just don't expect that it will make your system better, and don't try to convince others that without "it", they are missing half their music or their sounds are being mangulated in some mysterious way that can only be "fixed" by spending vastly more than they may be able to afford.

Note: It must be considered that there are some people whose hearing acuity is far greater than the average, and they may well hear things that we 'mere mortals' cannot. For such individuals, a particular cable might indeed show an improvement (or at least a difference), but this does not mean that the same improvement/difference will be audible to anyone else.

The majority of this series of articles is directed at the majority of listeners - no surprise there. Just because some rare person with hearing that is well above average can hear a difference does *not* mean that everyone will do so, although it is unlikely that anyone will admit to being unable to distinguish one from another. No-one wants to be classified as being 'tin-eared', and especially so if they have spent a lot of time and money on their system.

Yes, there are a (very) few people who can genuinely be considered to have 'golden ears', just as there are a few musicians who have perfect pitch, and various other individuals with a particular skill in some area that most of us lack. Just as no-one will normally reject the photographs taken from a camera (for example) that one person can see are ever so slightly flawed (but look fine to us), then nor should we reject a cable that sounds just fine.

Indeed, the variations in different recordings (even of the same material - and especially so with vinyl!) will be far greater than the variations of any cable with reasonable construction and sensible design.

Despite what you may read in various forum pages, this entire series of articles is not intended as a "beat up the subjectivists" tale, but rather a discourse based on research that I, and a great many others before me, have done. The idea is not to ruin anyone's enjoyment of audio, but to make sure that the facts are available, without the hype and BS so commonly associated with high fidelity.

The major (and well respected) audio companies did not develop their equipment using only their ears as a guide. Without exception, all the big (and very expensive in many cases) brands have been measured, probed, simulated, then measured some more - before anyone actually gets to hear one. How much of this pure research has gone into most of the overpriced cables and "accessories" currently available? I don't think I need to answer that, as we all have a pretty good idea.

So much has been said about cables over the past few years that there couldn't possibly be any more to discuss. Nice theory, but the wheel has turned a full circle, and there are now people claiming that there is no difference at all between any speaker cable or interconnect. In exactly the same way as the claims that there were "huge differences" were mainly false, so too are claims that there are none.

There is no "black and white" in this topic, but a great many shades of grey, and the latest update to this article attempts to clarify the position. Speaker cables in particular are still a major topic of conversation on many forum sites, and remain one of the more contentious issues.

A quick summary of the topics to follow (in the cable discussion, at least) would be ...

- Power leads will rarely (if ever) have any effect on the sound, provided they are of reasonable construction and are not inducing noise into (unshielded) interconnects. The only exceptions are those that use filters of some sort, which will reduce the noise floor in areas where interference is a problem.
  Some leads are of flimsy construction, and may reduce the available power for sustained loud passages, however, the difference will rarely exceed 1dB in most cases.
- Speaker cables *can* (and sometimes do) sound different with a given amplifier and loudspeaker combination, even where they are well designed and of reasonable gauge. Excluded are very thin or extremely silly combinations - these will always do something to the sound, rarely good.
- Interconnects *might* sound different, but only if they use odd construction techniques. Generally speaking, all properly (sensibly) designed and well made interconnects will sound the same - excluding noise pickup which is common with unshielded designs.

This is not to say that some people will not derive great enjoyment from the fact that they have spent as much on their cables as mere mortals can afford for their whole system, but this is "enjoyment", and has nothing to do with sound quality. This is about prestige and status, neither of which affect the sound.

Try This Next Time Someone Tries to Sell You Something ...

Thanks to a reader for the suggestion, this is a wonderful way to prove something to yourself. Next time a salesperson tries to flog you the latest and greatest (and of course most expensive) cable they have on offer, just use this technique ...

Suggest that you would like to hear the cable in action before committing yourself. As you walk to the demo room with the salesperson, come up with 'spontaneous' bright idea - suggest that you swap the cables, and if the salesperson can correctly identify the 'super cable' that s/he so desperately wants you to purchase, then you will do so. Naturally, you will want to make the swap several times, and the salesperson will have

to get it right at least 75% of the time.

There is every chance that the packet will never be opened, the comparison never done, and you will save a bunch of money. There is nothing dishonest about what you are doing - you simply want (and are entitled to) verification that the cable will make a difference, and if the salesperson is unwilling to participate in the test, s/he knows something that s/he hasn't told you!

Beware! If there is any suggestion that the cable needs to be 'broken in' before you hear the difference, the salesperson is lying! At this point, you should immediately let them know that you know that they are lying, and leave the shop. Cable 'break-in' is a myth, and is perpetuated by those with something to hide - no-one has *ever* been able to show that there is any scientific justification to the claim, nor shown that the performance has changed in any way whatsoever. Cable break-in is real, and occurs between the ears of the listener - nowhere else (most certainly not in the cable).

Preamble

The last link entry for the ABX Home Page has been included so you can have a look at some actual ABX double blind tests that have been carried out. The listing at the ABX site is not extensive, but is excellent reference material. You will find some of the results surprising, and when viewed and interpreted sensibly, they tend to support the comments I have made in this article.

In some cases, the results surprised me, in that I was expecting the listener panel to declare various items as different, and they instead thought they were the same (which is to say that the two items under test could not be identified with certainty, so any choice was pure guesswork).

In this article, I shall attempt to explain some of the misconceptions and untruths that are rife in the audio industry. This article is bound to offend some, but the information is based on fact, scientific data and the results of my own (and others') testing, plus the help I have received from readers, who have provided more information on a number of topics.

In contrast, much of the disinformation comes from the rantings of Hi-Fi reviewers, most of whom know so little about electronics that it is shameful (and fraudulent) for them to be in a position to tell the unsuspecting public what to buy, based on entirely subjective criteria.

In almost all other areas of human interest, objective measurements are paramount. A domestic vacuum cleaner's performance is based on how much dirt it collects from the carpet - any philosophical discussion about the type of motor used, or it's rotational direction having a subtle effect on how clean the carpet feels is at best a pointless and tiresome exercise, and (I hope) has never been entered into.

Discussion - indeed, heated debate - on parameters not dissimilar to those above are commonplace in the high end audio industry, and have been raging since the late 1970's. The majority of people who listen to music generally listen to a few systems at a non-specialist retail outlet, and buy a combination that sounds good (to them), has the features they want, and fits their budget. They are no more interested in the great audio debate than they would be in the philosophy of the rotating mechanical components of their vacuum cleaner.

In his article "Science and Subjectivism in Audio", Douglas Self [1] wrote

> A short definition of the Subjectivist position on power amplifiers might read as follows:
>
> - Objective measurements of an amplifier's performance are unimportant compared with the subjective impressions received in informal listening tests. Should the two contradict the objective results may be dismissed out of hand.
> - Degradation effects exist in amplifiers that are unknown to engineering science, and are not revealed by the usual measurements.
> - Considerable latitude may be used in suggesting hypothetical mechanisms of audio impairment, such as mysterious capacitor shortcomings and subtle cable defects, without reference to the plausibility of the concept, or gathering any evidence to support it.
>
> I believe this is a reasonable statement of the situation. Meanwhile the overwhelming majority of the public buy conventional hi-fi systems, ignoring the expensive and esoteric high-end sector where the debate is fiercest.

In the following articles I shall dissect some of the claims made on many of the components in the audio chain, and show why they are misleading, false, and in many cases downright dishonest. See Further Reading for ... well, further reading.

Preamble Part 2

A fairly well known person (rampant on certain forum pages) has claimed that I consider *all* conductors and insulators to be "perfect", and that "all engineers who design in the

real world know this is not the case". Oh really! ... and where **exactly** did I say that all conductors and insulators are "perfect"? Where did I *imply* that they are perfect? These questions remain unanswered (of course) because I have never claimed, assumed or implied that they are perfect.

No insulator or conductor is perfect - in fact, no "anything" is perfect. The simple fact of the matter is that these imperfections are not significant at audio frequencies, except perhaps in "unusual" cable constructions (of the type often suggested by the lunatic fringe). This is one of the typical "red herrings" that raving psychotics will bring up time and time again, to bolster their unsubstantiated and flawed "reasoning". Claims like that are typical of delusional thinking, and the delusional only have to claim that I (or someone else) said that "all conductors and insulators are perfect" (for example), and it somehow makes it "true" that these words were in fact used.

Well, I have some news that may come as a shock - anyone can *say* anything they like, but the saying does not make it so! I have *never* claimed that all conductors or insulators are perfect, but I have challenged anyone who claims that the imperfections are audible to please do so. So far, there has not been one shred of evidence that indicates that Teflon™ (wonderful stuff that may well be) is **audibly** superior to PVC in a properly controlled double-blind (or ABX) test. Differences are measurable (with the right equipment) but are not relevant to the audio range unless the "facts" or cable topology are manipulated to influence the test.

I have asked every person and/or company named in the Mad As Hell articles for any information they have that substantiates their outrageous claims, and not one, not a single **one**, has supplied anything more than some useless promotional material or "satisfied customer" e-mails. Why is "satisfied customer" in quotes? How do I, or anyone else, know that they are genuine? For all we know, they are fabricated (i.e. lies), without an iota of truth in any of them. Oh, but I am so *negative*!

Of course I am, these people are liars, charlatans and thieves, either by accident (they may actually *think* they are realistic because of mental illness [such as delusion or psychosis] or some other mitigating circumstance) or by design - they simply have one goal ... to separate people from their money. The actual "mechanism" is unimportant - the fact that they are wrong does not enter into their equation of life, so whether their claims are due to mental illness or greed makes no difference to the consumer, who is being ripped off and lied to either way.

I recently had an e-mail exchange on the topic of interconnects, and the "conversation" started out innocently enough. I was advised that by using the tape loop on a preamp, I could listen to the effects of different interconnect cables, simply by switching to/from tape monitor.

I firstly suggested the test methodology suggested was flawed, since any additional circuitry used to make up the tape loop circuit would have some influence. In addition, the feedback to the brain (knowing which switch setting was which) means that a genuinely objective (double blind) test was impossible. The test method does not even qualify as single blind - it is an open test, and the experimenter expectancy effect will confer non-existent attributes to the material being tested, based on preconceived ideas and expectations.

The e-mails went back and forth for a while, and eventually I was finding that it took up too much of my time, and the topic is not all that interesting anyway - after all, how excited can one get over ordinary signal leads.

This is doubly true when the other party invents reasons that ABX tests are "invalid" for audio - something about the signal complexity, and the psychological effects of the music was mentioned. This is exactly why we must use ABX or similar double blind tests - anything else will fail to properly eliminate feedback cues, and these will be used (albeit subconsciously) to determine whether the "standard" or "test" item is currently in circuit. Any test where there is any possibility of identifying the components under test is completely invalid.

It is interesting that in a relatively non-demanding application such as an interconnect, a material such as aluminium would likely be sneered at by any audiophile, yet this very same material is used regularly in loudspeaker voice coils. I am reasonably sure that sonic performance of an aluminium interconnect would be deemed to fall way short of excellence, yet I hear (or read) no highly critical comments about using it in a voice coil. This is an extremely demanding role, and the performance of aluminium is (or can be) audibly and measurably worse than copper. *

My (almost) final e-mail pointed out that no metallic conductor introduces distortion. Now, I must admit that I did not qualify this, but when I speak of distortion I refer almost invariably to non-linear distortion (i.e. the type introduced by all active components, that generates harmonics and intermodulation products not present in the original signal). A simple question would have cleared this up, but ...

The response I received astonished me - suddenly, my statement that "no metallic

conductor introduces distortion" was utterly misconstrued, and became "all metals are perfect conductors"! It was inferred (of course) that this was the reason that my tests and experiences are simply invalid, while those of my correspondent were reasoned and obvious.

This is absolutely the sort of thinking that got everyone to this impasse in the first place. I never suggested that all metals are perfect conductors - I said that they don't generate (non-linear) distortion. By means of misinterpretation, the subjectivist camp will now think it has another "weapon" against the enemy - the fact that it is the result of a gross mangling of the original statement is of no consequence ... "Never let the facts get in the way of a good story".

The fact of the matter is that no metallic conductor causes (non-linear) distortion. There are various resistances depending on the metal, but it's basic conductivity is completely linear. Check things like thermal coefficient of resistance for any metal - it is linear. There are no curves or "fudge factors" to be taken into account. While it may be possible to make an alloy that exhibits some degree of non-linearity, this would not be used as an electrical conductor, and would certainly not be suggested as an alternative to copper. Even then, within the very limited range of acceptable temperatures in the listening room, such non-linearities could easily be less than that of air - the medium that carries the sound from the speakers to our ears..

None of this has anything to do with skin effect, velocity factor or any of the other seemingly strange behaviours of all conductors at high frequencies (none of which are non-linear distortions), we are interested in the simple ability to conduct current from point A to point B without any form of rectification or other non-linear effect. All metallic conductors in common use will do this perfectly well, and will not add harmonics or change the waveshape in any non-linear way.

Harmonics can of course be removed - this is a filter effect (a completely passive linear function), and is caused by capacitance and inductance. All cables have these parameters as a fact of life - a silver wire and an aluminium wire of the same length and diameter have different resistance, but inductance and capacitance are the same.

The degree of hostility I experienced towards ABX testing was equally puzzling. I don't know of any designer who will claim that listening tests are invalid - only that they may not reveal the entire truth of the matter, and that additional "technical" evaluations may be needed to find out why the listening tests did (or did not) correlate with the measurements.

On the other hand, many subjectivists claim that anything ***other*** than a listening test is invalid, and commonly and even vigorously eschew ABX testing - possibly because they know in their hearts that they will be unable to find any difference. This is very confronting, and to have one's beliefs shattered is not a pleasant experience.

What is the most interesting to me is the "head in the sand" behaviour. I was automatically wrong in my thinking, and I suspect that anything that I said would have been twisted around to make sure that I stayed wrong. I could (of course) have simply agreed with the subjectivist's position, however to have done so would have been a lie on my part.

The issues at stake here are the crux of the on-going debate between the two "camps". While I will admit that not all designers will take any subjective opinion seriously, I do know from my own testing and from a huge amount of reader feedback that some of my designs sound better with different transistors or power supply configurations (for example). Most of these differences can be quantified, although some are elusive, and that is something that I live with, knowing that many of the further "tweaks" are assessed by purely subjective methods. There is every chance that ABX testing would reveal no audible difference.

*** More on Aluminium (Aluminum)**

I mentioned above that aluminium interconnects would generate scorn and derision from the audiophiles. Well, it seems that for some, even using it for shielding is bad ...

> "Unused RCA inputs on the back of [amplifiers] are prone to pickup stray RF Interference and EMI. This can cause a higher level of background noise, haze and grain. For years audiophiles have used shorting plugs or (gag!) aluminum foil, to remedy the situation. Unfortunately, many preamps do not like to have their inputs shorted. What to do?"

Wonder what "gag!" implies - I think I can guess. Needless to say, the answer was in the product line for the site in question - I shudder to think how much their little RCA "hats" cost.

I saw remarkably few references to aluminium even being used (let alone sounding "bad") in interconnects, and no adverse comments at all about it's use as a voice coil winding wire. I must confess that I did not spend a vast amount of time on this, partly because as I said early in this section - cables are just not very interesting :-)

How does this thinking occur? An excellent article on the human belief system is The Belief Engine, which is to be found at http://www.csicop.org/si/9505/belief.html. The

article describes the mechanisms we use to generate beliefs, and the ways that these beliefs are reinforced as we go along. One tiny quote from the article ...

> Our brains and nervous systems constitute a belief-generating machine, a system that evolved to assure not truth, logic, and reason, but survival.

What does survival have to do with interconnects - nothing at all, of course. But this does not change the way we think, and especially does not change the way we think we think. Beliefs are extremely powerful, and can be almost impossibly difficult to shed once they have become entrenched ... I have no expectations at all that this article will change that one little bit, but if it helps others (not yet contaminated) to stay well clear of pseudo science, then I have done what I could.

Introduction

This article is a republished version of that originally written by Roger Sanders (InnerSound), one of the "fathers" of the electrostatic loudspeaker. While it may appear that this is an advertisement for InnerSound, this is not the case at all, but to remove the name would be to unfairly remove the appropriate references to the source of this material. I have no affiliation with InnerSound or Roger Sanders, and references should not be seen as an endorsement or criticism of their products - I have not heard the ESLs, preamps or amplifiers, so any further comment on this is not appropriate.

This material is not published without considerable thought and soul-searching on my part. It reflects many of the things I (and many others before me) have already written on the subject. It is presented here as a public service - the hi-fi fraternity needs to be

aware that a great deal (the vast majority - OK, *all*) of the hype about 'cable sound' is pure, simple, and unadulterated bulls**t!

There are a very few things that make a difference, and these are explainable, repeatable and measurable.

There is no basis in reality for most of the claims made, and a search of the ABX site will confirm this. It is to be hoped that this article (which has apparently already caused some flak) will help to clear up some of the gross exaggerations and dis-information that abounds on the WWW and in magazines. Most of us may think that the dissemination of information should be factual, but unfortunately there are many people who publish 'information' purely for their own benefit.

Note: I have removed the pricing details from the original article, as these are not relevant to the discussion. Otherwise (apart from substituting Australian spellings) the article is untouched in terms of the content.

Speaker Cables Used With Electrostatic Loudspeakers

Electrostatic loudspeakers (ESLs) are different. The load they present to an amplifier and speaker cables is quite unlike that of conventional magnetic speakers. To a speaker cable, they appear as a capacitor, while magnetic speakers appear as a combination of a resistor and inductor. It therefore is not surprising that cables for ESLs have different requirements from those for magnetic speakers.

Cables have inductance, capacitance, and impedance. Cable manufacturers juggle these parameters to get the cables to sound the way they want. Let's look at these elements more closely and see how they should be optimised for ESLs.

An ESL is driven by a high-voltage, step-up transformer. This transformer is inside the speaker and converts the relatively low voltage of an amplifier to the several thousand volts needed to drive an ESL. Unfortunately, all transformers have leakage inductance. This inductance interacts with the capacitance of an ESL to form an L/C (inductance/ capacitance) resonant circuit. This produces an undesirable, high-frequency peak in the frequency response of the ESL.

It is essential that this resonance be kept well above the audio spectrum to prevent the sound from being excessively 'bright'. Since the capacitance of the ESL is fixed, the only way to get the resonance high is to build a transformer with very low leakage inductance.

Designing and building very low leakage inductance transformers that will operate over a wide frequency range and at high voltages is extremely difficult. One of the reasons that some ESLs sound better than others is the design and quality of their transformers.

Inductance is a big problem with ESLs due to the L/C resonance described above. ESL manufacturers expend great effort to obtain transformers with low inductance. So it is vitally important that the cables have low inductance too. If the cables add a lot of inductance to the circuit, they can undo the transformer designer's best efforts.

Inductance

In a speaker cable, inductance is largely determined by the area between the conductors. Most speaker cables have conductors that run side by side ('twin-lead') and that are separated by a small distance, so have moderate inductance. They do not have the low inductance desired for the best performance when driving ESLs. Some cables use many small wires that are woven together. This reduces inductance greatly, but at the cost of increased capacitance.

Capacitance

The capacitance also should be low. This is not as critical as inductance, but it is important. Remember that an ESL is a capacitor, and amplifiers find capacitors very hard to drive. If the cable adds more capacitance, it only makes things that much worse for the amplifier. Capacitance is highly affected by how close the conductors are to each other. So to keep the capacitance low, the conductors must be widely spaced. Note that this is just the opposite of what we need for low inductance.

Many cable manufacturers deliberately add a lot of capacitance to their cables. For example, you will find a box at the end of MIT cables, which contains capacitors. Alpha Core (Goertz) cables are made as a sandwich with two ribbon conductors very close together, and this type of construction produces high capacitance and often, amplifier instability. Woven wires are close together so have high capacitance. These types of high-capacitance cables are best avoided when operating ESLs.

Impedance

Impedance is the resistance to the flow of current in a cable. Most cables are designed

to have low impedance so that they don't significantly reduce the damping factor of the amplifier. But some manufacturers deliberately use high impedance cables to alter the sound of the speaker by both interacting with the speaker's crossover and reducing the damping factor. When the damping factor is reduced, the amplifier cannot keep the woofer under good, tight control. The result is that the bass becomes 'loose'.

In the case of an ESL, it is best to use a medium impedance cable as this will damp the L/C resonance and reduce its magnitude. Since the L/C resonance should be supersonic, this damping effect may not be audible. But reducing the resonance will make life much easier for the amplifier. Of course, if the ESL's transformer is poor, the L/C resonance will be in the audio range and damping it with a medium impedance cable will help smooth out the high frequencies.

ESL Speaker Cable Design

InnerSound's cables are uniquely designed to meet the needs of ESLs in three ways. They have low inductance, low capacitance, and moderate impedance. How is this done?

Because the conductors need to be close together for low inductance, but wide apart for low capacitance, simultaneously obtaining low inductance and low capacitance seems impossible. But surprisingly, there is a solution to this problem. Coaxial cable construction runs one conductor inside the other. So electricity 'sees' the conductors in the same place. This results in very low inductance.

InnerSound's coaxial, low-inductance design is enhanced by spiral-winding the conductors in opposite directions. This further cancels inductance.

But what about capacitance? Doesn't a coaxial design place the conductors close together forming a high-capacitance cable?

Not necessarily. The conductors can be physically separated by a significant distance using a thick, high-value dielectric to produce very low capacitance while maintaining ultra-low inductance.

The impedance is determined by the size and length of the conductor. InnerSound sizes the conductors to obtain medium impedance in the typical range of cable lengths used by most audiophiles.

Woofer Speaker Cable Design

For driving the conventional, magnetic woofers used in hybrid ESL/woofer systems, the demands for low capacitance and low inductance are relaxed, although maintaining these parameters at low levels is still desirable. At the same time, the impedance needs to be low to maintain a high amplifier damping factor to achieve tight control of the woofer.

InnerSound's bass cables meet these criteria by using dual pairs of coaxial cables. This technique drops the impedance to very low levels while maintaining low inductance and capacitance.

Interconnects

All interconnects are NOT equal. There are some very specific features that interconnects should have. InnerSound offers the excellent interconnects with all the finest features. But all the hype surrounding interconnects makes it very confusing to know what is important. The purpose of this paper is to explain the facts so you can make intelligent decisions. And the facts can be quite surprising as you will soon see.

There is no doubt that speaker cables can exert a small influence on the sound of your audio system. But interestingly, all well designed interconnects sound identical.

The above statement sounds absurd, since interconnect manufacturers all claim that their products will make your system sound better. They also claim that different types of wire (copper, silver, oxygen free copper, etc.) sound different, how skin effect causes transient smearing, and how dielectrics change the sound. So the idea that all interconnects sound identical is outrageous.

Or is it? Have you actually done a well controlled test to verify their claims? I strongly urge you to do your own testing rather than taking my word for it. It is very simple and easy to evaluate interconnects. Let me show you how.

The idea behind the test is to make it possible for you to switch back and forth between interconnects instantly and repeatedly while all other components in your stereo system remain the same. You can then listen very critically for any difference in sound between the interconnects you wish to test.

You cannot accurately test interconnects by listening to one for awhile, then unplugging them, connecting another set, and listening again. Our 'audio memory' for subtle details is too short to accurately remember any differences in sound in such a test, and we cannot check repeatedly to be sure of what we hear -- so we are easily deceived. You must be able to switch instantly and repeatedly to hear any real differences between interconnects.

You do not need any test equipment. You can use your preamplifier to do the switching. You will need a Y connector so you can connect the two interconnects under test (let's call them "A" and "B") to the same component -- probably your CD player.

Note that the Y connector is the same for both interconnects, so even if you believe that the Y connector somehow corrupts the sound (they don't), the same corrupted signal will pass through both interconnects so the test will still be valid. Remember that we are only listening for any difference between the interconnects, and you can hear that difference (if present) on any signal, even a corrupted and distorted one. Inexpensive Y connectors can be obtained from Radio Shack. If you want audiophile grade Y connectors, Sound Connections International (phone 813-948-2907) sells beautifully built, gold plated units at reasonable prices.

Connect one end of interconnects "A" and "B" to the Y connector. Do so for both channels.

Connect the other end of interconnect "A" to one of your preamp line level inputs (such as "CD"). Connect the other end of interconnect "B" to your tape monitor input. Do so for both channels. Be sure you don't reverse the channels. All line level inputs on a preamp are identical, so it doesn't matter which ones you use.

You could connect the interconnects to any other line level input on your preamp instead of Tape. But the tape monitor inputs allow to switch back and forth between interconnects by toggling the tape monitor switch instead of having to press different input switches, or rotating a knob. Toggling a single switch is more convenient and makes it easy to do the test 'blind' so you don't know which interconnect you are listening to. Doing the test blind is desirable so your personal prejudices don't influence the test results.

If your preamp doesn't have a tape monitor function, then use any two line level inputs. If you have to use a rotary selector switch, use two inputs that are next to each other on the rotary switch so you can easily move back and forth between them.

The test is done by simply listening to music while switching back and forth between the two sets of interconnects as much as you wish. The idea is to try to hear any difference between the interconnects. There is no time limit, you may switch whenever you wish and take as long as you want.

The test is easiest to do if you have a remote control preamp so you can sit in your listening chair and simply push the Tape Monitor button on the remote whenever you want to switch to the other interconnect. If you don't have a remote control preamp, then you may need an assistant to switch for you whenever you signal them to do so.

To do the test blind, press the tape button several times quickly so you get confused and don't know which interconnect you are listening to. If your preamp has an indicator light showing what you are listening to, then either put a piece of black electrical tape over the light or close your eyes while you do the test.

After doing this test, you will discover that all the hype surrounding interconnects is just that. The fact is that all well designed interconnects sound identical.

But please carefully note that I said all ***well designed*** interconnects sound identical. Some interconnects are badly designed and do indeed sound different. So just what is a "well designed" interconnect?

First, the interconnect must be shielded. Shielding prevents RFI (Radio Frequency Interference) and EMI (ElectroMagnetic Interference) from corrupting the sound. RFI can take several forms with the simplest being a buzzing sound (usually caused from light dimmers), to actually hearing radio or TV program transmissions faintly in the background of your music.

EMI is caused by magnetic flux lines cutting across the interconnect and inducing currents in it. This can take the form of hum if the interconnect is near an electrical transformer or motor, or will be crosstalk if the interconnect is near another interconnect that is active with a different signal.

Shielding is usually done by braiding a fine wire mesh around an internal conductor(s), making the interconnect coaxial in design. Although this mesh is usually adequate, there are small spaces between the wires in the mesh so that there is not 100% coverage. To obtain the greatest shielding, some interconnects are designed with a solid foil shield. This foil is prone to cracking and breaking if it is flexed, so the foil (usually aluminium) is often deposited on Mylar film that is wrapped around the wire to improve flexibility. But still, foil-shielded cables should only be used in stationary applications since frequent

flexing will eventually crack the shield. Braided-mesh shielding should be used for interconnects in home audio systems.

The second requirement is that the interconnect have low impedance. High impedance can cause loss of output at both high and low frequencies depending on the loads presented by the components connected to the interconnect. And when the frequency response is restricted in this way, the effects are indeed audible. Buy why would you want to limit your system's frequency response?

The third requirement is that the connectors at the ends of the wire be practical and trouble free. This encompasses several factors:

- They must not oxidise or corrode as this eventually will cause a high impedance contact and restrict the frequency response. Most connectors are gold plated to meet this criterion, although solid nickel connectors also work well. If they are gold plated, it is important that the plating be of high quality so it doesn't easily chip or flake off.

- The outside contacts of an RCA connector should NOT be tapered. If they grip only on the their tips, they can put great pressure on your components' jacks and can gouge or scratch their gold plating. Along these lines, it is best to avoid connectors that have clamping mechanisms that you tighten after insertion. These can put enormous pressure on your components' jacks and then the slightest motion can tear off the gold plating. And it is virtually impossible to tighten them without moving them.

  The best contacts are those that have precision machined, parallel walls in the shape of a perfect cylinder. These produce smooth, even, firm pressure on the jack without damaging the gold plating.

- The connector should have a strain relief. The purpose of the strain relief is to prevent tension on the interconnect cable from being transferred to the delicate connections inside the connector. This requires some kind of clamping mechanism so that the connector is solidly anchored to the outer covering of the interconnect cable, while the wires inside the connector are slack.

  Most RCA connectors don't have any strain relief. Some have springs around the cable near the connector to prevent excessive cable bending, but it doesn't prevent tension from damaging the internal connections. Some RCA connectors have a small metal strap inside the connector that is pinched around the cable, but this is weak and grips very poorly. The best connectors will have a clamp that can

be screwed down and that gets a really solid grip on the wire's outer cover, but these are very rare.

- The connector should have a tough, scratch resistant, attractive exterior surface. Most are painted, and paint is easily damaged. Some are gold plated. But gold is soft and easily scratched. The best have industrial hard chrome surfaces. This type of coating has an attractive, matte silver colour and is very durable.

- The connector, particularly small RCA connectors, should have a "grippy" surface so that you can grasp it firmly to remove it so you don't have to pull on the cable. A thick ring is nice, but often interferes with other connectors that are close by. So the best option is deep knurling on the surface that produces a rough, easily gripped surface, without increasing the size of the connector.

- The connector needs to be highly conductive to keep the impedance low. Steel is not a suitable material. Brass or copper should be used.

Amazingly, many very expensive interconnects fail to meet these basic criteria. In particular, many have no shielding at all! This is inexcusable in an expensive interconnect. The manufacturers of such poor interconnects only get away with this because most home environments have little RFI and EMI. But this isn't always the case and there are many systems that are plagued with buzzing and other noises due to the lack of shielding. The owner is very frustrated that he can't get the noise out and never suspects that his exotic interconnects are the cause.

Some interconnects have very high impedance. This is because the interconnect uses extremely tiny wire. The manufacturers of such interconnects claim that very small wire prevents "transient smearing" due to "skin effect" or some other arcane reason. But the fact is, wire size and type does not affect the sound (unless the impedance is too high). There is no such thing as "transient smearing" in interconnects and "skin effect" does not alter the sound at audio frequencies. You discovered this in your listening tests. But some of these interconnects have several thousand ohms of impedance and can adversely effect the frequency response of your system.

Very few interconnects have connectors that meet the "practical and trouble free" criteria outlined above. There are too many connector types to discuss here, but if you will examine them, you will see that few meet the criteria outlined above.

Interconnect Design

At InnerSound, we make no extravagant or false statements about our interconnects. We don't claim that they sound better than any other well designed interconnect. What we DO claim is that they are the very finest quality and are superbly engineered. And we sell them at a reasonable price.

Specifically, the cable itself is coaxial, low impedance design, with a braided mesh shield. The mesh is of unusually high quality and has a very tight weave. The shielding is so well done that we use a transparent covering over it so that you can actually see the quality. The bright copper braid is also looks very elegant. The cable is quite flexible and a medium size (5.5mm). Although it doesn't really matter (as proven in your listening tests), the metal used in the wire is oxygen free copper.

Our RCA connectors have precision machined, parallel jaws, in the shape of a cylinder. They grip firmly and so perfectly that you can actually feel a suction and "pop" as you remove them from the jack. All contact surfaces are gold plated over brass. Insulation is Teflon. The jaws are protected by a strong outer cylinder that is separated from the actual contact jaws. This prevents any damaged to the precision contact jaws. The outer surface of the connector is deeply knurled for a good grip and hard chrome plated for superior wear resistance. It has a superb strain relief with tapered jaws that clamp down on the outer coating of the cable as a ring clamp is tightened at assembly.

We also supply balanced interconnects that use professional studio cable with a black covering. It is 7mm in diameter, heavily shielded, and flexible. XLR connectors have anodised aluminium housings and gold plated, brass connector pins. Excellent strain relief clamps are used.

Conclusion

Much as I would like to hope otherwise, I know that this will not make a great deal of difference to the believers of the "Cable Gods", who postulate that the use of unshielded pure silver interconnects make a difference (they do, because they pick up noise), or that exotic mains or speaker leads will change the character of their systems (they won't).

If you have vast amounts of money and want to impress your friends with your $5,000 speaker leads, then far be it from me to deny you this (dubious) pleasure. However, if you are like most of us, and don't have that sort of money to throw around frivolously, then don't for an instant think that you are missing out on musical "Nirvana", because it just isn't true. As I have suggested before, make your own leads, and use the money to

buy more music! This is infinitely more satisfying in the long run.

For the original article, see the original InnerSound white paper, and have a look at their home page too.

I strongly suggest that the disbelievers visit the ABX site, and look at some of the tests that have been performed on all manner of equipment.

Further information can also be found in some of my own articles, in particular Cables, Interconnects and Other Stuff - the Truth. Also see how you can make your own AB switch box, which can be used to test amplifiers, cables, capacitors and most other audio components.

1.0 Introduction

What is the effect of the characteristic impedance of a loudspeaker cable? Is it important to match the cable to the speaker load impedance, or is this simply a marketing ploy?

Much has been said by many cable vendors about loudspeaker cables characteristic impedance, with claims that it should match the speaker impedance for "optimum results". Likewise, there is also a great deal that we are *not* told, and this is of much greater concern.

One thing the cable vendors have completely neglected to point out, is that the characteristic impedance is *only* important (and relevant) when the source impedance, cable impedance and load impedance are all matched. Having an extremely low impedance at one end (the amplifier) and a variable impedance at the other (the majority of all loudspeakers) makes true matching impossible.

Having said that, even with a very low impedance at one end of the cable, most cables can be made to have a passable match at low to mid radio frequencies (RF) by terminating at the far end only. (Note that at the frequencies we are looking at they are not really transmission lines, although I may use the two terms interchangeably.) Some degree of "matching" may be (to a degree) because the amplifier's output impedance rises as the frequency increases, but all amplifiers will be different in this respect.

To improve the impedance match and reduce the reflections that are caused by an unterminated transmission line, some vendors recommend a Zobel network - a resistor and capacitor in series, typically 10 ohms and 100nF. This, they tell you, should be installed at the speaker end of the cable. The usefulness of this may be dubious as will be shown later in this article, but in most sensible cable constructions, it will do no harm. For some of the more exotic constructions, a far-end Zobel is essential, however most are incorrectly designed.

Another "minor" detail that the cable vendors fail to mention is that the characteristic impedance of a cable varies with frequency. At DC, the characteristic impedance of all cables is infinite (for all intents and purposes), and the rated impedance is usually not reached until the signal frequency is well above the audio band - typically around 100kHz or more, depending on the cable's construction and length. Any cable consisting of parallel or concentric conductors (including flat conductors, multi-wire ribbon cables and Litz cables) acts as a transmission line at high frequencies, or (at least to a degree) if the line is extremely long (usually several to many kilometres). All transmission lines have a characteristic impedance, and this is a basic principle of physics - at issue is the

flippant way many vendors handle the truth.

But wait! What *is* characteristic impedance anyway? The characteristic impedance of a cable (Zo) is a complex function of the diameter (or dimensions if other than round) of the conductors, their relative spacing, and the insulation material. Simplified, it is determined (for high frequencies) as Zo = $\sqrt{}$L/C, where Zo is characteristic impedance, L is inductance and C is capacitance.

Note that Zo is a constant, and is independent of the length of the cable. An ideal cable (for a high powered audio system) will have low inductance, low capacitance and low DC resistance (DCR), but it is important to understand that the Zo of the cable is completely unimportant at audio frequencies.

In order to obtain a low characteristic impedance, it is necessary to have very low inductance and relatively high capacitance, and the high capacitance may impose serious constraints on the amplifier. Indeed, many amplifiers will become unstable if there is sufficient capacitance connected directly to the output, causing oscillation which may damage the amplifier. As described above, regardless of anything else, the cable does *not* act as a true transmission line at audio frequencies, and claims to the contrary are fallacious.

For these esoteric cables, their high capacitance dictates that there will be the opportunity for the insulating material to contribute its "sound" to the overall signal fed to the loudspeakers. It must be pointed out that this is hotly disputed by many engineers, and there is no conclusive evidence that any one dielectric material is "sonically superior" to any other. I know of no properly conducted Double-Blind Test (DBT) where the listening panel was able to pick the difference with greater than 50% accuracy - i.e. pure chance. However, the possibility cannot be discounted, so it is worth mentioning.

1.1 Impedance Matching

For RF applications, or for extremely long signal runs, such as telephone circuits, impedance matching is essential. Matched impedances mean that the source, cable and load impedances are all the same. For video, the standard impedance is 75 ohms, so the output impedance of a video line driver will be 75 ohms, 75 ohm coaxial cable is used for connections, and the receiving end is also 75 ohms. There are nearly always mismatches because of the use of RCA connectors (typically about 40 ohms impedance), but in a domestic installation this usually does not cause a problem, since the cable runs are relatively short. It is generally accepted that if the transmission line

length is less than around 1/10th of the shortest wavelength, then impedance matching is not overly important - again, we will see that this is not necessarily the case, since an audio amplifier's bandwidth can easily exceed the audio bandwidth by a factor of 10 or more - the effects may not be directly audible, but amplifier oscillation is to be avoided under any circumstances.

Matched impedances ensure maximum power transfer from source to load, and this is obviously very important for RF transmitters and telephony applications. It is completely irrelevant for a solid state audio power amplifier however, since the drive principle (known as voltage drive, or constant voltage) does not rely on maximum power transfer, but relies instead on the amplifier maintaining a low output impedance with respect to the load.

The ratio of amplifier output impedance to load impedance is called "damping factor", and with modern amplifiers it can easily exceed all normal (real life) requirements. Power amplifiers usually have an output impedance of between 10 and 100 milliohms, giving damping factors of between 800 and 80 (respectively). Valve amplifiers may have a damping factor as low as unity (i.e. the amplifier's output impedance is equal to the load impedance). No amplifier manufacturer quotes damping factor with cables attached, and in reality it is always less than claimed.

The damping factor (DF) figures are theoretical, and are rarely (if ever) achieved in practice. For the remainder of this article, I will use the output impedance of my simulated amplifier for reference (about 24 milliohms). This figure is passably realistic in a real world amplifier, but the internal wiring will increase it somewhat.

Even though most power amplifiers are limited to at most a few hundred kHz or so, there can still be some energy at higher frequencies - typically noise. What often happens is that an amp can be quite stable with a capacitive load and no signal, but as soon as it is driven it "excites" the whole system, and it then bursts into sustained oscillation.

It is almost impossible for any amp to reproduce high levels at extremely high frequencies, and they are not present in the source material. This has never stopped an amp from oscillating though, usually at a frequency high enough to cause simultaneous conduction of the power transistors, since they cannot switch off quickly enough, and both will be turned on at the same time.

This simultaneous conduction is what causes damage, since the output devices heat up very quickly and may go into second breakdown - if that happens, then it's all over - the amplifier will fail with blown output devices. Anyone who has had an amplifier on a test

bench and supplied it with an input signal at 100kHz or more will have seen this - even with no load, the amp will draw a lot of current even at low output levels. If maintained for any period of time, the amp will fail.

2.0 About the Simulations

The details of any test or simulated test are imperative for a full understanding. With this in mind, the following section describes the simulated amplifier that was used, the unloaded frequency and phase response, and the simulated cable and loudspeaker details.

2.1 Amplifier

The simulated amplifier schematic is shown in Figure 1. The phase angle at unity gain - at round 10MHz - is 150° (or a phase margin of 30° - i.e. a very stable amplifier). Phase is relatively unaffected by load resistance, or the presence of the amplifier's internal Zobel network. The latter is to ensure stability with an inductive load, but is ineffectual against capacitive loading.

To verify that the simulation represents reality to an acceptable degree, a 100nF capacitor placed across the output will cause instability, and this is substantially in agreement with empirical data on real amplifiers. It is worth noting that the simulated transistors have a much wider bandwidth than the majority of real life transistors, and this shifts the results up in frequency. Most of the amplifier effects seen at 10MHz will actually occur at perhaps 1MHz. All transmission line effects (in particular the peaks caused by impedance mismatches are exactly as shown - these are determined by the cable and its length, and are independent of the amplifier. Also note that many amplifiers will oscillate with a great deal less capacitance than the simulated version.

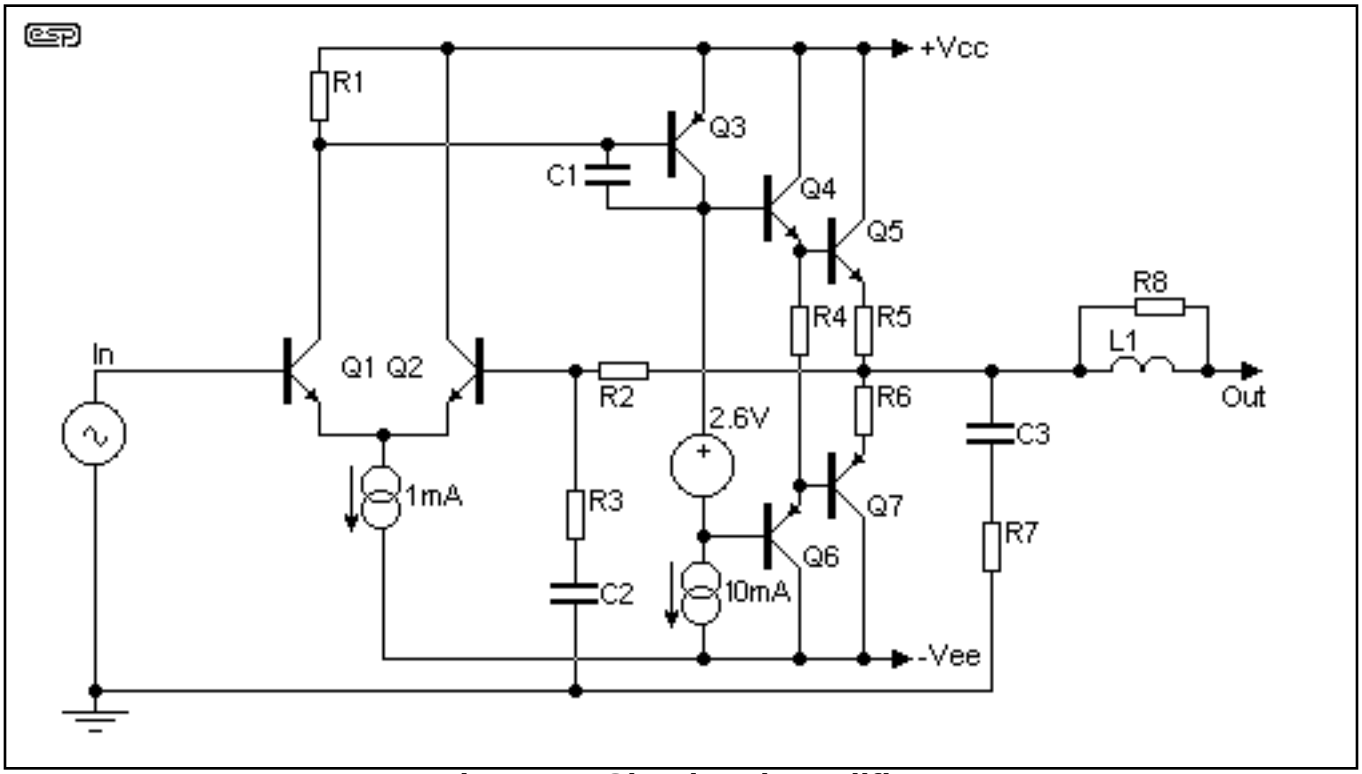

Figure 1 - Simulated amplifier

The amplifier used for these simulations was as shown in Figure 1 and it is a completely conventional (if somewhat simplified) circuit, typical of those used for hi-fi applications (in fact, fairly typical of the majority of amplifiers for any purpose). The closed loop frequency and phase response are shown in Figure 2. The phase margin (the number of degrees of phase shift between the actual unity gain frequency (Ft, or transition frequency) and 180 degrees. At 180 degrees phase shift, an amplifier's negative feedback is reversed in phase, so becomes positive feedback. If the amplifier has gain greater than unity at that frequency, it will oscillate.

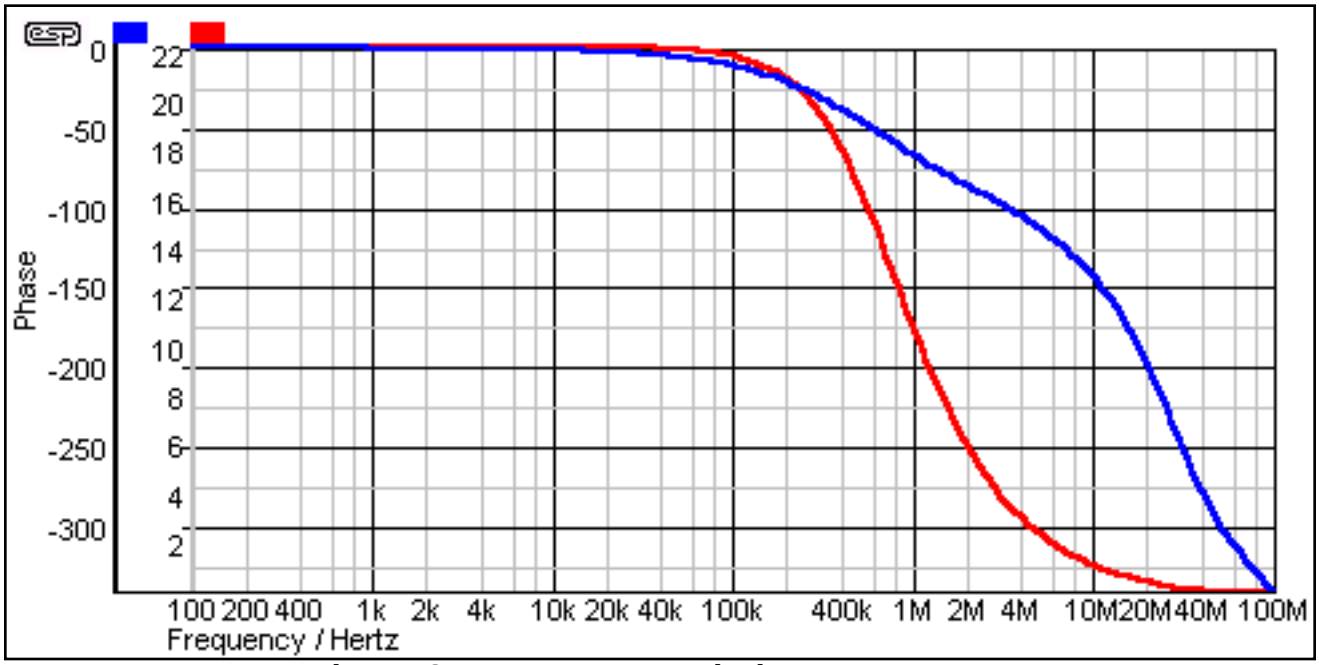

Figure 2 - Frequency and Phase Response

Neither frequency response nor phase response are affected by a resistive load. Inductive loads (of less than a few hundred uH - micro Henrys) are compensated by the Zobel network C3 and R7, with typical values being 100nF and 10 ohms, although this varies to some degree with the particular design. For reference, the simulated amp's output impedance at selected frequencies is shown below.

Frequency	1 kHz	20 kHz	100 kHz	1 MHz	2 MHz
Impedance	24 mΩ	25 mΩ	45 mΩ	444 mΩ	515 m&Omega

Table 1 - Output Impedance Vs. Frequency

In many amplifier designs, the speaker line capacitance is "decoupled" from the amplifier by the combination of L1 and R8. Again, fairly typical values are 800nH in parallel with 10 ohms, but as always, this can vary. Inductance above 1 or 2uH is rare, as it will have an audible effect on the overall frequency response, especially with low impedance speakers (for example, a 10uH inductance causes a 0.4dB loss at 20kHz and a 4Ω load, and that's with no cable at all). The resistor damps the Q of the inductor to prevent (or at least minimise) the possibility of the inductor and cable forming a resonant circuit. This network can be replaced with an 0.1 ohm resistor, but that approach is rare. Simulations were performed without the series inductor, since its presence swamps the very effects we are looking for so that amplifier instability can occur. The amplifier's RC Zobel network was retained for all simulations - very few amplifiers will be stable with any normal speaker and load without this network.

Note that in some of the simulations that follow, the phase margin may *appear* adequate to maintain a stable system. This is a direct result of simulations and real life failing to coincide, and it is imperative that you understand that the results shown may appear to "trivialise" the effects. Cables such as Sample #3 *will* cause most amplifiers to become unstable - the phase results shown also appear to be static, but in fact they change with amplitude, and anything that creates a radical phase shift at the amp's output will almost certainly cause oscillation in real life.

2.2 Cable

Figure 3 shows the schematic of the simulated cable, and the "far-end" Zobel network. Also shown is a "near-end" (i.e. at the amplifier) Zobel, but this is not needed for the most part. It is recommended if you use a series inductor at the amplifier output (or if you know that one has been included by the manufacturer). Leaving it out of circuit will normally have little or no effect on amplifier stability, and only serves to terminate the cable properly at very high frequencies.

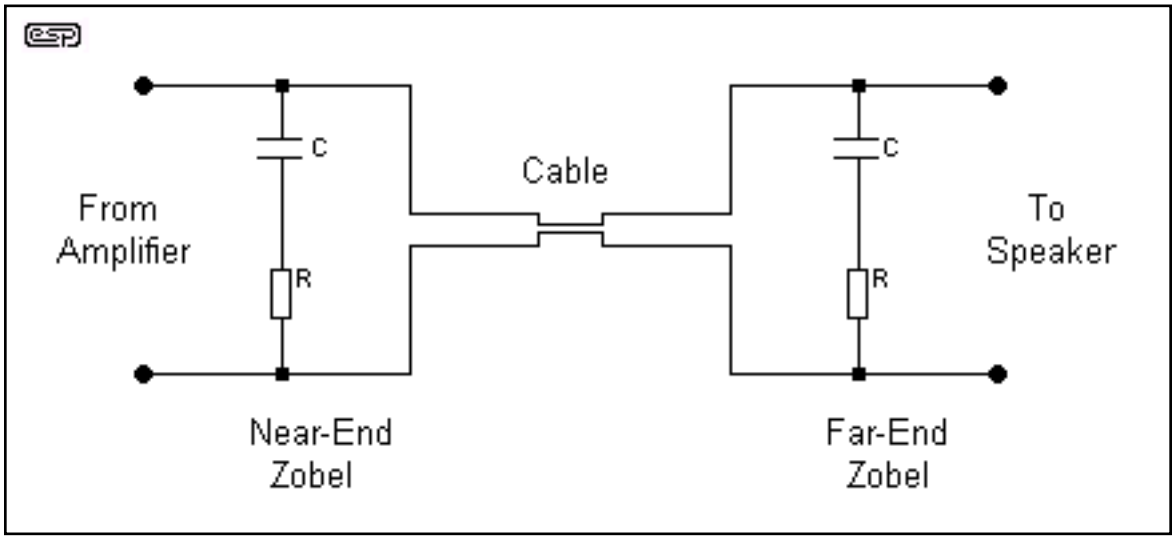

Figure 3 - Simulated Cable & Termination

Although most people (myself included) will not like the idea of a ceramic capacitor in the audio path (for the C element of the zobels), ceramic is actually the best choice for this application. It is important that the inductance of the capacitor (primarily lead and capacitor body length) is as low as possible, or response will be limited at exactly the frequencies where it becomes important. Even if the capacitor is non-linear (which is a characteristic of ceramics), it is in parallel with the load and amplifier output, and will have no audible effect on the signal. Remember that we are dealing with a small capacitance (100nF is typical), and its reactance (or impedance) is 100Ω at about

16kHz. A non-linear device with that much impedance will not affect any known amplifier, and the cap is also in series with a resistor, further reducing its already negligible contribution.

The use of "audiophile grade" polypropylene or other film caps is strongly discouraged, since their performance at several MHz is degraded by internal inductance (which determines the 'self resonant frequency of the cap). The capacitor(s) should be rated at a minimum of 50V AC (or 100V DC), although the voltages actually developed across the caps should be much lower than this at any frequency.

The resistor should be a carbon or metal film type, and a rating of 0.5 - 1W is normally quite sufficient. The power developed with normal signal will be a lot less than 0.5W, even with powerful amplifiers. If you feel that you *must* use a wirewound resistor, then it must be a non-inductive type.

2.3 Loudspeaker

The loudspeaker is a two-way, fully impedance compensated design. It uses a Zobel network to null the woofer's rising impedance caused by voicecoil inductance, and a tweeter resonance compensation circuit. This is based on a simulated loudspeaker system used by Jon Risch (the designer of Cable Sample #2) for some of his measurements and simulations, and is a reasonable approximation of a real speaker system. A resistance (or a much simpler simulated loudspeaker) could have been used, but this would not provide a "real life" experience for the simulations.

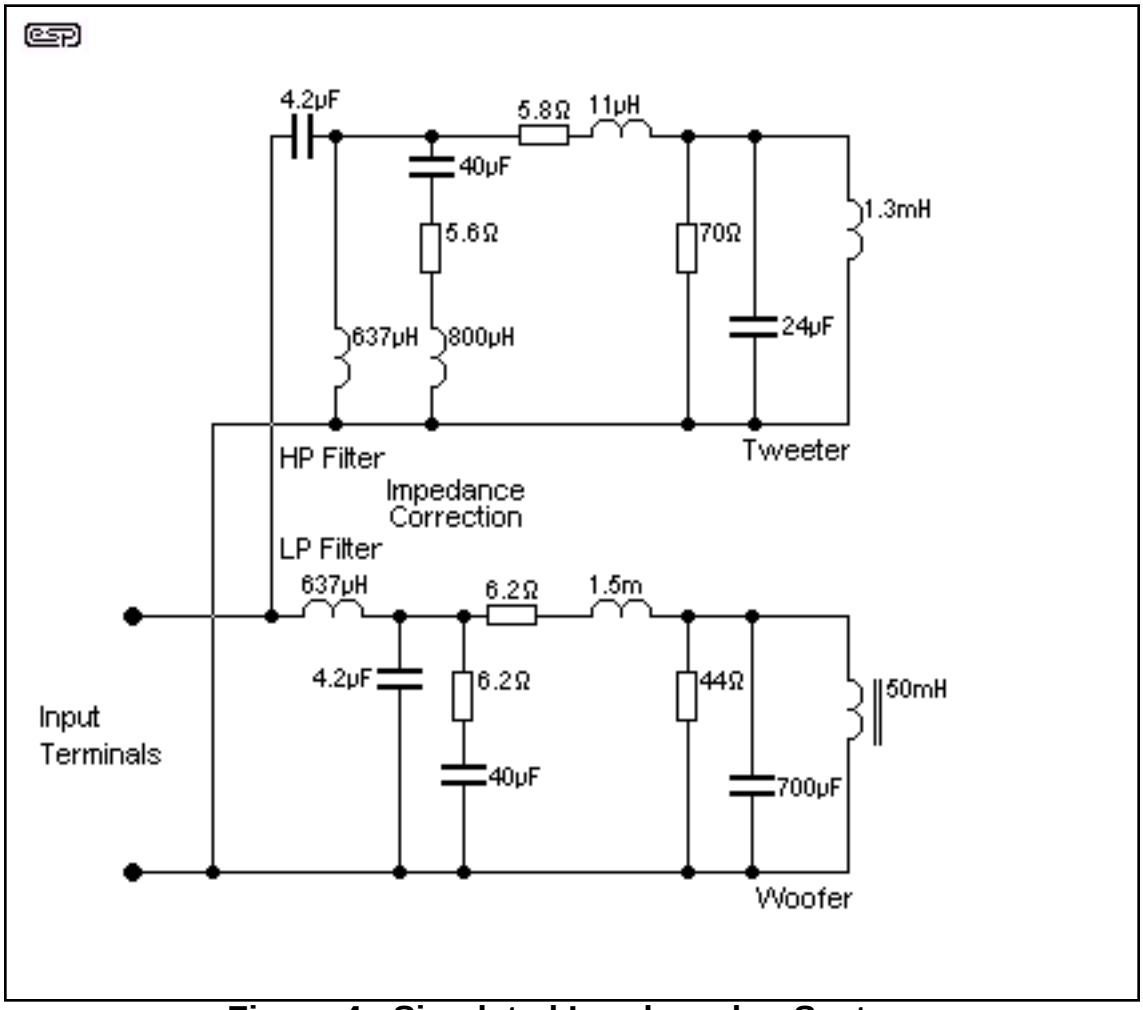

Figure 4 - Simulated Loudspeaker System

3.0 Simulations

Three different cables were used in the simulations that follow. It is important to note that these are simply used as representative, and no conclusions should be formed when comparing to manufacturer's stated (or claimed) data. No endorsement is implied for any configuration, manufacturer or anything else, other than a final recommendation below.

Sample	Resistance	Inductance	Capacitance	Impedance	Reference
1	11.15 mΩ	626.64 nH	68.90 pF	95.37 Ω	12# Zip
2	14.57 mΩ	219.82 nH	114.83 pF	43.75 Ω	Jon Risch
3	14.44 mΩ	32.81 nH	1640.42 pF	4.47 Ω	Goertz MI 1

Table 2 - Simulated Cable Parameters (per metre)

All values are per metre of cable length, and the simulations were performed using a 4

metre length (a little over 13 feet), as this is fairly typical of most domestic installations. As cables are made longer, the effects described occur at lower frequencies.

In the following sections, a great many possibilities are looked at, and graphs of the response are provided. By necessity, these are smaller than optimum, otherwise the page would take 3 weeks to load. The effects of different combinations are very clear, and additional descriptions point out the areas of interest.

3.1 "Special" Cable

The first graph shows Cable 3. I selected this for the first simulation, as it is the most likely to cause amplifier instability with no termination Zobel. Although the radical changes in phase are quite visible, it is a little difficult to see the effect on the amplifier. It transpires that this cable produces an output phase on the amplifier of that is well outside its phase margin, at around 192°.

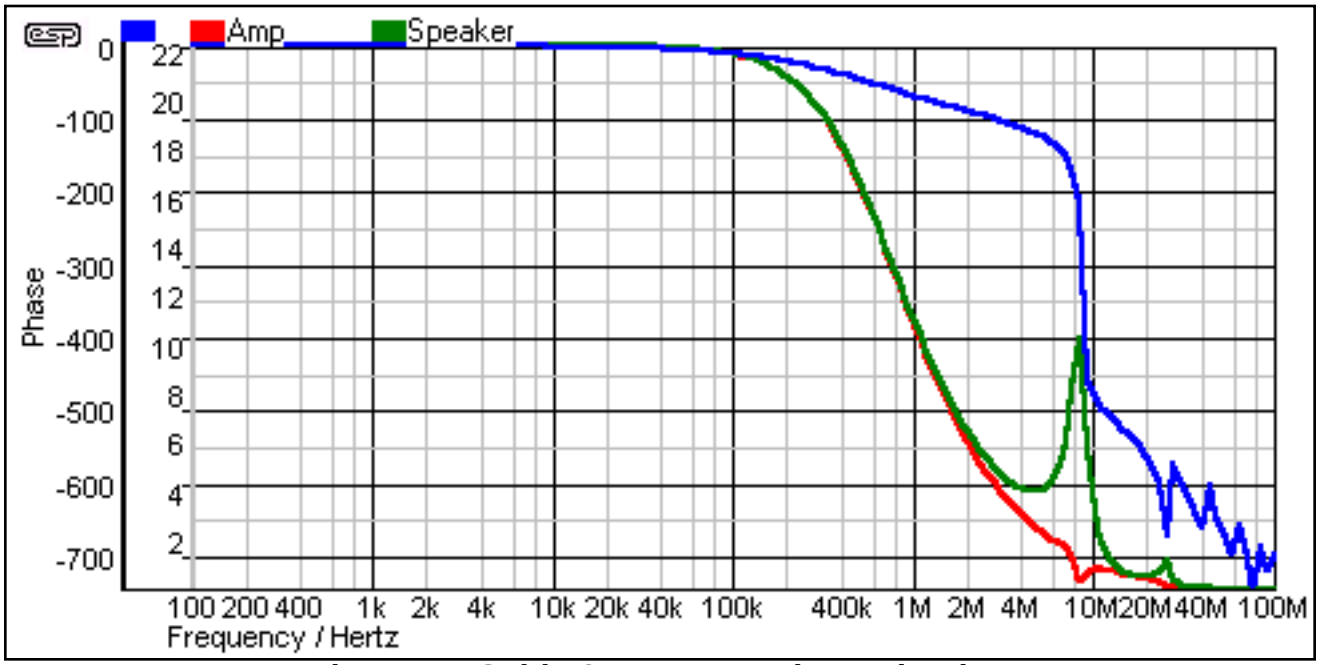

Figure 5 - Cable 3, No Far End Termination

As you can see, the cable has a large peak in the response at a little under 10MHz, and the phase response is savage. Each kink or discontinuity in the plot indicates a reflection, and note the phase angle - it shows 700° of phase shift at 100MHz!

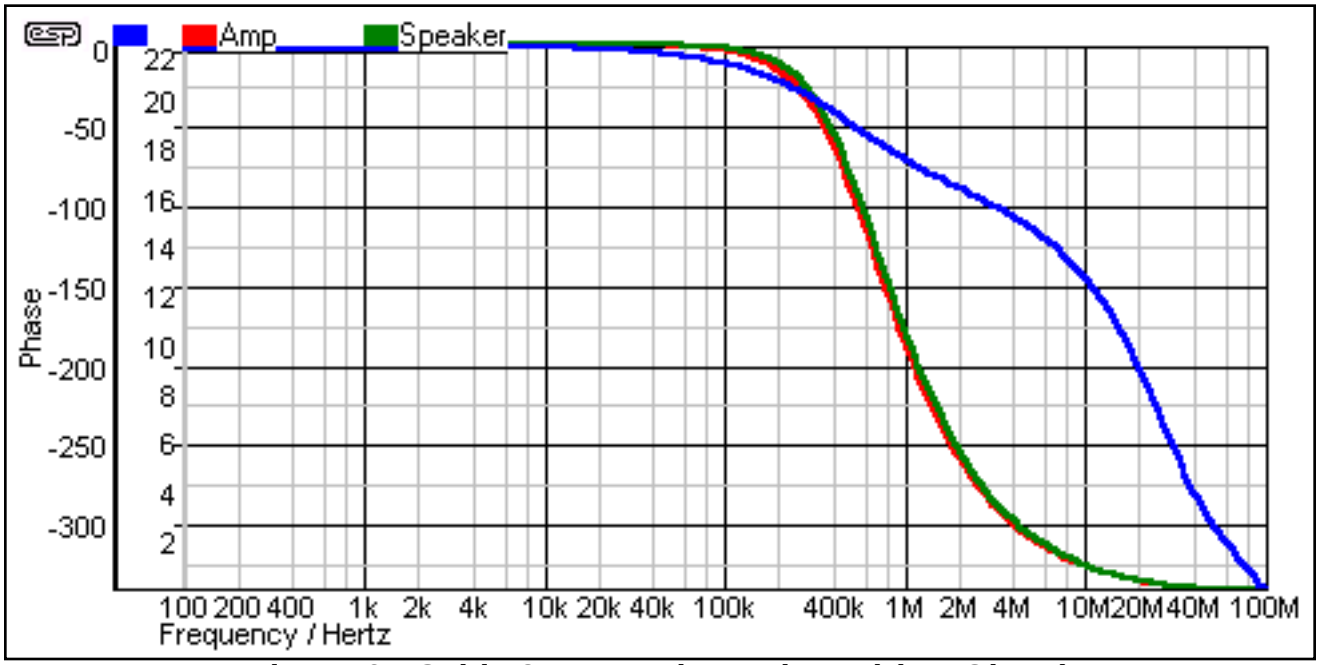

Figure 6 - Cable 3, Far End Terminated (4.7 Ohms)

Adding the far end Zobel network, as you can see here the cable's response decay is perfectly smooth with a 4.7 ohm resistor. This is the optimum match, and is the value that *should* be used - *not*10 ohms as supplied (see below).

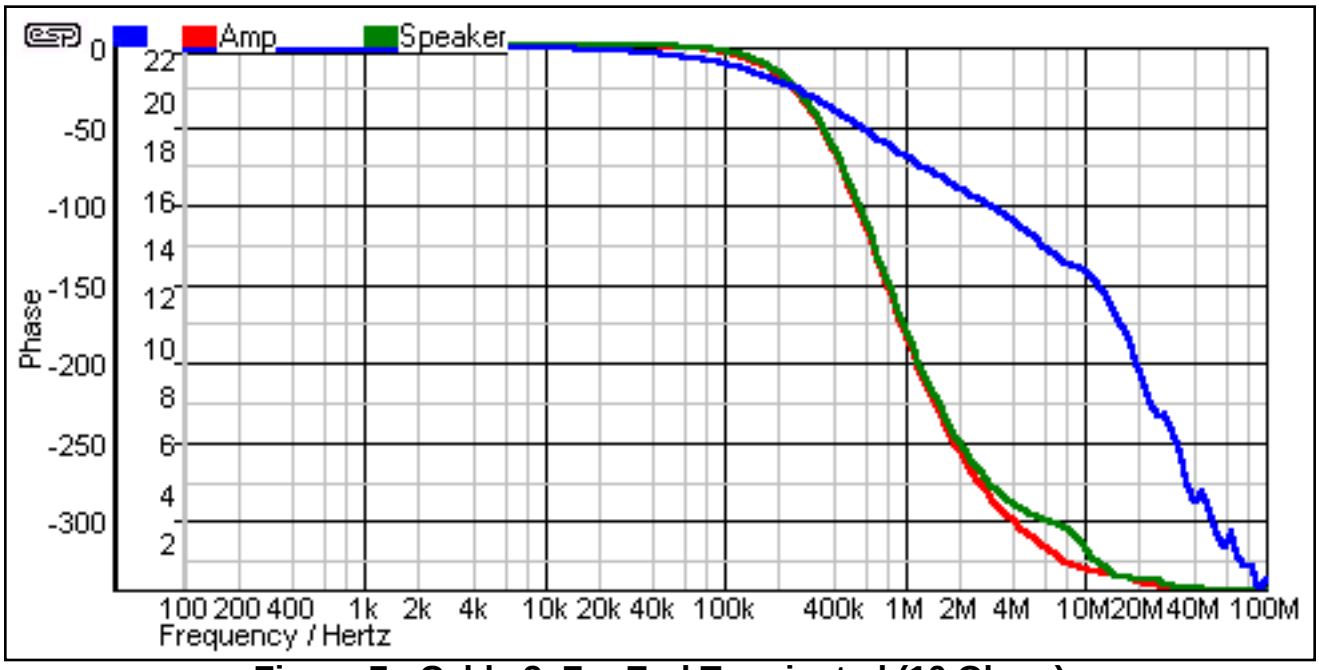

Figure 7 - Cable 3, Far End Terminated (10 Ohms)

Even 100nF in series with 10 ohms restores the amplifier phase margin to normal (150°). As seen above, 4.7 ohms is preferable, but the phase margin is barely affected.

The speaker end response has a small "lump" with 10 ohms, and phase goes "wobbly" at above 20MHz. This is probably not a concern, and you will almost certainly get away

with it. It is very evident that this particular cable should *never* be used without a Zobel at the speaker end, and it is equally obvious that the vendor does not really understand transmission line theory, since the zobels supplied with the cable (and you have to ask!) are incorrect. This is not difficult to get right, and if they are off base with something a simple as a resistor value, I would be disinclined to believe their other material.

While the results aren't actually appalling, it is quite obvious that the performance is not as good as with the correct termination resistance. At this level (and since the impedance of the cable is quoted on the web site), I find it difficult to understand how they could have made such an error. Not that this manufacturer is alone by any means - "experts" will emerge from the woodwork, suggesting a that 10 ohm, 100nF Zobel is the panacea - it is, but *only* for 10 ohm cables!

3.2 12 Gauge "Zip" Cable

This seems to be the standard against which all other cables are judged, so it is next on the list. As you can see, there is a pronounced reflection at almost exactly the same frequency as before. This must be, since the cable (transmission line) is the same length, and the first reflection will occur at the same frequency. Small variations do occur, and are the result of differing velocity factors. Velocity factor refers to the speed at which an electrical signal passes through a cable. Typically, this is between 0.6 and 0.8 of the speed of light (3 x 10^8 metres per second.)

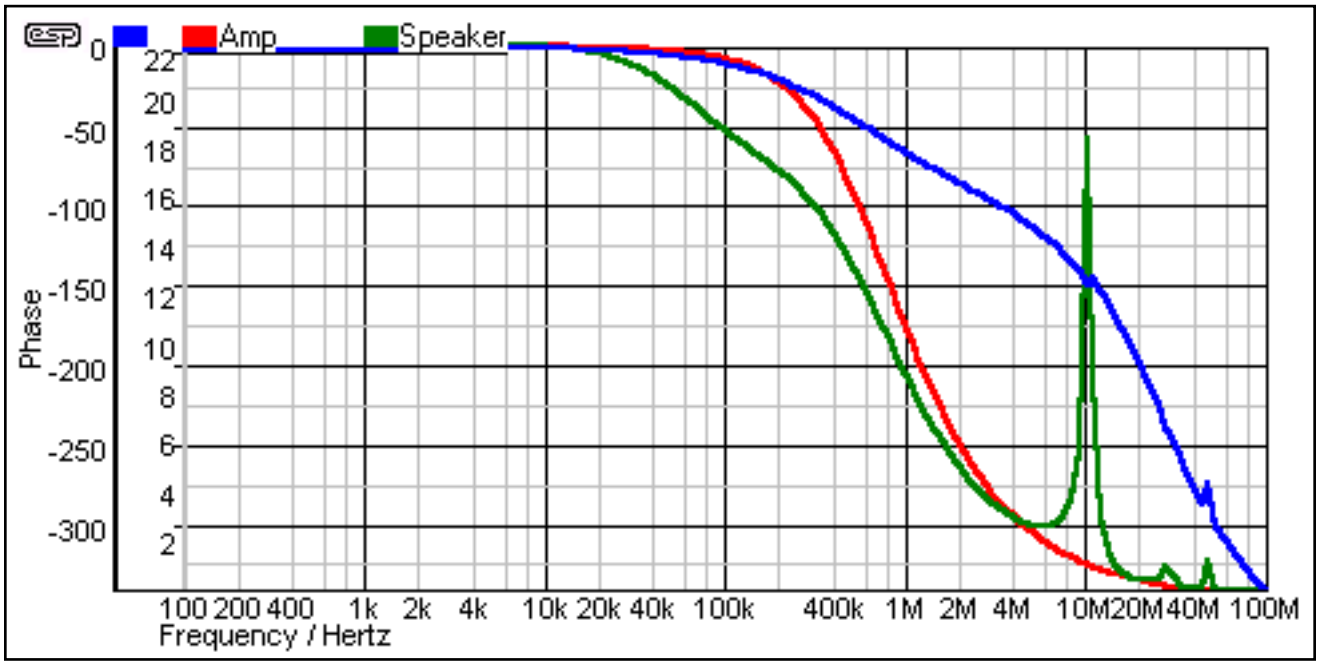

Figure 8 - Cable 1, No Termination

The response is relatively benign, despite the quite large peak at 10MHz. The reflection

spike causes no change to the amplifier's phase response until it is above 40MHz and will have no effect. There is a very slight reduction of level at 100kHz (and down to 20kHz), but this is measured in fractions of a dB, so can safely be ignored. A greater disturbance to the in-room response will be experienced by moving the listening chair or a nearby coffee table.

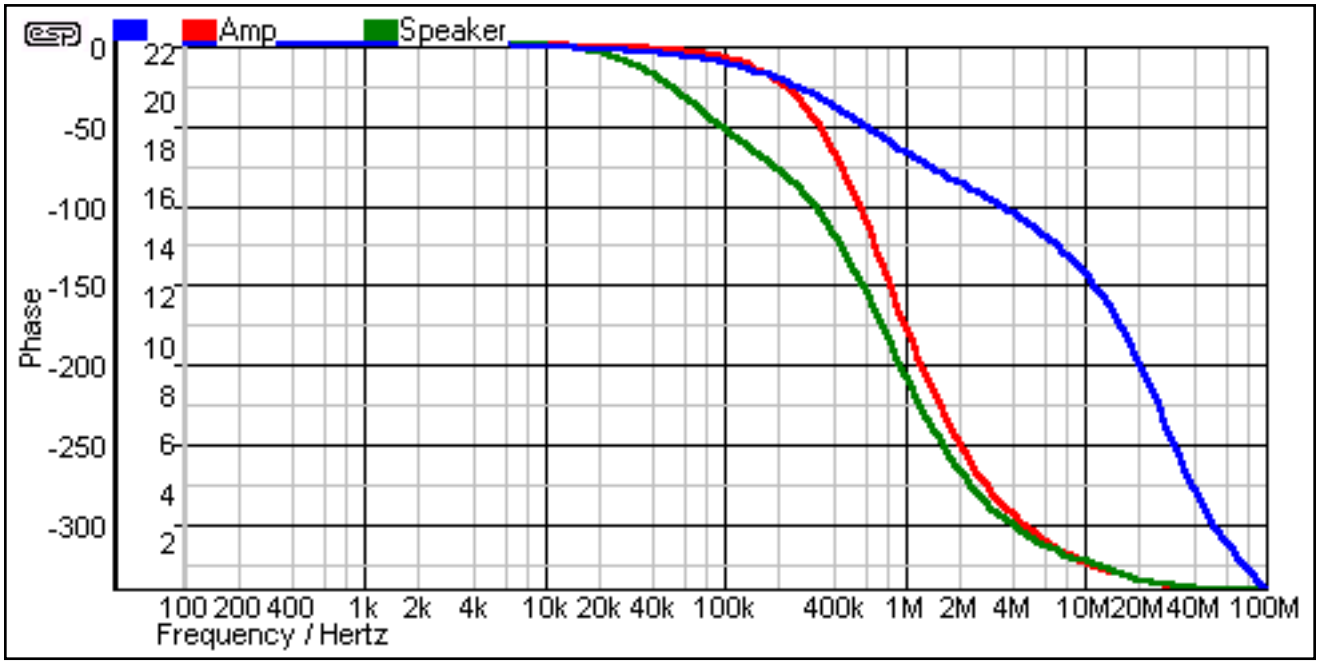

Figure 9 - Cable 1, Far End Terminated (100 ohms)

This is a perfect result. There are no spikes, no response anomalies, and the amp's phase margin is unchanged. For the cost of a 100 ohm resistor (close enough) and a 100nF ceramic capacitor, the cable is nicely terminated, and although virtually any amplifier will drive this cable with no ill effects even when unterminated, there is the potential to reduce RF pickup.

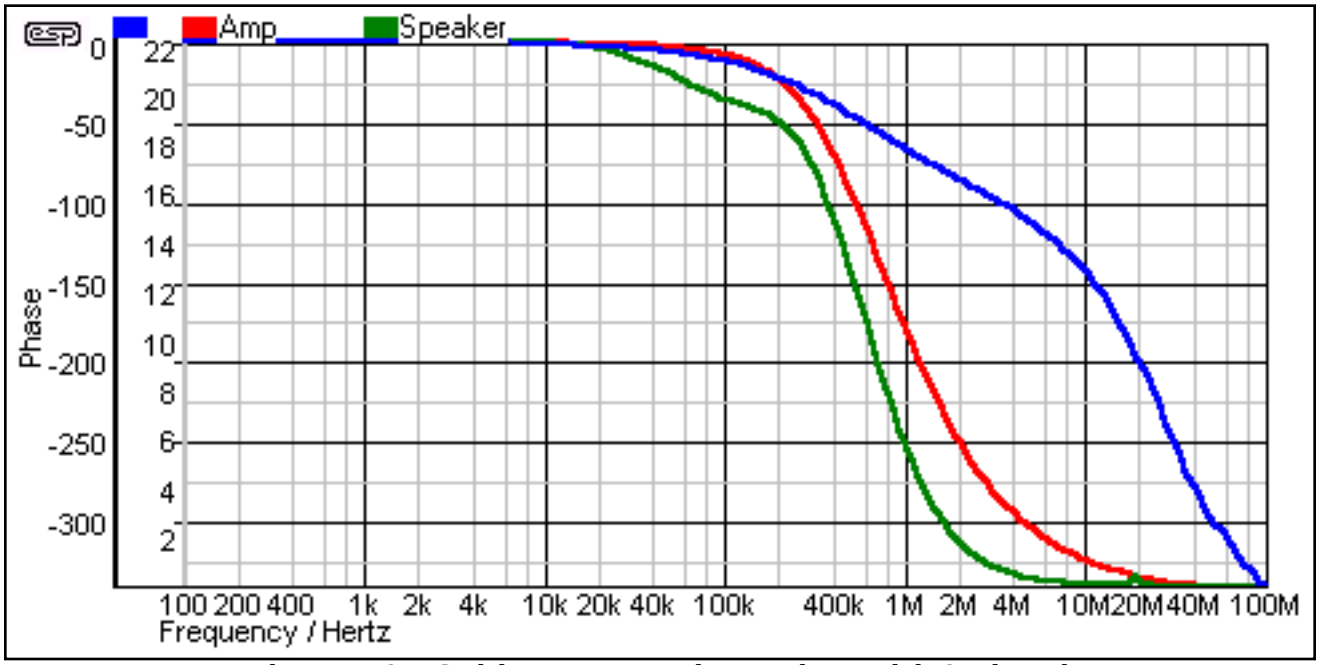

Figure 10 - Cable 1, Far End Terminated (10 ohms)

It is apparent that a 10 ohm termination impedance is "sub-optimal". In reality, it is not that bad, and the effects will almost certainly be inaudible. Something that is not obvious is a peak at around 10kHz - it is not large (about 0.1dB relative to 1kHz), and the top-end response is down by about 0.2dB at 23kHz (note that the effect will be a little worse with a 4Ω speaker). As a compromise, a 47 ohm resistor will cause no major peaking, and presents a passable match to a wide range of "zip" cables. Because these cables are already benign, they are much more tolerant of mismatch.

3.3 DIY Cross Connected Coax Cable

It was actually a reference to this particular cable on the Audioholics website that caused this investigation in the first place. Comments were posted and re-posted, as were claims and counter-claims. This design is also relatively benign, and I do not propose to cover all the issues raised previously - I am interested only on the cable's effect on the amplifier, and whether it is likely to cause instability.

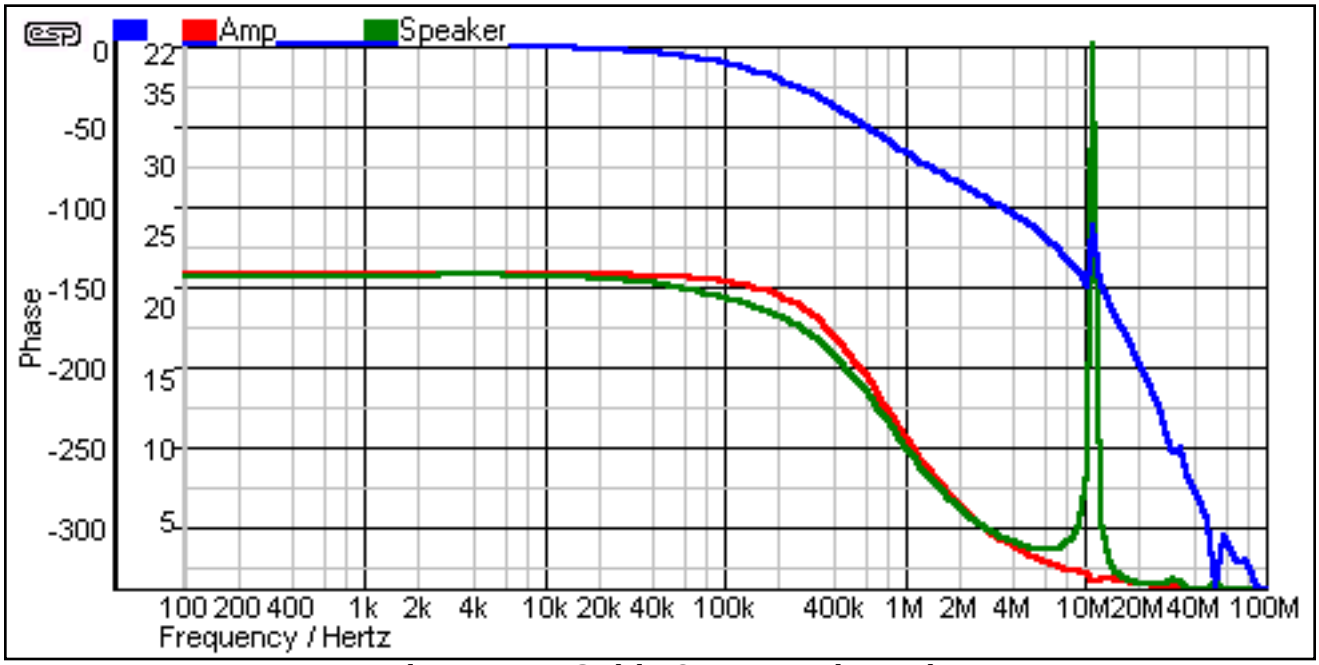

Figure 11 - Cable 2, Unterminated

As can be seen in Fig. 10, even when unterminated, the result *looks* pretty severe (note the height of the spike at 10MHz), but is not very much worse than cable #1. There is a phase anomaly at 10MHz, but the amplifier is well within its phase margin, and few (if any) amplifiers will be affected by this. Not as visible on the chart, but present nonetheless, is a slight broad peak in response centred on 5kHz. The amplitude is well under 0.1dB (0.04dB to be precise) and is insignificant. Amplifier phase margin is not affected, but cable response extends to over 100kHz - I can't hear it and nor can anyone else, but this also means that there is less rolloff with a lower impedance speaker.

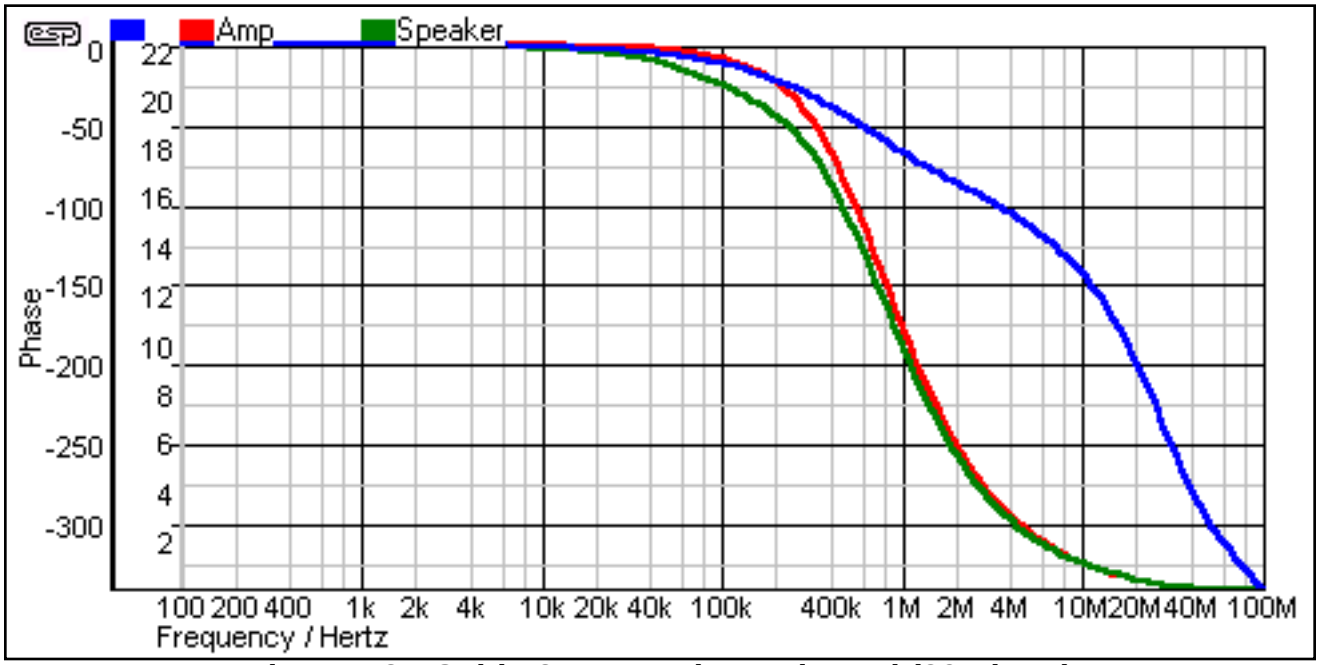

Figure 12 - Cable 2, Far End Terminated (39 ohms)

Since this cable has a Zo of 37 ohms, a 39 ohm termination resistance is close to optimum. The response again is virtually flawless, and reflections are eliminated completely.

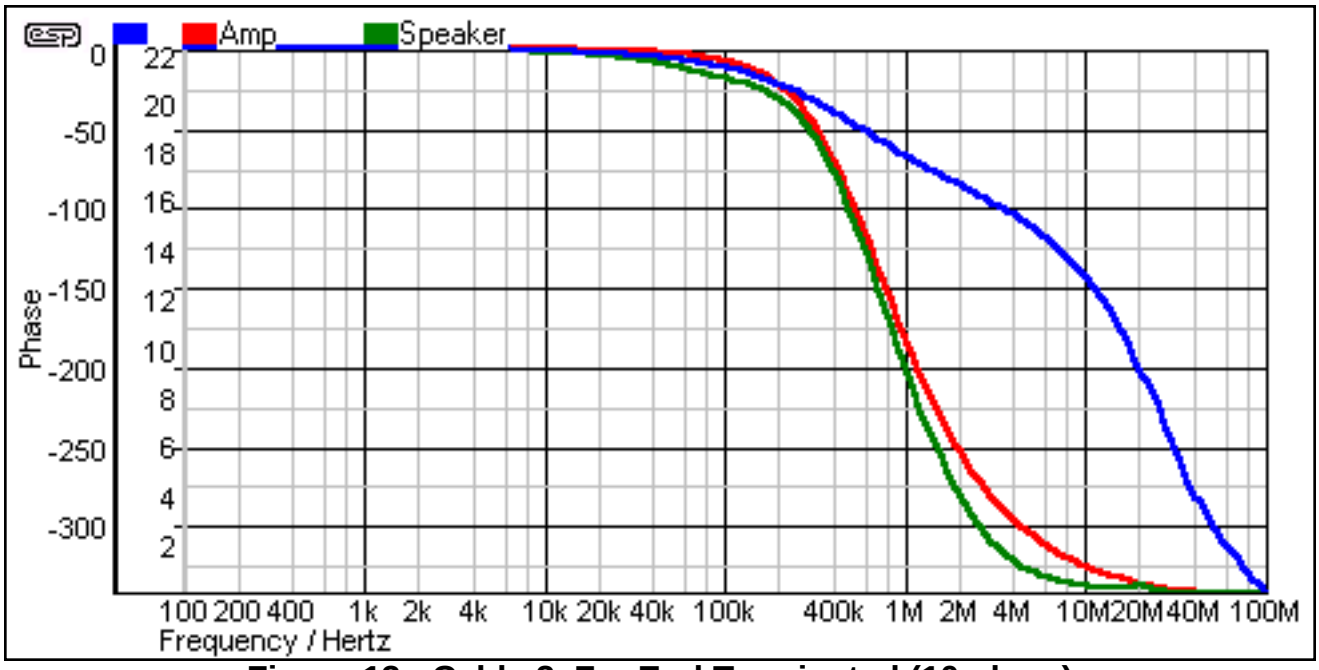

Figure 13 - Cable 2, Far End Terminated (10 ohms)

Overall, this cannot be considered a bad result. In fact, the mismatch actually improves the response, although it is well outside the audio spectrum. That it is less than optimum is not at all obvious (although there are some tiny ripples on the phase response at above 20MHz), but amplifier stability is not compromised, and there is no peaking. Also obvious is the divergence of the amplifier and loudspeaker-end responses (also visible on the other graphs where impedances were mismatched), and this is a clear indicator of a mismatch - even if it is well outside the audio bandwidth.

My personal choice would be to use a 39 ohm resistor, since that is a much closer match to the line impedance, but the resulting differences will certainly not be audible.

4.0 Further Investigations

Using the decoupling RL network at the output of the amplifier will provide protection against all but the most radical of speaker cable designs, but it must be noted that it is a rather pointless exercise to spend a great deal of money to get cables with the lowest possible inductance, and then have to add an inductor so your amplifier doesn't oscillate

The obvious (and recommended) cable constructions are samples 1 and 2, and both of

these will give good performance for a very reasonable outlay. Cable sample #3 cannot be recommended, not only because of its high capacitance, but because it is much more expensive than the other two, and the actual benefits are minimal. If you can afford to purchase such cables, then that is up to you, but bear in mind that the manufacturer cannot even manage the correct value for the Zobel network that *they* supply. In my books, that does not qualify them for anything more than a shake of the head, a mild chuckle and "Not today, thanks".

4.1 Aussie "Figure 8" Cable

Since I had the simulations all set up, I figured that a quick test of what is commonly known in Australia as "Figure 8" cable (basically the same as zip cable) was in order. The standard "hardware store" offering is not especially robust, being 22 strands of 0.022mm wire per conductor (0.75mm^2). It is 240V insulated wire, commonly used for lamps and the like ("lamp cable"). I use this for basic test leads in my workshop, and the figures for a 4 metre length are ...

Resistance = 150 mΩ
Inductance = 3.9 uH
Capacitance = 217 pF

Impedance works out to about 134 Ω. This is a very benign cable, and I have never seen an amplifier oscillate because of it, so, what do the simulations say?

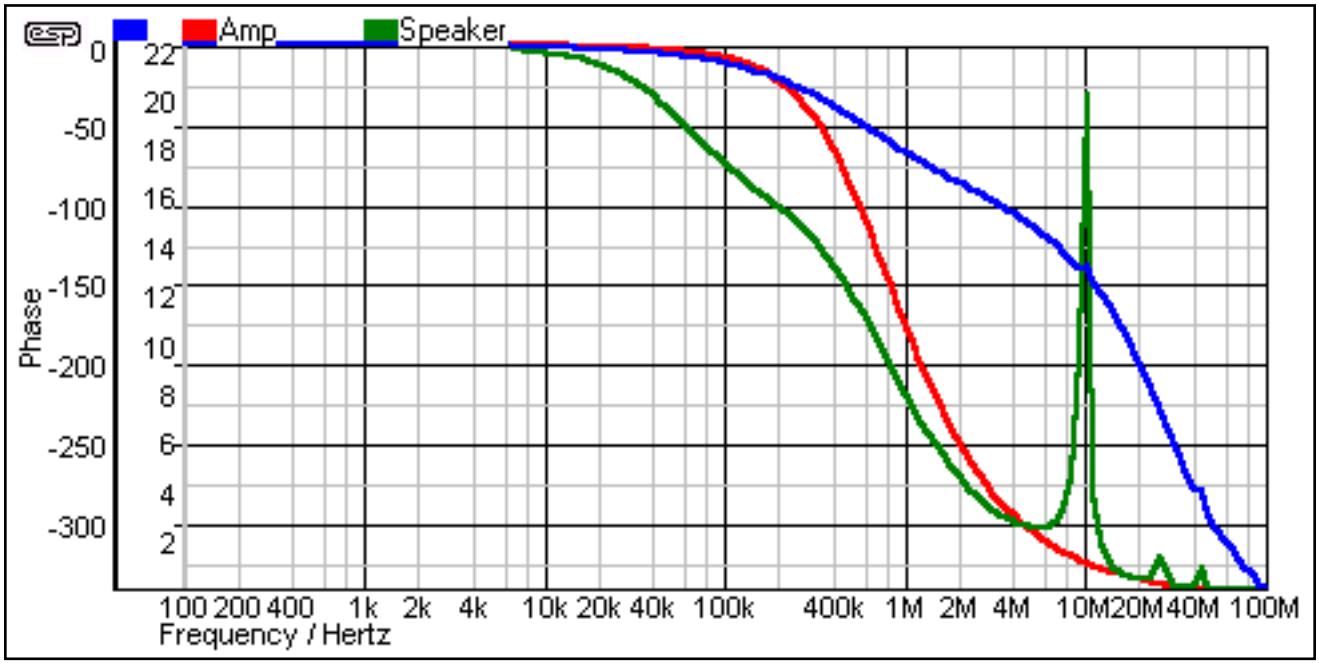

Figure 14 - "Figure 8", No Termination

No surprises at all really. There is an obvious loss at 20kHz (still less than 0.5dB though), the spike that we now expect, and zero phase anomalies.

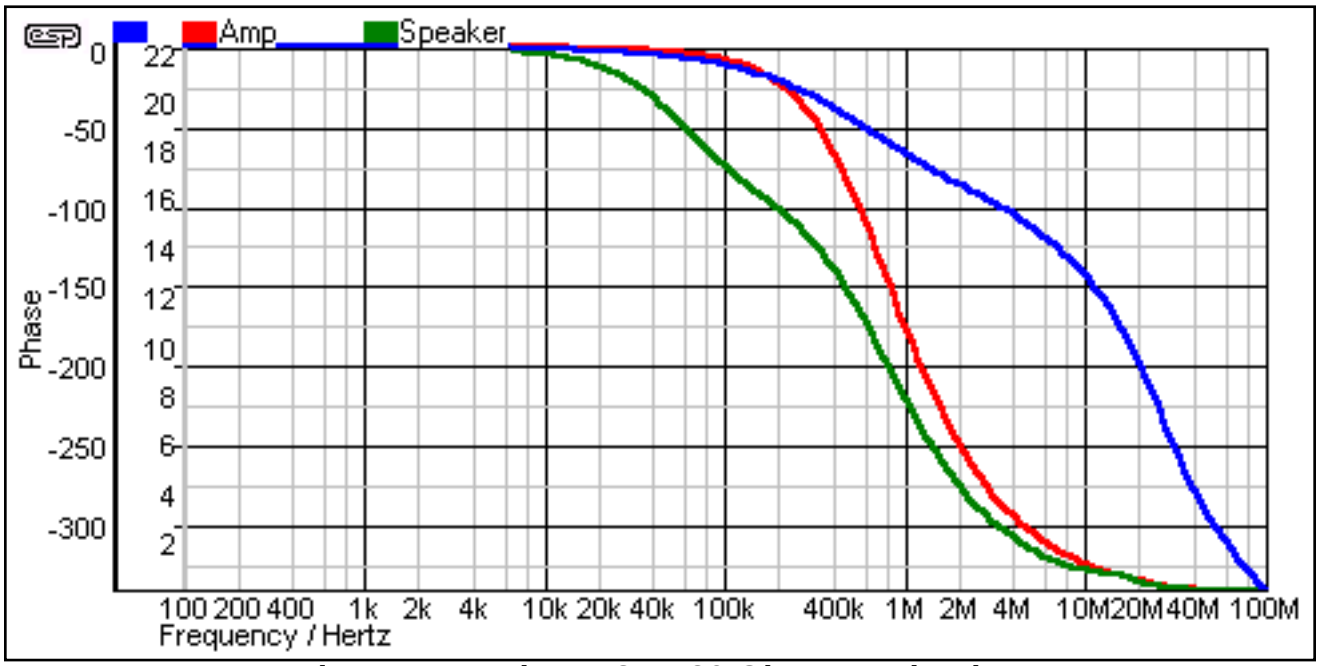

Figure 15 - "Figure 8", 120 Ohm Termination

Again, this is to be expected. Response is -3dB at 67kHz at the speaker end, which actually will do me just fine, since I certainly can't hear the loss (less than 1dB at 20kHz). The termination again removes the spike in the response, and there are zero phase effects at the amplifier. It goes without saying (but I will anyway ;-) that termination causes zero audible difference, however, in the presence of strong RF fields, a terminator *should* reduce or even eliminate RF interference. This is difficult to test because my workshop is nowhere near any RF sources powerful enough to cause problems, but a friend is going to run a test for me when he gets the opportunity, and I will add the results when known.

4.2 Transmission Line or Cable?

It is worth noting that any of these cables will exhibit further anomalies and discontinuities if driven from an amplifier with infinite bandwidth. These have not been invented yet, so the amplifier-end mismatch is not a major problem, but if an inductance isolation network is used in an amplifier, then a second Zobel following the inductor is recommended. This ensures that the transmission line is terminated with the correct impedance at both ends.

In addition, it was stated at the beginning of this article that characteristic impedance is

irrelevant at audio frequencies. The frequency at which a pair of wires line starts to act like a transmission line is determined primarily by its length. Fortunately for the purposes of research, simulators can provide a signal source with zero impedance and infinite bandwidth, so the limitations of the physical world need not concern us. Using a 50 ohm transmission line (purely for convenience), the following points are of interest ...

- When driven and terminated by 50 ohms, a line with (essentially) zero DCR has a flat response from DC to daylight. It is true transmission line, and behaves exactly as one would expect, regardless of length.
- A line with "typical" DC resistance is dominated by the DCR up to a frequency that is dependent upon its length. A transmission line is not influenced by DC resistance, so as long as the DCR is dominant, the line is *not* a true transmission line. This is hard to comprehend, but it is so, and any reference book on the topic will verify this "strange but true" fact.
- At audio frequencies, speaker cables are *not* transmission lines. They are merely cables, with inductance, capacitance and resistance. Despite popular belief, they are bereft of any magical properties, only physics.

Now, let's look at each of these claims. If a cable acts like a transmission line, is properly matched at each end, and has essentially zero resistance, then 1V from the generator will result in 0.5V at the input of the cable, and 0.5V at the output, since the system behaves like a simple resistive voltage divider. The cable is irrelevant. I will spare you the tedium of looking at a graph with a straight line at exactly 0.5V from 1Hz to 100MHz, since it has zero interest value.

In order to highlight the resistive effects, I simulated a 100 metre cable, with 1 ohm per metre DCR. This is obviously not a useful cable (at least not as a speaker cable), but it shows the effect very clearly. Figure 14 shows the test circuit, and current was monitored at the output of the AC generator.

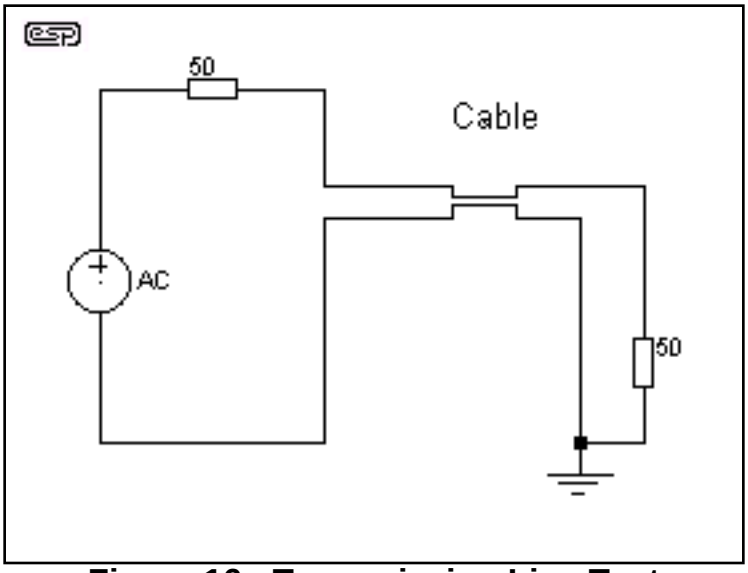

Figure 16 - Transmission Line Test

In Fig. 17, you can see that the output current is clearly dominated by the resistance until the cable behaves like a transmission line. The current from the generator (AC) should be equal to V/R ... V is 1 Volt, and R (for the 100 metre line at 1 ohm/ metre) is 200 ohms (including the two external resistors). This works out to 5mA, and indeed, that's exactly what is measured - until the "magic" frequency of 100kHz, where the current increases.

Above 1MHz, the current is 10mA (1V /100Ω), meaning that the cable resistance has disappeared! In the space of one decade in frequency, the cable has transformed itself into a true transmission line, where the signal is not conducted as such, but transferred by a waveguide (waveguides are usually just tubes for UHF signals [e.g. microwave], however a wired transmission line is also a waveguide). Naturally, the resistance never *really* disappears, but its influence is greatly reduced.

It is worth noting that a cable will *never* act as a true transmission line with a defined (and maintained) Zo unless its source and load impedances are equal to the line impedance. This means that no audio cable will ever be a transmission line, (almost) regardless of length, unless the amplifier output impedance, cable impedance and load impedance are all equal at all frequencies within the desired range. No known amplifier or loudspeaker system can meet these criteria. Alternatively, the cable may be infinitely long, however this is usually impractical in a domestic environment.

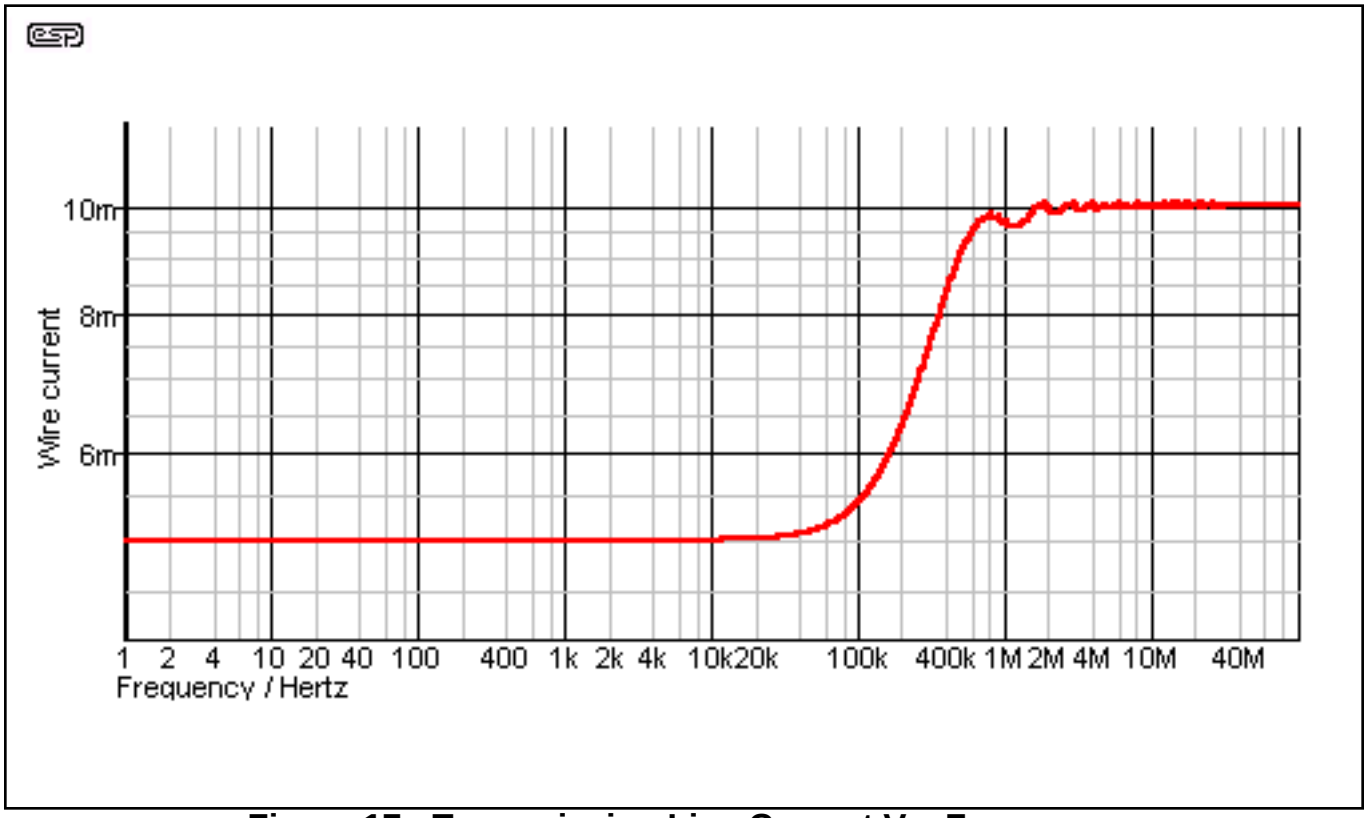

Figure 17 - Transmission Line Current Vs. Frequency

Obviously, the cable is just a pair of wires below the transition frequency, and *your* speaker cables (regardless of claims or cost) are exactly the same. In case you may want to simulate this effect yourself, I used DCR=1Ω, L=200nH and C=100pF per metre, and used a 100 metre line. A shorter line does exactly the same thing, but the frequency where it becomes a transmission line (rather than a couple of wires) increases as the line length is reduced. For a 10 metre cable, the frequency is 1Mhz, and for 3 metres this increases further to 3.3MHz. These effects were present in all the previous simulations, but were masked by the amplifier's rolloff.

5.0 Frequency Response

To be fair, it is unreasonable to investigate these cables without looking at the frequency response, so the following tests were done. In each case, response at the far end (loudspeaker) was plotted in dB, with only the cables resistive component (red graph) and with inductance and capacitance included (green graph). Response plots were done from 10Hz to 100kHz, and it is obvious that there are some differences. The same simulated amplifier was used for all tests, so its influence on the response is included. Again, all cables were measured using a 4 metre length.

Even with the very worst cable (the Aussie "Figure 8" lamp cable), response is

dominated by resistance at low frequencies. The addition of inductance and capacitance actually improved matters for the 12 gauge zip cord and Figure-8, and the far-end Zobel makes no difference (it was included for all tests, and was 100nF in series with 100Ω).

5.1 Amplifier Vs. "Ideal" Source

For comparison purposes, I checked the 12 gauge zip cable with a "perfect" zero ohm source. The maximum deviation was 0.106dB, and the predominant frequency was at 7.8kHz. This shows quite clearly that for most cable constructions, the amplifier's output impedance is a factor at low to medium frequencies. Cable inductance affects the signal at above 20kHz, while capacitance is not really an issue at all - other than its potential to make an amplifier oscillate if high enough.

The variation between a "perfect" (or ideal) source having zero ohms impedance and response from DC to daylight, compared to an amplifier with 24mΩ output impedance is not great with any cable - the 12 gauge zip shows a variance of only 0.03dB (close enough) between the two sources, and this has the lowest DC resistance of the cables tested. Obviously, the lower the DCR of a cable, the more influence the amp's output impedance has on the overall result ... until inductance becomes the predominant factor.

Note that all response measurements were done using a nominal 8 ohm load, and that inductance will have a greater effect if the load is 4 ohms (or less). The following table shows the -1dB frequency for 8Ω and 4Ω loads, with a range of inductances from 1uH to 10uH.

Inductance	8Ω -1dB	4Ω -1dB
1 uH	647 kHz	325 kHz
2 uH	324 kHz	162 kHz
3 uH	216 kHz	109 kHz
4 uH	162 kHz	82 kHz
5 uH	130 kHz	65 kHz
6 uH	108 kHz	54 kHz
7 uH	92 kHz	46 kHz
8 uH	81 kHz	41 kHz
9 uH	72 kHz	36 kHz

10 uH	65 kHz	32 kHz

Table 3 - Frequency Rolloff Vs. Inductance and Load Impedance

It is quite obvious that a total inductance of up to 10uH will be quite acceptable for the highest of fidelity with any loudspeaker that has a benign impedance at the high end of the audio spectrum, at either 4 or 8 ohms. Most speaker systems are reasonably consistent at the high frequency end, but obviously there are exceptions, and these *will* cause audible differences.

5.2 Response Simulations

These results are all simulated (rather than measured), since this is the fastest way to achieve the results, and the simulations will agree with "reality" very well. While there are other factors that are not taken into account (such as skin effect or insulation material "soakage"), these are generally considered to be inaudible, and no proof has ever been offered that anyone can distinguish the difference in a DBT. That there *are* differences is undeniable, they can be measured quite easily with the right equipment (which I don't have), but any such effects are well below the noise floor and/or resolution of even the best amplifiers and speakers. Indeed, atmospheric changes will cause *far* greater variations in the signal you hear.

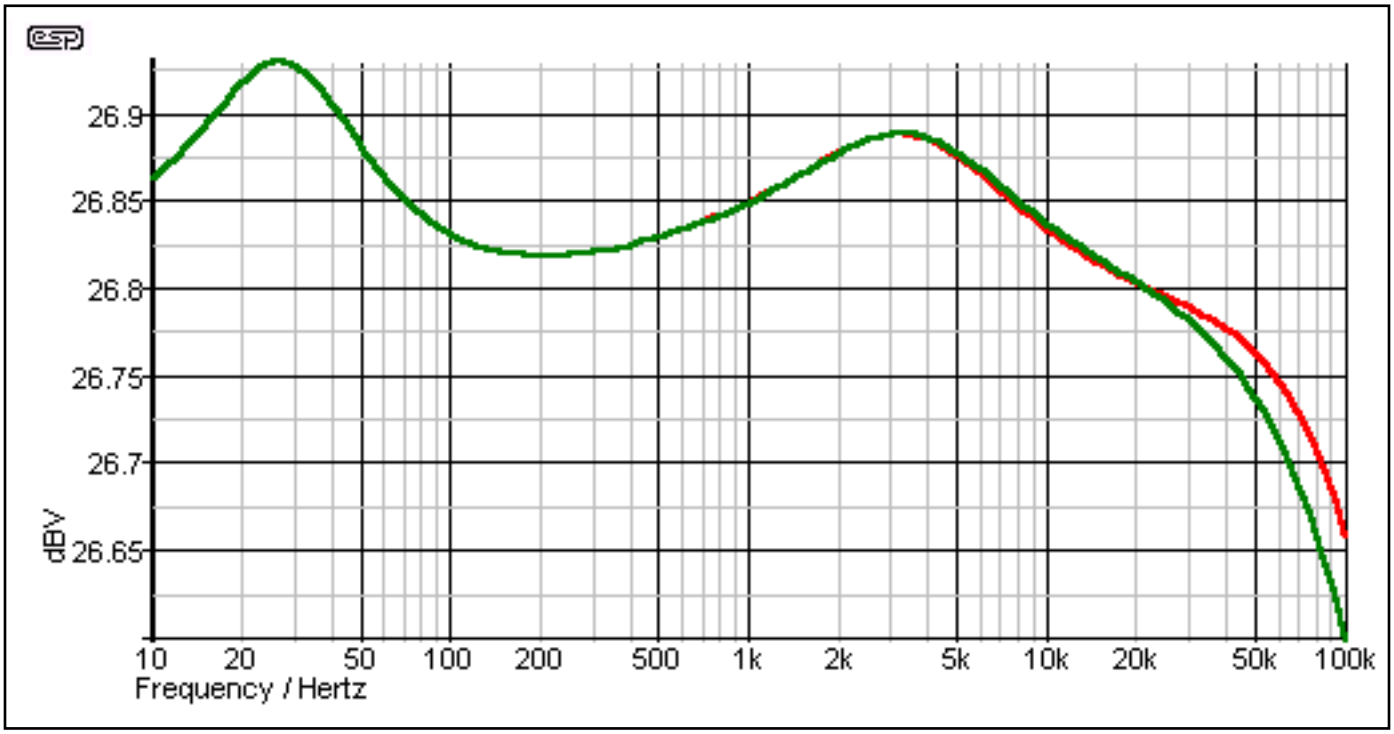

Figure 18 - Cable #3 Frequency Response

This looks terrible, until you notice the dB range. Total variation is from a low of 26.8dB

at 20kHz to a peak of 26.93dB at about 27Hz (woofer resonance, and the highest impedance the loudspeaker presents). A total variation of 0.13dB. Midband level is 26.826dB at 200Hz.

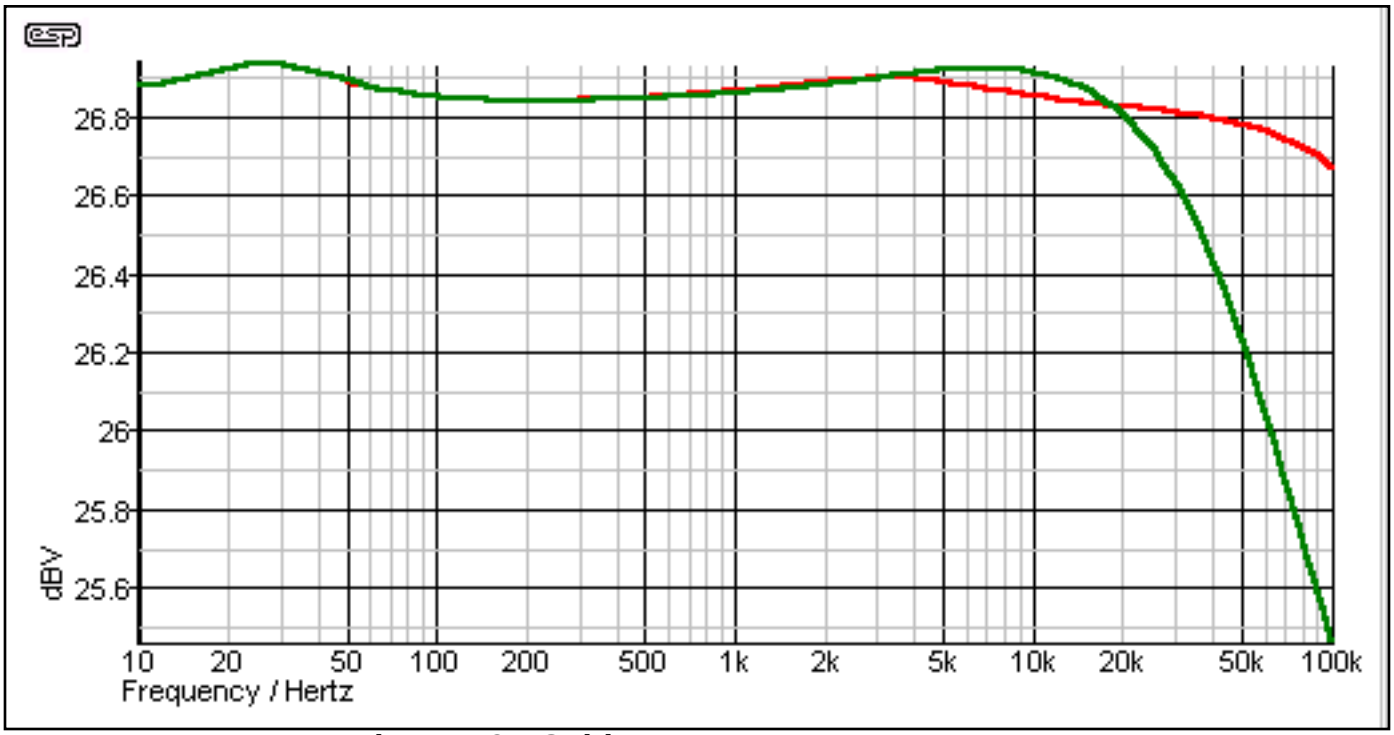

Figure 19 - Cable #1 Frequency Response

The zip cable looks better, and at a very small fraction of the cost. Minimum is 26.8dB at 20kHz and maximum is 26.93dB at woofer resonance - a total deviation of 0.13dB. The HF rolloff between 10kHz and 20kHz is 0.1dB (hardly woeful - find a tweeter that good!) Midband level is 28.84dB at 200Hz.

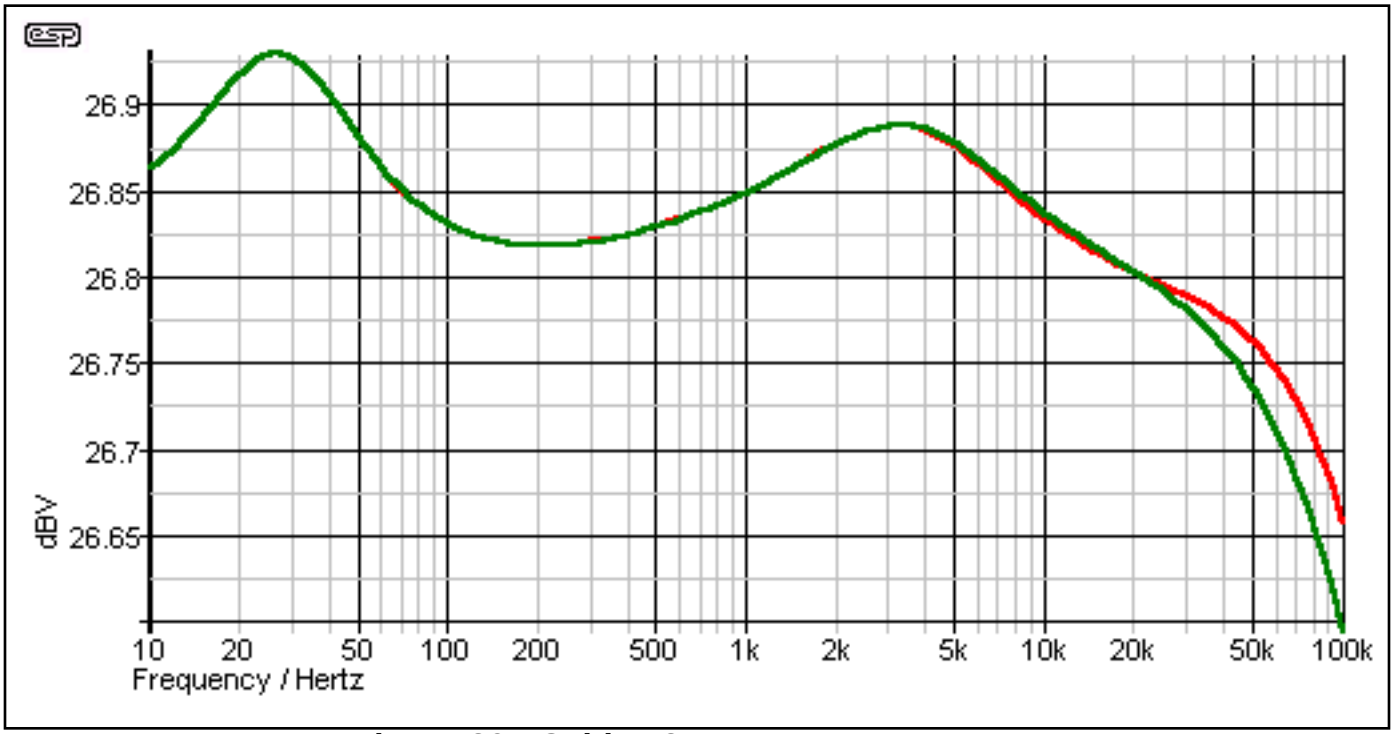

Figure 20 - Cable #2 Frequency Response

Cable #2 is again at 26.8dB at 20kHz, peaking at 26.93dB - a total variation of 0.13dB. Midband level is 26.82dB at 200Hz.

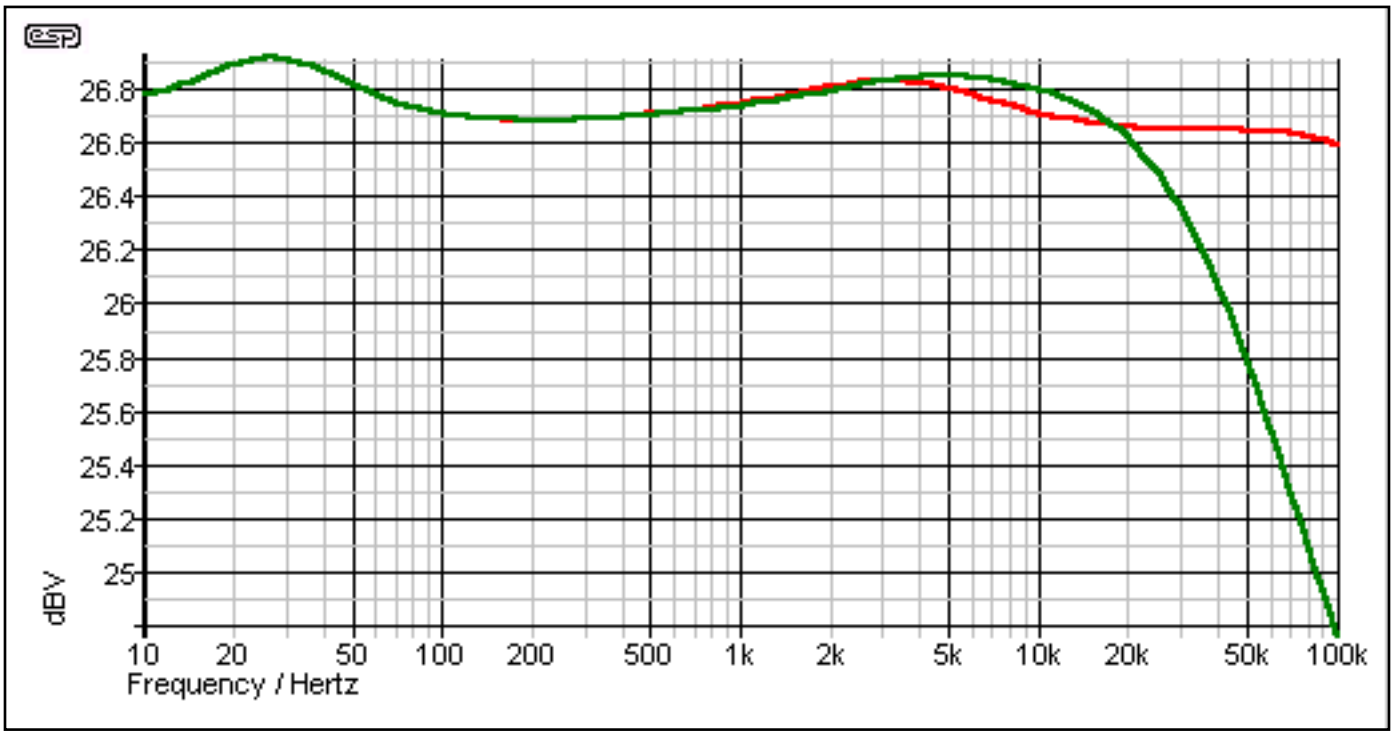

Figure 21 - "Figure 8" Frequency Response

Last (in all respects) comes the Figure-8 cable, but at the equivalent of perhaps 14 gauge (US gauge numbering), one expects it to be less than impressive. Minimum level is 26.6dB at 20kHz, and maximum is around 26.91dB - a total deviation of 0.31dB.

Midband level is about 26.68dB at 200Hz.

It is worth noting that none of these cables is 1dB down on midband level at any frequency up to 20kHz, and even the Figure-8 lead is only 1dB down at 50kHz - it is a rare tweeter indeed that will be anywhere near as good, regardless of price.

So, what do you get for your money? Quite obviously, very little improvement is afforded by any of these cables over another - 12 gauge zip cable is cheap and easy to make into a speaker lead, Jon's cable is a little more expensive, and there is a fair amount of work involved, and the Goertz cable will set you back about US$200 a pair for 4 metre lengths (and maybe make your amplifier oscillate). Naturally, you can spend a great deal more (and still make the amp oscillate), but I don't see much point.

If it makes you feel better to have sexy looking cross-connected coax leads, then far be it for me to attempt to deny you that pleasure, besides, it might be fun to do (which is far more important). I still can't recommend the Goertz cable, as its capacitance is just too high. A Zobel tames that, but I would be reluctant to use it anyway, and I certainly wouldn't pay their prices for it!

The Web has a great many examples of over-the-top cable pricing (although some are a lot cheaper than others), claims and mistakes. This is not to single out any manufacturer - it is simply to point out that a great many examples can be found of "high-end" cables with claims that cannot be substantiated by DBT listening test or simulation. There are (of course) so many that they are too numerous to mention.

Decisions, decisions ....

6.0 References

Online Radio and Electronics Course

Principles of Transmission Lines

All simulations were carried out using SIMetrix, and a free demo version is available from Catina Software Ltd in the UK. This is (IMO) an outstanding simulator, and regularly produces results that can be transferred directly from a simulation to a working circuit, without the need for any changes at all.

Cable parameters were taken from the Audioholics website, and I thank Gene DellaSala for permission and for his support for this article.

The simulated loudspeaker is based on a version published by Jon Risch, and his DIY cross-connected coaxial cable was used for sample #2 in the simulations. For those who wish to experiment with "exotic" designs, those published by Jon are high performance and cheap to build - certainly a major departure from the US$1000/metre offerings that seem to proliferate in the market. Jon's designs are also far less likely to cause amplifier instability than many of the commercial offerings!

Finally, the parameters for cable #3 were obtained from the Alpha-Core website.

Elliott Sound Products **Amplifier Sound - What Are The Influences?**

Rod Elliott (ESP)

Articles Index

Main Index

Introduction

The sound of an amplifier is one of those ethereal things that seems to defy description. I will attempt to cover the influences I know about, and describe the effects as best I can. This is largely hypothesis on my part, since there are so many influences that, although present and audible, are almost impossible to quantify. Especially in combination, some of the effects will make one amp sound better, and another worse - I doubt that I will be able to even think of all the possibilities, but this article might help some of you a little - at least to decipher some of the possibilities.

I don't claim to have all the answers, and it is quite conceivable that I don't have any (although I do hope this is not the case). This entire topic is subject to considerable interpretation, and I will try very hard to be completely objective.

Readers' input is encouraged, as I doubt that I will manage to get everything right first time, and there are some areas where I do not really know what the answers are. The only joy I can get from this is that I doubt that anyone else can do much better. If you can, let me know.

The Components of Sound

When people talk about the sound of an amplifier, there are many different terms used. For a typical (high quality) amplifier, the sound may be described as "smeared", or having "air" or "authoritative" bass. These terms - although describing a listener's experience - have no direct meaning in electrical terms.

Electrically, we can discuss distortion, phase shift, current capability, slew rate and a myriad of other known phenomena. I don't have any real idea as to how we can directly link these to the common terms used by reviewers and listeners.

Some writers have claimed that all amplifiers actually sound the same, and to some extent (comparing apples with apples) this is "proven" in double-blind listening tests. I am a great believer in this technique, but there are some differences that cannot be readily explained. An amp that is deemed "identical" to another in a test situation, may sound completely different in a normal listening environment. It is these differences that are the hardest to deal with, since we do not always measure some of the things that can have a big influence on the sound.

For example; It is rare that testing is done on an amplifier's clipping performance - how the amp recovers from a brief transient overload. I have stated elsewhere that a hi-fi amplifier should never clip in normal usage - nice try, but it IS going to happen, and often is more common than we might think. Use a good clipping indicator on the amp, and this can be eliminated, but at what cost? It might be necessary to reduce the volume (and SPL) to a level that is much lower than you are used to, to eliminate a problem that you were unaware existed.

Different amplifiers react in different ways to these momentary overloads, where their overall performance is otherwise almost identical. I have tested IC power amps, and was dismayed by the overload recovery waveform. My faithful old 60W design measures about the same as the IC in some areas, a little better in some, a little worse in others (as one would expect).

Were these two amps compared in a double blind test (avoiding clipping), it is probable that no-one would be able to tell the difference. Advance the level so that transients started clipping, and a fence post would be able to hear the difference between them. What terms would describe the sound? I have no idea. The sound might be "smeared" due to the loss of detail during the recovery time of the IC amp. Imaging might suffer as well, since much of the signal that provides directional cues would be lost for periods of time.

Measurable Performance Characteristics

A detailed description of the more important (from a sound perspective) of the various amplifier parameters is given later in this article, but a brief description is warranted first. Items marked with a * are problem areas, and the effect should be minimised wherever possible. The parameters that should normally be measured (although for those marked # this is rare indeed) are as follows:

* Important parameter
# Rarely measured

- **Input Sensitivity :** The signal level required to obtain full power at the amplifier's output. This is determined by the gain and power rating of the amp. A 10W amplifier requires far less gain than a 200W amplifier to obtain full power for the same input voltage. It would be useful if all amplifiers had the same gain regardless of power, but this is not the case. Sensitivities vary widely, ranging from about 500mV up to 1.5V or more.
- **Total Harmonic Distortion (THD) * :** This is a measure of the amount of distortion (modification) of the input signal, which adds additional signal frequencies to the output that are not present in the input signal. THD is commonly measured as a percentage, and can range from 0.001% to 0.1% for typical hi-fi amplifiers. A theoretically perfect amplifier contributes no distortion.
- **Transient Intermodulation Distortion (TIM) * :** Also sometimes called slew induced distortion, this is a form of distortion said to occur when the input signal changes so fast that the output cannot keep up with it. When this happens, feedback ceases to be effective, since the output signal is delayed too long. This remains somewhat contentious, and most modern amplifiers are quite capable of handling the normal programme amplitude and frequency range without difficulty.
- **Crossover Distortion *# :** A form of distortion caused by the power output devices in a push-pull amplifier operating in Class-AB. This occurs in valve and solid state designs, and is caused by one device switching off as the other takes over for its half of the waveform. There are some designs that claim to eliminate this distortion by never turning off the power devices, but in reality, only Class-A amplifiers have zero crossover distortion. This is generally measured as a part of the THD of an amplifier, and becomes worse as power is reduced from the maximum.
- **Frequency Response * :** The amount of frequency versus amplitude distortion in an amplifier. A perfect amplifier will amplify all signals equally, regardless of frequency. Realistically, an amplifier needs a

response of about 5Hz to 50kHz to ensure that all audible signals are catered for with minimal modification.

- **Phase Response :** This indicates the amount of time that the input signal is delayed before reaching the output, based on the signal frequency. Variations in absolute phase are not audible in an amplifier system, but are generally considered undesirable by the hi-fi press. Since it is not difficult to ensure phase linearity, this is not generally a design issue except with valve amplifiers.
- **Output Power :** This is most commonly measured into a non-inductive resistive load. This is not done to improve the figures or disguise any possible shortcomings, but to ensure that measurements are accurate and repeatable. Power should only ever be quoted as "RMS", which although is not strictly correct, is accepted in the industry, and may be measured into 8 Ohms, or other impedances that the amplifier is capable of driving.
- **Output Current # :** Not often measured, but sometimes quoted by manufacturers, this represents the maximum current the amplifier can supply into any load. It is rare that any amplifier will be called upon to deliver any current greater than about 3 to 5 times the maximum that the nominal speaker impedance would allow for the amplifier's supply voltage. Greater variations may be possible with some speaker designs, but (IMO) this represents a flaw in the design of the loudspeaker.
- **Power Bandwidth :** This is usually taken as the maximum frequency at which the amplifier can produce 1/2 of its rated output power (this is the -3dB frequency). A 100W amplifier that can produce 50W at 50kHz will be deemed as having a 50kHz power bandwidth.
- **Slew Rate # :** Closely related to power bandwidth, the slew rate is the maximum rate of change (measured in Volts per microsecond) of the amplifier output. The higher the amplifier power, the higher the slew rate must be to obtain the same power bandwidth.
- **Open Loop Bandwidth # :** The bandwidth of the amplifier with no AC feedback applied. Very few amplifiers will have an open loop bandwidth greater than a few kilo-Hertz, but valve amps and some solid state designs have a comparatively high open loop bandwidth.
- **Open Loop Gain # :** Rarely quoted except for DIY amps (and few of them as well), this is the gain of the amplifier without any AC signal feedback. It is not really a helpful parameter for most people, but can be used to determine the ...
- **Open Loop Distortion #* :** The THD of the amplifier with no feedback applied. This should be as low as possible, but realistically will usually be quite high by normal standards. The open loop distortion is reduced by an amount approximately equal to the feedback ratio.
- **Open Loop Output Impedance # :** The output impedance of the amplifier with no AC feedback applied. This may range from a few Ohms to 10 or more Ohms, depending on the design of the amplifier. Valve amplifiers will normally have an open loop output impedance of 0.7 of the designed speaker impedance.
- **Feedback Ratio # :** How much of the open loop gain is fed back to the amplifier's input to obtain the sensitivity figure quoted for the amp. For example if an amplifier has an open loop gain of 100dB, and a gain of 20dB, then the feedback ratio is 80dB. The application of feedback will
  - Increase bandwidth
  - Reduce phase shift
  - Reduce distortion
  - Reduce output impedance
- **Output Impedance * :** This is the actual output impedance of the amplifier, and has no bearing on the amount of current that can be supplied by the output stage. Valve amplifiers usually have a relatively high output impedance (typically 1 to 6 Ohms), while solid state amps will normally have an output impedance of a fraction of an Ohm. By use of feedback, it is possible to increase output impedance (> 200 Ohms is quite easy), or it can be made negative. Negative impedance has been tried by many designers (including the author), but has never gained popularity - possibly because most speakers react very poorly to negative impedances and tend to sound awful.

Every amplifier design on the planet has the same set of constraints, and will exhibit all of the above problems

to some degree. The only exception is a Class-A amplifier, which does not have crossover distortion, but is still limited by all other parameters.

The difficulty is determining just how much of any of the problem items is tolerable, and under what conditions. For example, there are many single ended triode valve designs which have very high distortion figures (comparatively speaking), high output impedance and low output current capability. There are many audio enthusiasts who claim that these sound superior to all other amplifiers, so does this mean that the parameters where they perform badly (or at least not as well as other amps) can be considered unimportant? Not at all!

If a conventional (i.e. not Class-A) solid state amplifier gave similar figures, it would be considered terrible, and would undoubtedly sound dreadful.

Although all the issues described above are separate in their own right, many can be lumped together under a single general category....

Distortion
Technically, distortion is any change that takes place to a signal as it travels from source to destination. If some of the signal "goes missing", this is distortion just as much as when additional harmonics are generated.

We tend to classify distortion in different ways - the imperfect frequency response of an amplifier is not generally referred to as distortion, but it is. Instead, we talk about frequency response, phase shift, and various other parameters, but in reality they are all a form of distortion.

The bottom line is that amplifiers all suffer from some degree of distortion, but if two amplifiers were to be compared that had no distortion at all, they must (by definition) be identical in both measured and perceived sound.

Naturally, there is no such thing as a perfect amplifier, but there are quite a few that come perilously close, at least within the audible frequency range. What I shall attempt to do is look at the differences that do exist, and try to determine what effect these differences have on the perceived "sonic quality" of different amplifiers. I will not be the first to try to unravel this mystery, and I doubt that I will be the last. I also doubt that I will succeed, in the sense that success in this particular area would only be achieved if everyone agreed that I was right - and of that there is not a chance! (However, one lives in hope.)

In this article I use the somewhat outdated term "solid state" to differentiate between valve amps, and those built using bipolar transistors, MOSFETs or other non-vacuum tube devices.

I have also introduced a new (?) test method, which I have called a SIM (Sound Impairment Monitor), the general concept of which is described in the appendix to this article.

Clipping Distortion

How can one amplifier's clipping distortion sound different from that of another? Most of the hi-fi fraternity will tend to think that clipping is undesirable in any form at any time. While this is undeniably true, many of the amps used in a typical high end setup will be found to be clipping during normal programme sessions. I'm not referring to gross overload - this is quite unmistakable and invariably sounds awful - regardless of the amplifier.

There are subtle differences between the way amplifiers clip, that can make a very great impact on the sound.

Valve amps are the most respectable of all, having a "soft" clipping characteristic which is comparatively unobtrusive. Low feedback Class-A amplifiers are next, with slightly more "edge", but otherwise are usually free from any really nasty additions to the overall sound.

Then there are the myriad of Class-AB discrete amps. Most of these (but by no means all) are reasonably well behaved, and while the clipping is "hard" it does not have significant overhang - this is to say that once the output signal is lower than the supply voltage again it just carries on as normal. This is the ideal case - when any amp clips, it should add no more nastiness to the sound than is absolutely necessary. Clipping refers to the fact that when the instantaneous value of output signal attempts to exceed the amplifier's power supply voltage, it simply stops, because it cannot be greater than the supply. We know it must stop, but what is of interest is how it stops, and what the amplifier does in the brief period during and immediately after the clipping has occurred.

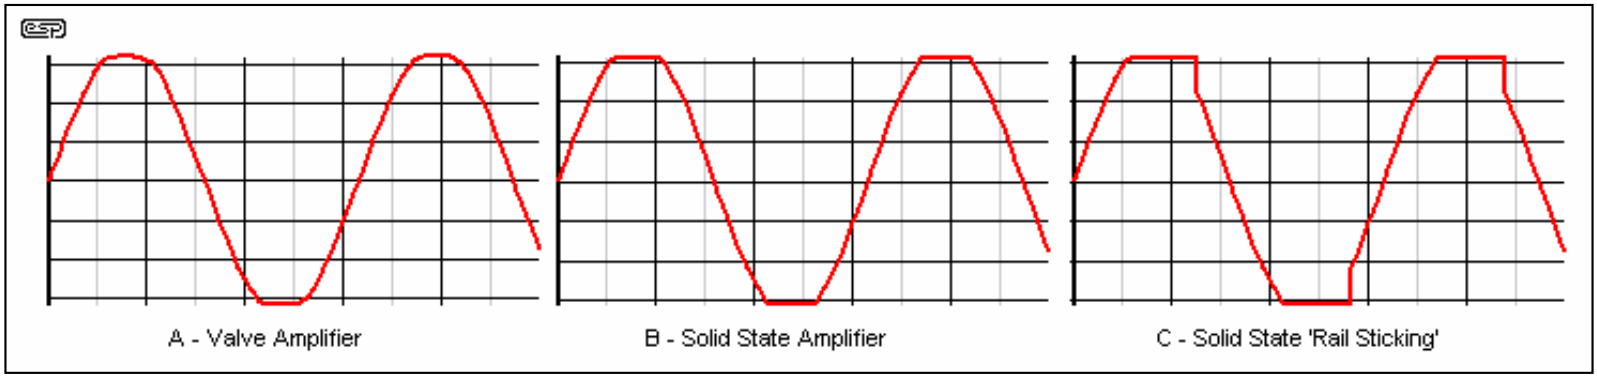

Figure 1 - Comparison of Basic Clipping Waveforms

In Figure 1, you can see the different clipping waveforms I am referring to, with "A" being representative of typical push-pull valve amps, "B" is the waveform from a conventional discrete Class-AB solid state amp, and "C" shows the overhang that is typical of some IC power amps as well as quite a few discrete designs. This is a most insidious behaviour for an amp, because while the supply is "stuck" to the power rail, any signal that might have been present in the programme material is lost, and a 100Hz (or 120Hz) component is added if the clipping + "stuck to rail" period lasts long enough. This comes from the power supply, and is only avoidable by using a regulated supply or batteries. Neither of these is cheap to implement, and they are rarely found in amplifier designs.

Although Figure 1 shows the signal as a sinewave for ease of identification, in a real music signal it will be a sharp transient that will clip, and if the amp behaves itself, this will be (or should be) more or less inaudible. Should it stick to the supply rail, the resulting description of the effect is unlikely to accurately describe the actual problem, but describe what it has done to the sound - from that listener's perspective. A simple clipped transient should not be audible in isolation, but will have an overall effect on the sound quality. Again, the description of this is unlikely to indicate that the amp was clipping, and regrettably few amps have clipping indicators so most of the time we simply don't know it is happening.

To be able to visualise the real effect of clipping, we need to see a section of "real" signal waveform, with the lowest and highest signal frequencies present at the same time. If the amp is clipped because of a bass transient (this is the most common), the period of the waveform is long. even if the signal is clipped for only 5 milliseconds, this means that 5 complete cycles of any signal at 1000Hz is removed completely, or 50 complete cycles at 10kHz. This represents a significant loss of intended information, which is replaced by a series of harmonics of the clipped frequency (if clipping lasts for long enough), or more typically a series of harmonics that is not especially related to anything (musically speaking - all harmonics are related to something, but this is not necessarily musical!)

I think that no review of any amplifier should ever be performed without some method of indicating that the amp is clipping (or is subject to some other form of signal impairment), and this can be added to the reviewer's notes - along the lines of:

"This amplifier was flawless when kept below clipping (or as long as the SIM failed to show any noticeable impairment), but even the smallest amount of overload caused the amp to sound very hard. Transparency was completely lost, imaging was impaired badly, and it created listener fatigue very quickly."

Now, wouldn't that be cool? Instead of us being unaware (as was the reviewer in many cases) that the amp in review was being overdriven - however slightly - we now (all of us) have that missing piece of information that is not included at the moment. I have never seen a review of an amp where the output was monitored with an accurate clipping indicator to ensure that the reviewer was not listening to a signal that was undistorted. I'm not saying that no-one does this, just none that I have read.

The next type of overload behaviour is dramatically worse, and I have seen this in various amps over the years. Most commonly associated with overload protection circuits, the sound is gross. I do not know the exact mechanism that allows this to happen, but it can be surmised that the protection system has "hysteresis", a term that is more commonly associated with thermal controllers, steel transformer laminations and Schmitt trigger devices. Basically, a circuit with hysteresis will operate once a certain trigger point is reached, but will not reset until the input signal has fallen below a threshold that is lower than the trigger point. The typical waveform of an amplifier with this problem is shown in Figure 2, and I believe it IS a problem, and should be checked for as a normal part of the test process. This type of overload characteristic is not desirable in any way, shape or form.

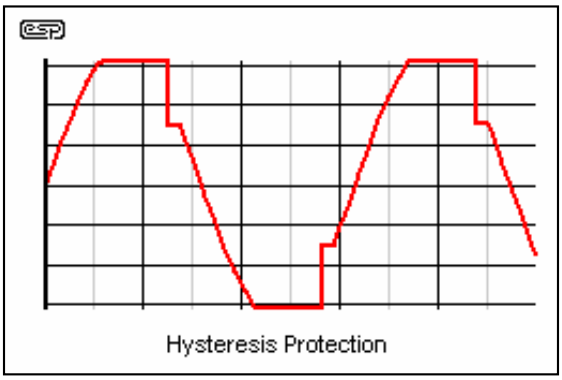

Figure 2 - Hysteresis Overload Waveform

In this case, the additional harmonic components added to the original sound will be more prominent than with "normal" clipping. As before, I cannot even begin to imagine how the sound might be described - all the more reason to ensure that testing includes informing the reader if the amp was clipping or not during the listening tests. The loss of signal with this type of distortion will generally be much greater than simple clipping, and the added harmonic content will be much more pronounced, especially in the upper frequencies.

Clipping Synopsis

Tests conducted as a part of any review would be far more revealing if the clipping waveform were shown as a matter of course. After some learning on our behalf, we would get to know what various of the hi-fi press meant when they described the sound while the amp was clipping, versus not clipping, or what the amp sounded like when it's overload protection circuits came into action.

To this end I have designed a new distortion indicator circuit, which not only indicates clipping, but will show when the amp is producing distortion of any kind beyond an acceptable level. One version has been published

as a project, and I have chosen the acronym SIM (Signal Impairment Monitor) for this circuit.

The SIM will react to any form of signal modification, and this includes phase distortion and frequency response distortion. I do not believe that this approach has been used before in this way. It is not an uncommon method for distortion measurement, but has not been seen anywhere as a visual indicator for identifying problem areas that an amp may show in use. This circuit will also show when an amplifier's protection circuit has come into effect.

Although the detector has no idea what type of problem is indicated, it does indicate when the input and output signals no longer match each other - for whatever reason. Oscilloscope analysis would be very useful using this circuit, as with a little practice we would be able to identify many of the currently unknown effects of various amplifier aberrations. Note that it is unable to reveal crossover distortion unless it becomes quite high, which is extremely unlikely in any modern amplifier design.

Crossover Distortion

Class-A amplifiers have no crossover distortion at all, because they maintain conduction in the output device(s) for the entire waveform cycle and never turn off. Class-A is specifically excluded from this section for that reason.

For the rest, a similar question as the one before - how can one amplifier's crossover distortion sound different from another? Surely if there is crossover distortion it will sound much the same? Not so at all. Again, valve amplifiers are much better in this area than solid state amps (at least in open loop conditions). When valves cross over from one output device to the next (standard push-pull circuit is assumed), the harmonic structure is comprised of mainly low order odd harmonics. There will be some 3rd harmonics, a smaller amount of 5th, and so on.

Solid state amps tend to create high order odd harmonics, so there might be more of the 5th harmonic than the 3rd, and even more 7th (and so on). Transistor and MOSFET amps have very high open loop gains, and use feedback to reduce distortion. In all cases, the crossover distortion is caused because the power output devices are non-linear. At the low currents at which the changeover occurs, these non-linearities are worse, as well, the devices usually have a lower gain at these currents.

This has two effects. The open loop gain of the amplifier is reduced because of the lower output device gain, so there is less negative feedback where it is most needed. Secondly, the feedback tries to compensate for the lower gain (and tries to eliminate the crossover distortion), but is limited by the overall speed of the internal circuitry of the amplifier. This results in sharp transitions in the crossover region, and any sharp transition means high order harmonics are produced (however small they might be).

One method to minimise this is to increase the quiescent (no signal) current in the output transistors. With a linear output stage in a well designed circuit, crossover distortion should be minimal with any current above about 50 to 100mA. Figure 3 shows the crossover distortion (at the centre of the red trace) and the residue as seen on an oscilloscope (green trace, amplified by 10 for clarity) - this is the typical output from a distortion meter, with an amplifier that has noticeable crossover distortion. If measured properly, the distortion is highly visible, even though it may be barely audible. Note that the waveform below would not qualify for the last statement - this amount of crossover distortion would be very audible indeed.

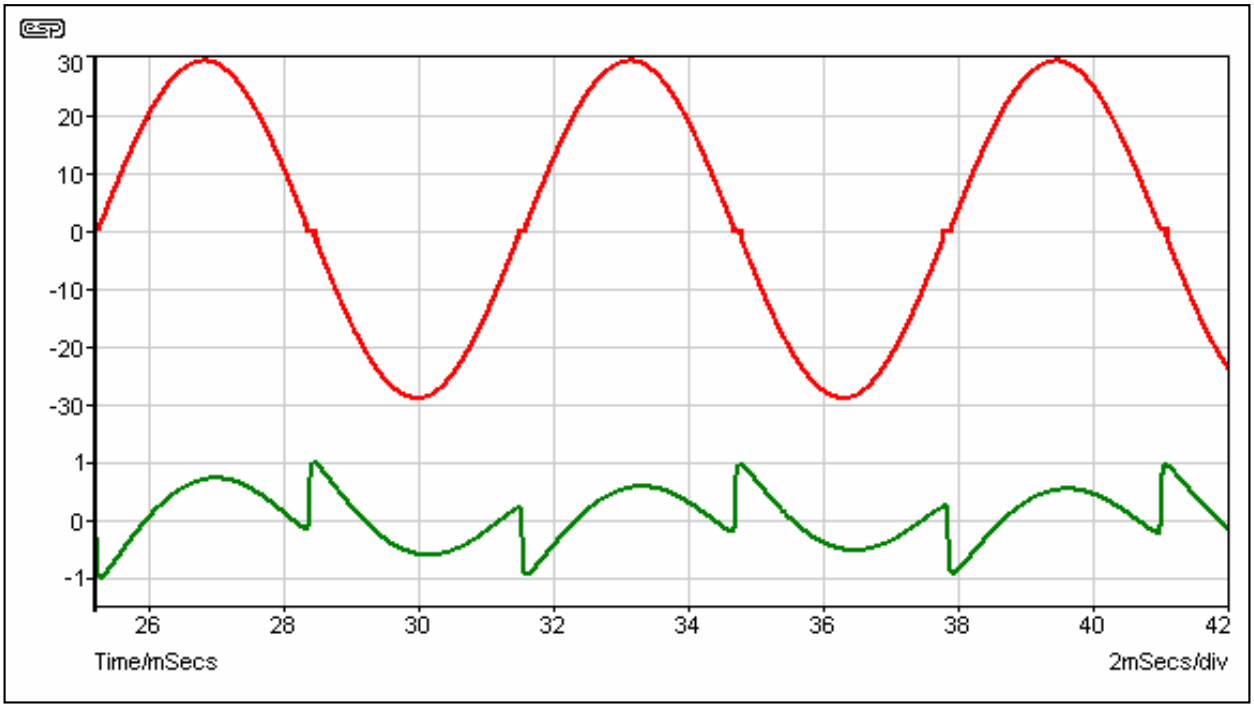

Figure 3 - Crossover Distortion Waveform

If THD is quoted without reference to its harmonic content, then it is quite possible that two amplifiers may indicate identical distortion figures, but one will sound much worse than the other. Distortion at a level of 1W should always be quoted, and the waveform shown. Once the waveform can be seen, it is easy to determine whether it will sound acceptable or dreadful - before we even listen to the amp. Listening tests will confirm the measured results with great accuracy, although the descriptive terms used will vary, and may not indicate the real problem.

Crossover Distortion Synopsis

Although this is one area where modern amplifiers rarely perform badly, it is still important, and should be measured and described with more care than is usually the case. While few amplifiers will show up badly in this test now, crossover distortion was one of the main culprits that gave solid state a bad name when transistors were first used in amplifiers.

I do not believe that we can simply ignore crossover distortion on the basis the "everyone knows how to fix it, and it is not a problem any more". I would suggest that it is still a real problem, only the magnitude has been reduced - the problem is still alive and well. Will you be able to hear it with most good quality amp? Almost certainly not.

Frequency And Phase Distortion

Distortion of the frequency response should not be an issue with modern amplifiers, but with some (such as single ended triode valve designs), it does pose some problems. The effect is that not all frequencies are amplified equally, and the first to go are the extremes at both ends of the spectrum. It is uncommon for solid state amps to have a frequency response at low powers that extends to anything less than the full bandwidth from 20Hz to 20kHz. This is not the case with some of the simple designs, and single ended triode (SET) Class-A - as well as inductance loaded solid state Class-A amps - will often have a less than ideal response.

I would expect any amplifier today should be no more than 0.5dB down at 20Hz and 20kHz, referred to the mid-band frequency (usually taken as 1kHz, but is actually about 905Hz). (My preferred test frequency is 440Hz

(concert pitch A, below middle C), but none of this is of great consequence.) 0.5dB loss is acceptable in that it is basically inaudible, but most amps will do much better than this, with virtually no droop in the response from 10Hz to over 50kHz.

For reference, the octaves included for "normal" sound are:

20 40 80 160 320 640 1280 2560 5120 10240 20480

To determine the halfway point between two frequencies one octave apart, we multiply the lower frequency by the square root of 2 (1.414). The halfway point is between 650 and 1280Hz, or 904.96Hz. You must be so pleased to have been provided with this piece of completely useless information! Just think yourselves lucky that I didn't tell you how to calculate the distance between the frets on a guitar. :-D

Most amplifiers will manage well beyond the range necessary for accurate reproduction, at all power levels required to cater for the requirements of music. So why are some amps described as having poor rendition of the high frequencies? They may be described a "veiled" or something similar, but there is no measurement that can be applied to reveal this when an amplifier is tested. Interestingly, some of the simpler amplifiers (again, such as the single ended triode amps) have poorer response than most of the solid state designs, yet will regularly be described as having highs that "sparkle", and are "transparent".

These terms are not immediately translatable, since they are subjective, and there is no known measurement that reveals this quality. We must try to determine what measurable effect might cause such a phenomenon. There are few real clues, since amplifiers that should not be classified as exceptional in this area are often described as such. Other amps may be similarly described, and these will not have the distortion of a single ended triode and will have a far better response.

We can (almost) rule out distortion as a factor in this equation, since amps with comparatively high distortion can be comparable to others with negligible distortion. Phase shift is also out of the question, since amps with a lot of phase shift can be favourably compared to others with virtually none. One major difference is that typical SET amplifiers have quite high levels of low order even harmonics. Although these will give the sound a unique character, I doubt that this is the sole reason for the perceived high frequency performance - I could also be wrong.

Phase distortion occurs in many amplifiers, and is worst in designs using an output transformer or inductor (sometimes called a choke). The effect is that some frequencies are effectively delayed by a small amount. This delay is usually less than that caused by moving one's head closer to the loudspeakers by a few millimetres. It is generally thought to be inaudible, and tests that I (and many others) have conducted seem to bear this out.

Frequency And Phase Distortion - Synopsis

There must be some mechanism that causes multiple reviewers to describe an amplifier as having a poor high frequency performance, such as (for example) a lack of transparency. There are few real clues that allow us to determine exactly what is happening to cause these reviewers to describe the sound of the amp in such terms, and one may be tempted to put it all down to imagination or "experimenter expectancy". This is likely to be a mistake, and regardless what we might think about reviewers as a species, they do get to listen to many more amplifiers than most of us.

One of the few variables is a phenomenon called slew rate. This is discussed fully in the next section.

Slew Rate Distortion

This has always been somewhat controversial, but no-one has ever been able to confirm satisfactorily that slew rate (within certain limits) has any real effect on the sound. Figure 4 is a nomograph that shows the required slew rate for any given power output to allow full power at any frequency. To use it, determine the power and calculate the peak voltage, and place the edge of a ruler at that voltage level. Tilt the ruler until the edge also aligns with the maximum full power frequency on the top scale. The slew rate is indicated on the bottom scale.

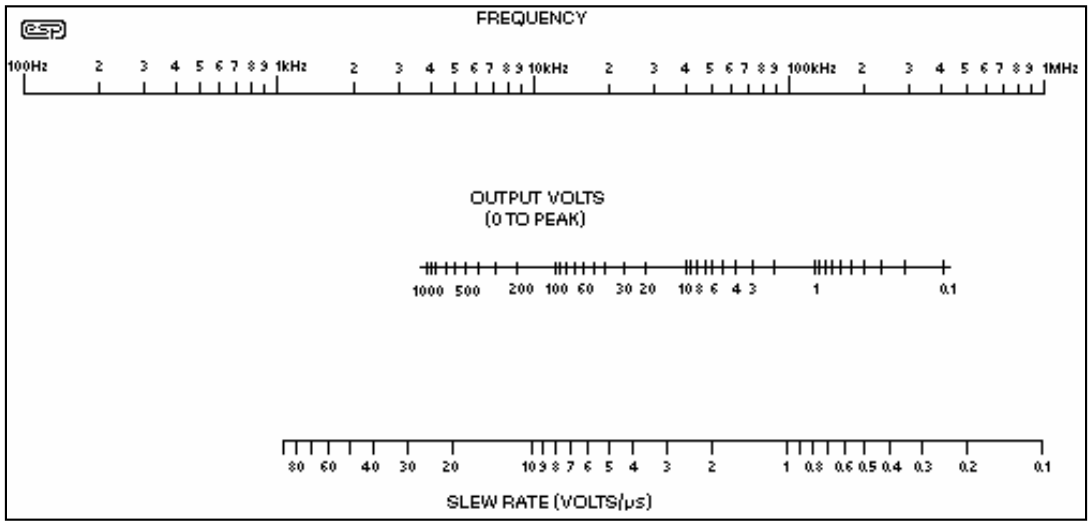

Figure 4 - Slew Rate Nomograph

Slew rate distortion is caused when a signal frequency and amplitude is such that the amplifier is unable to reproduce the signal as a sine wave. Instead, the input sine wave is "converted" into a triangle wave by the amplifier. This is shown in Figure 5, and is indicative of this behaviour in any amplifier with a limited slew rate. The basic problem is caused by the "dominant pole" filter included in most amplifiers to maintain stability and prevent high frequency oscillation. While very few amplifiers even come close to slew rate induced distortion (AKA Transient Intermodulation Distortion) with a normal signal, this is one of the very few possibilities left to explain why some amps seem to have a less than enthusiastic response from the reviewers' perspective.

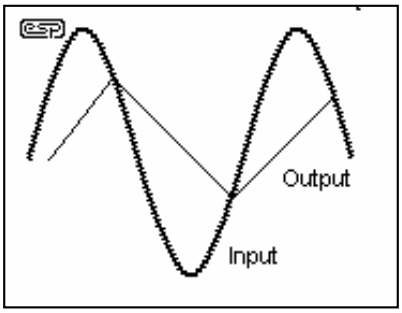

Figure 5 - Slew Rate Limiting In An Amplifier

Is this the answer, then? I wish it were, since we could all sleep soundly knowing exactly what caused one amp to sound the way it did, compared to another, which should have sounded almost identical.

A further test is to apply a low frequency square wave at about half to 3/4 power, mixed with a low-level high frequency sinewave to the amplifier. At the transitions of the squarewave, the sinewave should simply move up and down - "riding" the squarewave. If there is any mis-behaviour in the amp, the sinewave may be seen to be compressed so its shape will change, or a few cycles may even go missing entirely. Either is unacceptable, and should not occur.

This is an extremely savage test, but most amplifiers should be able to cope with it quite well. Those that don't will modify the music signal in an unacceptable way in extreme cases (which this test simulates). Again, this is an uncommon test to perform, but may be quite revealing of differences between amps.

Frequency And Slew Rate Distortion - Synopsis

We need to delve deeper, and although there seems to be little (if any) useful evidence we can use to explain this particular problem, there is an answer, and it therefore possible to measure the mechanism that causes the problem to exist.

Open Loop Responses

The performance of a feedback amplifier is determined by two primary factors. These are

- Open loop performance
- Feedback ratio

If the amp has a poor open loop gain and high distortion, then sensible amounts of feedback will not be able to correct the deficiencies, because there is not sufficient gain reserve. By the time the performance is acceptable, it may mean that the amplifier has unity gain, and is now impossible to drive with any normal preamp.

Many amplifiers have a very high open loop gain, but may have a restricted frequency response. Let's assume an amp that has a gain of 100dB at 20Hz, and 40dB gain at 20kHz. If we want 30dB of overall gain (which is about standard), then there is 70dB of feedback at 20Hz, but only 10dB at 20kHz. As a very rough calculation, distortion and output impedance are reduced by the feedback ratio, so if open loop distortion were 3% (not an unreasonable figure), then at 20Hz, this is reduced to 0.0015%, but will be only just under 1% at 20kHz.

Because these figures are so rarely quoted (and I must admit, I have not really measured all the characteristics of the 60W amp in Project 03 - open loop measurements are difficult to make accurately), we have no idea if amplifiers with poor open loop responses are responsible for so many of the failings we hear about. It is logical to assume that there must be some correlation, but we don't really know for sure.

Ideally, an amplifier should have wide bandwidth and low distortion before global feedback is applied, which will just make a good amp better. Or will it? I have read reviews where a very simple amp was deemed one of the best around (this was quite a few years ago), and I was astonished when I finally saw the circuit - it was almost identical to the "El Cheapo" amplifier (see the projects pages for more info on this amp).

The only major difference between this amp and most of the others at the time was the comparatively low open loop gain, and a somewhat wider bandwidth than was typical at the time, because it does not need a miller capacitor for stability. So the amp was better in one respect, worse in another.

In the end, it doesn't really matter what the open loop response is like, as long as closed loop (i.e. with feedback applied) performance does not degrade the sound. Again, we have the same quandary as before - unless we can monitor the difference between input and output at all levels and with normal signal applied, we really don't know what is going on. The usual tests are useful, but cannot predict how an amp will sound. I have heard countless stories about amps that measure up extremely well, but sound "hard and dry", and have no "music" in them.

Unless these measurements are made (or at least some modified form), we will still be no further in

understanding why so many people prefer one brand of amp over another (other than peer pressure or advertising hype).

One possibility is to measure the amp with a gain of 40dB. This is an easy enough modification to make for testing, and the performance is far easier to measure than if we attempt open loop testing. The difference between measured performance at 30dB gain (about 32) versus 40dB (100) would be an excellent indicator of the amp's performance, and it is not too hard to predict the approximate open loop response from the different measurements. To be able to do this requires that all measurements be very accurate.

Would these results have any correlation with the review results? We will never know if someone doesn't try it - work the techniques discussed here thoroughly, with a number of different amps. It would be useful to ensure that the reviewer was unaware of the test results before listening, to guard against experimenter expectancy or sub-conscious prejudice.

It is very hard to do a synopsis of this topic, since I have too little data to work with. Only by adopting new ideas and test methods will we be able to determine if the "golden-ear" brigade really does have golden ears, or that they actually hear much the same "stuff" as the rest of us, but have a better vocabulary. That is not intended as a slur, just a comment that we have to find out if there is anything happening that we (the "engineering" types) don't know about, or not. Unless we can get a match between measured and described performance, we get nowhere (which is to say that we stay where we are, on opposite sides of the fence).

Speaker - Amplifier Interface

Many is the claim that the ear is one of the most finely tuned and sensitive measuring instrument known. I am not going to dispute this - not so that I will not offend anyone (I seem to have done this many times already), but because in some respects it is true. Having said that, I must also point out that although extremely sensitive, the ear (or to be more correct, the brain) is also easily fooled. We can imagine that we can hear things that absolutely do not exist, and can just as easily imagine that one amplifier sounds better than another, only to discover that the reverse is true under different circumstances.

Could it be the influence of speaker cables, or even loudspeakers themselves? This is quite possible, since when amps are reviewed it is generally with the reviewer's favourite speaker and lead combination. This might suit one amplifier perfectly, while the capacitance and inductance of the cable might cause minute instabilities in other otherwise perfectly good amplifiers. Although it a fine theory to suggest that a speaker lead should not affect the performance of a well designed amplifier, there are likely to be some combinations of cable characteristics that simply freak out some amps. Likewise, some amps just might not like the impedance presented by some loudspeakers - this is an area that has been the subject of many studies, and entire amplifiers have been designed specifically to combat these very problems [1].

Many published designs never get the chance of a review, at least not in the same sense as a manufactured amplifier, so it can be difficult (if not impossible) to make worthwhile comparisons. In addition, we sometimes have different reviewers making contradictory remarks about the same amp. Some might think it is wonderful, while others are less enthusiastic. Is this because of different speakers, cables, or some other influence? The answer (of course) is that we have no idea.

We come back to the same problem I described earlier, which is that the standard tests are not necessarily appropriate. A frequency response graph showing that an amp is ruler flat from DC to daylight is of absolutely no use if everyone says that the highs are "veiled", or that imaging is poor. Compare this with another amp that is also ruler flat, and (nearly) everyone agrees that the highs are detailed, transparent, and that imaging is

superb.

We need to employ different testing methodologies to see if there is a way to determine from bench (i.e. objective) testing, what a listening (i.e. subjective) test might reveal. This is a daunting task, but is one that must be sought vigorously if we are to learn the secrets of amplifier sound. It is there - we just don't know where to look, or what to look for ... yet. Until we have correlation between the two testing methods, we are at the mercy of the purveyors of amplifier snake oil and other magic potions.

The SIM distortion indicator is one possible method that might help us, but it may also react to the wrong stimulus. Perhaps we need to add the ability to detect small amounts of high frequencies with greater sensitivity, but now a simple idea becomes quite complex, possibly to no avail. It is also important that such a device has zero effect on the incoming signal itself, so some care is needed to ensure that there is negligible loading on the source preamplifier.

This is not the only avenue open to us to correlate subjective versus objective testing. Both are important, the problem is that one is purely concerned with the way an amplifier behaves on the test bench, and a whole series of more or less identical results can be expected. The other is veiled in "reviewer speak", and although it might be useful if the reviewer is known and trusted, is not measurable or repeatable. The whole object is to try to determine what physical factors cause amplifiers to sound different, despite that fact that conventional testing indicates that they should sound the same.

Impedance

The output impedance of any amplifier is finite. There is no such thing as an amplifier with zero output impedance, so all amps are influenced to some degree by the load. An ideal load is perfectly resistive, and has no reactive elements (inductance or capacitance) at all. Just as there is no such thing as a perfect amplifier, there is also no such thing as a perfect load. Speakers are especially gruesome in this respect, having significant reactance, which varies with frequency.

A genuine zero impedance source is completely unaffected by the load, and it does not matter if it is reactive or not. If such a source were to be connected to a loudspeaker load, the influence of the load will be zero, regardless of frequency, load impedance variations, or anything else.

Since this is not the case in the real world, the goal (or at least one of them) is generally to make the amplifier have the lowest output impedance possible, in the somewhat futile hope that the amp will not be adversely affected by the variable load impedance. In essence, this is futile, since there will always be some output impedance, and therefore the load will always have some influence on the behaviour of the amp.

Another approach might be to make the output impedance infinite, and again, the load will have zero effect on the amplifier itself. Alas, this too is impossible. Given that the conventional approaches obviously cannot work, we are faced with the problem that all amplifiers are affected by the load, and therefore all amplifiers must show some degree of sensitivity to the speaker lead and speaker.

The biggest problem is that no-one really knows what an amplifier will do when a reactive load reflects some of the power back into the amp's output. We can hope (without success) that the effects will be negligible, or we can try to make speakers appear as pure resistance (again, without success).

A test method already exists for this, and uses one channel of an amp to drive a signal back into the output of another. The passive amplifier is the one under test. It is also possible to use a different source amplifier

altogether, since there is no need for it to be identical to the test amp. Use of a "standard" amplifier whose characteristics are well known is useful, since the source will be a constant in all tests. Differences may then be seen clearly from one test to the next.

The method is shown in Figure 6, and is a useful test of the behaviour of an amp when a signal is driven into its output. This is exactly what speakers do - the reactive part of the loudspeaker impedance causes some of the power to be "reflected" back into the amplifier. Since one amplifier in this test is the source, the device under test can be considered a "sink"

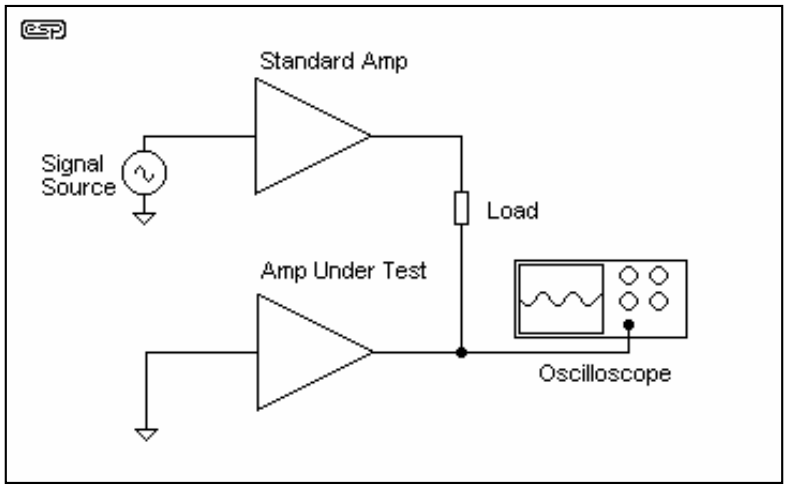

Figure 6 - Amplifier Power Sink Test

I have used this test, and although it does show some interesting results, they are essentially not useful unless used as a comparative test method. The driven amplifier is also subjected to very high dissipation (well above that expected with any loudspeaker load), because the transistors are expected to 'dump' the full current, while they have the full rail voltage across them. There is a real risk of damaging the amplifier, and I suggest that you don't try this unless you are very sure of the driven amplifier's abilities.

We may now ask "Why is this not a standard test for amplifiers, then?". The answer is that no-one has really thought about it enough to decide that this will (or should) be part of the standard set of tests for objective testing of an amplifier. The results might be quite revealing, showing a signal that may be non-linear (i.e. distorted), or perhaps showing a wide variation in measured signal versus frequency.

If either (or both) is the case, then we have some more information about the amplifier that was previously unknown. It might be possible to correlate this with subjective assessments of the amp, and gain further understanding of why some amps sound better (?) than others. We might discover that amps with certain characteristics using this test are subjectively judged as sounding better than others.

If this test became standard, and was routinely allied with the SIM tester described above, we might become aware of many of the problems that currently are audible, but for which there is no known measurement technique.

Conclusion

This article has described some tests that although not new, are possibly the answer to so many questions we have about amplifiers. The tests themselves have been known for some time, but their application is potentially of benefit for all of us. We may be able to finally perform an objective test, and be able to predict with a degree of confidence how the amp will sound. It may also happen that these tests are not sufficient to reveal all the

subtleties of amplifier sound, but will certainly be more useful than a simple frequency response and distortion test.

Any change to the testing methods used is not going to happen overnight, and nor are we going to be able to see immediately which problems cause a difference, and which ones have little apparent effect. Time, patience, and careful correlation of the data are essential if this is to succeed. There are laws of physics, and there are ears. Somewhere the two must meet in common ground. We already know that this happens, since there are amplifiers that sound excellent - according to a large number of owners, reviewers, etc. - now we need to know why.

There is a test method (or a series of methods) that will allow us to obtain a suite of tests that makes sense to designers and listeners alike, so we can get closer to the ideal amplifier, namely the mythical "straight wire with gain", but from the listener perspective rather than the senseless repetition of tests that seem to have no bearing on the perceived quality of the amp. This is not to say that the standard tests are redundant (far from it), but they do not seem to reveal enough information.

For this to succeed, the subjectivists must be convinced, as must the "objectivists". We are all looking for the same thing - the flawless reproduction of sound - but the two camps have drifted further and further apart over the years.

These are my musings, and I am open to suggestions for other testing methods that may reveal the subtle differences that undeniably exist between amplifiers. At the moment we have a chasm between those who can (or think they can) hear the difference between a valve and an opamp, a bipolar junction transistor and a MOSFET, or Brand "A" versus Brand "B", and those who claim that there is no difference at all.

The fact that there are differences is obvious. The degree of difference and why there are differences is not. It would be nice for all lovers of music (and the accurate reproduction of same) if we can arrive at a mutually agreeable explanation for these differences, that is accurate, repeatable, and measurable.

If these criteria are not met, then the assessment is not useful to either camp, and the chasm will simply widen. This is bad news for all - it is high time we all get together and stop arguing amongst ourselves whether (for example) it is better to use one brand of capacitor in the signal path or another.

These testing methods can also be applied to the measurement of individual components, speaker cables, interconnects and preamps, particularly the SIM tester. Using the amplifier power sink test with different cables and speakers might give us some clues as to why so many people are adamant that one speaker cable sounds better than another, even though there is no measurable difference using conventional means.

The greatest benefit of these tests is that they will reveal things we have not been looking at (or for) in the past, and may show differences that come as a very great surprise to designers and listeners alike.

For information on the use of the SIM, and an initial article describing how it works and my results so far, please see "Sound Impairment Monitor - The Answer?".

Class-A Part 2

Introduction

Recently there has been a resurgence of two "ancient" technologies - vacuum tube (valve) amplifiers and Class-A systems. The big question is .... is there a difference? This discussion centres on the Class-A amplifier, and explains (or attempts to) how it is different from a conventional power amplifier.

Why would someone want to build or buy an amplifier which is sooo inefficient? A Class-A power amp will typically draw anything from 1/2 to about 1½ times the peak speaker current in its quiescent state (i.e. while it is just sitting there doing nothing).

To put this into perspective, for a measly 8 Watts into 8 Ohms, the RMS current is 1 Amp. The peak current is just over 1.4 Amps, so a typical 8 Watt Class-A amp will draw anything from 700mA to 2 Amps continuous. This equates to a quiescent (no signal) power dissipation of between 17 Watts and 48 Watts, based on a 24 Volt supply (+/- 12 Volts). At very best, such an amplifier will have an efficiency of less than 35% at full power - at worst, this will be perhaps 15% or less.

The basic premise of a Class-A amp is that the output device(s) shall conduct all the time (through 360 degrees of the signal waveform). This means that in the simplest form, the power devices must conduct a continuous current which exceeds the

maximum peak load (loudspeaker) current. If we use a power level of 20 Watts (hardly a powerhouse) for all further calculations, we can see the whole picture.

In contrast, a typical Class-AB power amplifier's output devices only conduct for about 182 degrees (at full power), which means that for much of the signal's duration, only one or the other device is conducting. The other is turned off. The "crossover distortion" so often referred to is nothing to do with the frequency divider in the speaker system, but is created as the signal "crosses over" the 0 Volt point (see Figure 3).

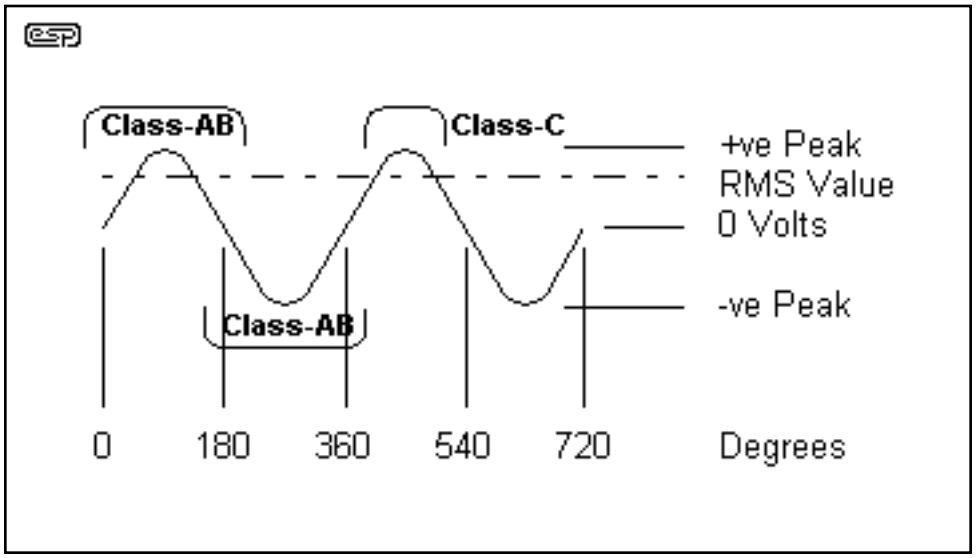

Figure 1 - The Sinewave Cycle

Let's have a quick look at some of the power amp "classes", so we have all the info:

- **Class-A** Output device(s) conduct through 360 degrees of input cycle (never switch off) - A single output device is possible. The device conducts for the entire waveform in Figure 1
- **Class-B** Output devices conduct for 180 degrees (1/2 of input cycle) - for audio, two output devices in "push-pull" must be used (see Class-AB)
- **Class-AB** Halfway (or partway) between the above two examples (181 to 200 degrees typical) - also requires push-pull operation for audio. The conduction for each output device is shown in Figure 1.
- **Class-C** Output device(s) conduct for less than 180 degrees (100 to 150 degrees typical) - Radio Frequencies only - cannot be used for audio! This is the sound heard when one of the output devices goes open circuit in an audio amp! See Figure 1, showing the time the output device conducts (single-ended operation is assumed, and yes this does work for RF).

When I first wrote this article, I had completely forgotten about the Quad "Current-Dumping" amp, which uses a low power "good" amplifier, with a push-pull Class-C type amp to supply the high currents needed for high power. Although these enjoyed a brief popularity, they seem to have faded away. I was reminded of their existence by an article by Douglas Self ("Class Distinction", in the March 1999 issue of Electronics World), in which he quite rightly points out that the current-dumper is (at least in part) Class-C.

- **Class-D** Quasi-digital amplification. Uses pulse-width-modulation of a high frequency (square wave) carrier to reproduce the audio signal - although my original comments were valid when this was written, there have been some very significant advances since then. There are some very good sounding Class-D amplifiers being made now, and they are worthy of an article of their own.

There are many amplifier topologies which I have not mentioned above, mainly because most of them are either too bizarre, not worth commenting on, or are too complex to explain simply. Of these, Class-G and Class-H use power supply switching and modulation (respectively). This provides greater than normal efficiency and lower dissipation, but both are essentially Class-AB designs.

Although many audio amps may be called Class-B, generally they are not. Virtually without exception they are Class-AB, although most will be at the bottom end (conduction for 181 degrees for each device). Most power amps operate in Class-A up to about 5 to 10mW, after which they become Class-B.

In the device department - For the remainder of this paper, I shall use bipolar transistors for the power devices, since they exhibit highly desirable characteristics for this application. They are also far more linear than MOSFETs, and some of the newer bipolar devices are outstanding in this regard. Note that there are two types of MOSFET in common use - Lateral devices are designed for audio, and although less linear than bipolar transistors can make a very good amp indeed (see Project 101). Power switching MOSFETs are (IMHO) not suitable for use in audio except where very high power is needed and extreme linearity is not required.

Power	20W (continuous)
Load Voltage (at Speaker)	12.65 Volts RMS (17.9 Volts Peak)
Load Current (through Speaker)	1.58 Amps RMS (2.23 Amps Peak)
Supply Voltage	+/- 20 Volts (constant)

Supply Current	+/- 2.25 Amps (peak)

Table 1 - Class-A Amplifier Requirements (Approx.) - 8Ω Load

In amplifier design, we are interested in the peak voltage and current, since if these are not met, then the required RMS values cannot be achieved. The ratio of RMS to peak (for a sine wave) is the square root of 2 (1.414), so RMS values must be multiplied by this constant to derive the peak values of voltage and current. (Refer to Figure 1 to see the relationship between peak and RMS voltages.)

This is how the values in the table were determined. The supply voltage needs to be slightly higher than the actual speaker peak voltage because the output devices (transistors) are not perfect, and some voltage will be lost even when they are turned on fully. (If MOSFETs were to be used, the losses may be much greater, unless an additional power supply is employed.)

Ok. We have determined that the peak speaker current is 2.25 Amps, so in the simplest of Class-A designs this will require a quiescent current of 2.25 Amps. Given that the voltage is +/- 20 Volts, this means that the power output stage will have to dissipate 40 x 2.25 = 90 Watts (45 Watts per output device).

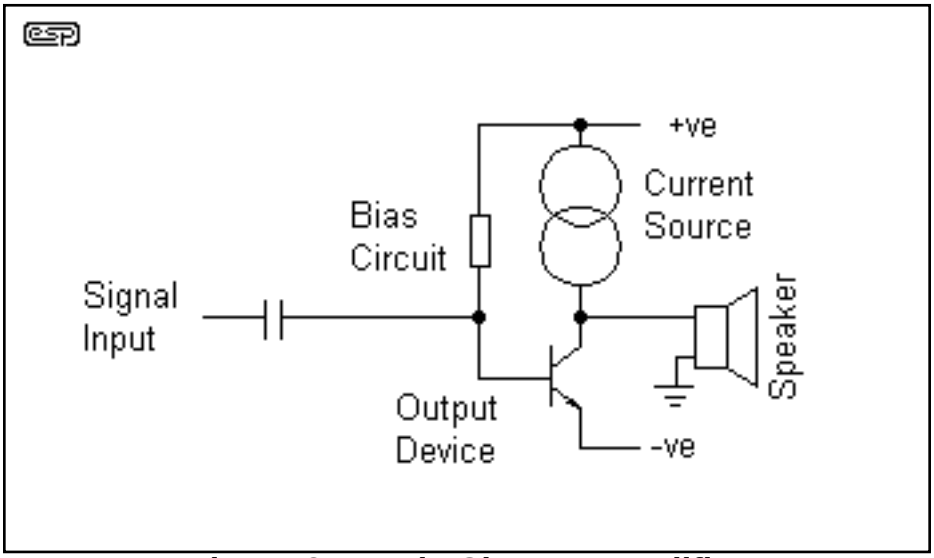

Figure 2 - Basic Class-A Amplifier

Figure 2 shows what a simple Class-A amp looks like. The current source is a simple circuit, which will provide a current which remains constant regardless of the load placed at its output. The output transistor "dumps" any current which is not needed by the load (speaker), so when it is completely turned off, all the current source output flows through the speaker. Conversely, when it is turned on, the speaker current flows through the output transistor (as well as the current from the current source!), so its current will vary

from almost 0 Amps, to a maximum of 4.5 Amps for our example. When there is no input signal, the output transistor's current must exactly equal the output of the current source. If it does not, then the difference will flow through the speaker. It is allowable (generally speaking) for an absolute maximum of 100 mV DC to be present across the speaker terminals - this equates to 1.67 mW of DC for an 8 Ohm system, assuming a 6 Ohm DC resistance for the voice coil. (Power = (V x V) / Impedance)

This simple model is not really appropriate for general use, since it wastes far too much power, although many Class-A amps still use this principle. The next step is to operate the current source at about 1/2 the speaker's peak current, and modulate its current output to ensure that both current source and power amplifier output device conduct during the entire signal cycle, but are able to vary their current in an appropriate manner. This improves efficiency (which remains dreadful, but slightly less so), and lowers the quiescent dissipation to more manageable levels.

The simple Class-A amplifier described by John L Linsley-Hood and the very similar looking Death of Zen (DoZ) amp on these pages use this latter approach, and it is a sensible variant of the various Class-A designs. As an example, the amplifier will only (?) need to dissipate about 50 Watts when idle, since the quiescent current is reduced to around 1.2 Amps.

Another version of the Class-A amp looks exactly the same as a standard Class-AB (Class-B) power amp, except the quiescent current is increased to just over 1/2 of the peak speaker current. This is thought by some (including me up until I was shown the error of my ways) that this is not a "real" Class-A amplifier. It is real Class-A, and is best described as push-pull (as opposed to single ended) operation. If the bias current is not high enough for the actual reactive speaker load (not some quoted nominal resistive load), it is still possible that one transistor or the other will switch off at some part of the signal cycle. This will happen at a much higher power level than is normally the case, but if this happens, then the amplifier ceases to be true Class-A.

As an extension of the above, it is possible to design an amp that looks remarkably like a conventional Class-AB amp, but with additional circuitry is biased in such a way that the output transistors do not turn off - ever. This technique can also be used with Class-AB, and supposedly reduces crossover distortion. I have not used this method, since in my experience the crossover distortion in a well designed output stage should be sufficiently low that the additional complexity is not warranted.

The last three "variants" cause the current to be modulated in each supply rail, so there is not the steady state current one expects from a Class-A amp, but a waveform that

varies with the signal. When properly designed and biased, the output devices conduct at all times, but the power supply has to contend with a varying load. I have not investigated this fully, but it makes the design of the supply a little more difficult (or simpler in some ways) because of the varying load current. Tests I have performed with the DoZ amp do not show any audible effect on the sound quality - provided the supply is designed to handle the variations without any problems.

Actually, the idea that a Class-A amp draws a continuous steady current from the supply is true *in one case only*. A single ended amp using a current source as the collector load will draw a continuous steady current - but ***only*** if it uses a single supply. In the case of a dual supply, the same amp will draw a continuous current from one supply, and a varying current from the other. (My thanks to Geoff Moss for pointing this out - a detail that few published designs have ever mentioned !)

An amp that uses a fixed current source of (say) 2.5A from the positive supply will draw 2.5A regardless of load or signal level, but only from the positive supply. The negative supply current will vary from 2.5A at no signal, but will be almost zero at maximum positive swing, when the lower transistor is turned off, and the current flows from the current source to the load. At maximum negative signal swing, the negative supply current will be close to double the quiescent current, since the lower transistor now carries the current from both the load *and* the current source.

This "small" detail seems to have received scant reference in any of the articles I have read, but it will make a very big difference to the power supply. In this respect, I do not feel that the single ended version should be operated from a dual supply. If it is so important to you to eliminate the coupling capacitor, then I suggest that either a push-pull Class-A design be used, or build separate power supplies for each polarity.

There is some evidence (I refer again to Doug Self) to indicate that the distortion of a "true" Class-AB amp will often be worse than that of a Class-B design, since the switching transients are larger due to the output devices' higher gain at moderate (0.5A to 1.5A) currents. I have not been able to verify this, and the tests I have done indicate that there are definite benefits in the higher quiescent currents, provided the current is chosen reasonably carefully.

One of the biggest problems with Class-A amps is that the simple power supply used with conventional Class-AB amps is usually no good to us. The reason is that the AC ripple on the DC power rails is injected into the amp, and emerges as hum (at 120 or 100Hz, depending on location - US or elsewhere, respectively). The magnitude of this ripple is far greater than with a Class-AB amp, because a considerable amount of

current is being drawn at all times, rather than during signal peaks (etc). A power supply which provides a no-load ripple of perhaps 50 mV for a Class-AB amp may have 1 Volt (or more) of ripple at a current of 1.2 Amps. This will be audible at low signal levels.

Adding capacitance helps, but by the time the ripple is reduced to a reasonable level, you have sold the car to pay for the capacitors, and no longer have a vehicle to carry them home in. You will need a ridiculous amount of capacitance to obtain reasonable hum levels (> 70dB signal to noise ratio) unless a regulated supply is used. The fact is that many Class-A power amps do not have particularly good power supply rejection (Ok, it is not generally too bad, but cannot compete with the likes of an operational amplifier), and a regulated power supply is recommended for all such amps. In case you were wondering, that does indeed mean that you need more transistors, more heatsinks, and it will cost more money. Such is the price we pay for perfection.

There is an alternative (which I have not tried for this application, but have carried out numerous spice simulations) called a capacitance multiplier, which is simpler and cheaper than a regulated supply, but should be capable of reducing the ripple to very low levels. I have had a few e-mails from readers who have built the capacitance multiplier project (see the Projects page), and the results have been very positive, so this makes the Class-A idea far more attractive from a cost and heat perspective. (Capacitance multipliers are not required to regulate, so operate with a much lower input to output differential voltage - therefore, less heat!) Indeed, the design by John Linsley-Hood referenced on these pages uses a capacitance multiplier, although its performance can be improved dramatically.

- John L Linsley-Hood's Class-A amplifier design
- Simple Capacitance Multiplier Power Supply

Decisions, Decisions

The question now is - is this *really* what I want to do? The answer might be a resounding **yes** (after all, there is no good reason that a Class-AB amp cannot be just as good) - but to be sensible, we should apply the Class-A amp for the tweeters in the system, and use conventional Class-AB amps for the low and mid frequencies. To obtain adequate sound pressure levels, most modern speakers need lots of power, since they are not very efficient (i.e. electrical power in versus acoustical power out).

Rather than extend this page to a short text book on the subject, I shall leave you with a

simplified model, which I produced for a reader who had a speaker system which was even less efficient than is common. The table shows the power needed to achieve various peak SPLs (at one metre) for a speaker with an efficiency of 85dB/m/W.

Based on the sensitivity of these speakers, the following shows roughly what you can expect, based on a single amplifier for clarity (i.e. not bi-amped or tri-amped):

dB SPL at 1 metre	Amp Power, Watts, one channel
85	1
88	2
91	4
94	8
97	16
100	32
103	64
106	128
109	256
112	512

Table 2 - Power Vs. SPL

This is not good news for the most part, as it clearly shows that vast amounts of power are needed to achieve a realistic SPL in a typical listening environment. Remember that the figures shown are at a distance of only one metre - the SPL will fall by a further 6dB each time the distance is doubled. (Mind you this is a theoretical figure, which is generally not met in practice - perhaps 5dB would be closer to the truth?)

Realistic SPL in this context is worthy of a page (book?) in itself, but remember that for an average SPL of (say) 85dB, transients will require between 10 and 20dB of headroom. This means that the peak power needed will be between 10 and 100 times the power needed to reproduce the average of 85 dB. At a distance of 2 metres, something around 3 Watts will be needed for this example. To reproduce the transients, the actual power needed must be between 30 and 300 Watts!

In case you were wondering, 85dB SPL is not loud (although "s/he who must be obeyed" will almost certainly disagree). In fact, it is only marginally louder (by about 5dB) than the recognised optimum level for normal speech.

Class-A Benefits

Since Class-A amps are inefficient, generate lots of heat, and require a far more complex power supply than conventional Class-AB amplifiers, there have to be some compelling reasons to use this arrangement. The first is circuit simplicity. In the light of the above discussion, the circuit is not simple, but for the audio signal it can be far less complex than for a conventional power amp.

The benefit of this is that the signal is subjected to comparatively little amplification, resulting in an open loop (i.e. without feedback) gain which is generally fairly low - probably less than 250 (48dB), and possibly as low as 50 or so (34dB). This means that very little overall feedback is used, so stability and phase should be excellent over the audio frequencies. A well designed Class-A amplifier should not require any frequency compensation (or very little), so the open loop gain will remain reasonably constant over the audio range. This results in superior transient response, and dramatically reduced "Transient Intermodulation Distortion" (or TID, aka Dynamic Intermodulation Distortion), which is thought by many designers to be caused by phase and time delays between the input and feedback signals. It may be possible that this is the cause, although the existence of TID is virtually zero in any competently designed amp.

The simple fact is that the more amplifying devices that are introduced into the chain, the more phase shift must be introduced. No amplifying device is capable of responding instantaneously to a change of input - all have some inherent delay (which usually includes different turn-on and turn-off times). With fewer devices in the audio circuit, there must be less delay between a change in the input causing a change in the output. The simplified topology used for most Class-A amps can also be used with Class-AB - often with very good results indeed.

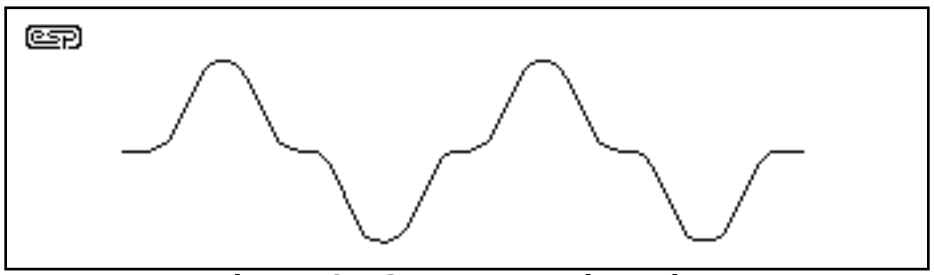

Figure 3 - Crossover Distortion

Figure 3 shows the crossover distortion of a Class-B type amplifier. This is exaggerated for clarity, and the "soft" crossover distortion shown is actually more typical of a push-pull valve (vacuum tube) or lateral MOSFET amplifier (without proper bias adjustment). As can be seen, when the signal is reduced, the ratio of distortion to signal will become

much worse, resulting in an increase in distortion as power is reduced. Indeed, this is exactly what happens in many amplifiers, but it generally is "swamped" by so much feedback that it seems to disappear. It can be seen from the diagram that for this crossover distortion to appear, the amplifier's gain must fall as the signal level approaches 0 Volts.

The point that distortion "seems to disappear" is the operative term here - it does not go away at all, and worse, as the crossover point is reached, the open loop gain of the amplifier is reduced, meaning that there is not as much feedback as at higher signal levels. This will be apparent to readers with an electronics background - note that near the crossover point, the amplitude of the signal is much lower than it should be (this is what causes the problem in the first place!). Since the amplitude is reduced, it is obvious that the amplifier's gain must be lower at this level than at higher levels.

Therefore, if the open loop gain is lower, then the available feedback must also be lower. This is an area that has received some study, and this is illustrated by the very 'flat' gain vs. collector current curves of many of the more desirable audio output transistors. It is certainly a cause for some concern, and indicates that the open loop behaviour of a power amp should minimise crossover distortion before any feedback is added. Simply increasing the quiescent current is not always a complete answer, because this problem is created by the inherent non-linearity of the output devices as they commence (or cease) conduction. Increasing quiescent current will move the "kink" further away from the 0 Volt point, but it will still be there - and may actually be worse than at lower quiescent currents. A major advantage is that the distortion components will be (potentially) somewhat less audible, and will affect the signal while it is comparatively loud - this will reduce its audibility further.

I bagged MOSFETs earlier in this article because they are actually more non-linear in this region than transistors. Since this is the most critical part of the signal, it is important that it is treated with the utmost respect.

This does not mean that MOSFETs are not capable of exemplary performance. A carefully designed MOSFET amp will sound every bit as good as a bipolar amp, whether it is operated in Class-A or Class-AB.

In the light of this, it is a wonder that any Class-AB (conventional) power amplifiers sound any good at all. Historically, it is exactly the problems I have highlighted here which created the term "transistor sound" (used in a derogatory sense of course) when transistor or "solid state" amplifiers first appeared. Despite anything you may read, these problems are caused by the physical and electrical characteristics of transistors, and have never gone away. New devices are far more linear than those of the 60s and 70s,

but they are not perfect. Operation at higher quiescent currents (i.e. more into the Class-AB region) will reduce the non-linearity at crossover, but it can never be eliminated altogether - at least not with any devices currently available.

It is fair to say that although the problem cannot be eliminated, the effects can be reduced to such an extent that many amplifiers have almost unmeasurably small levels of crossover distortion. It is not at all uncommon that to be able to see the distortion residual (after the fundamental has been removed with a distortion analyser), it is necessary to use a digital oscilloscope that can apply averaging. The distortion is buried below the amplifier noise floor, and is not visible without the averaging feature. In tests I have performed, listening to the residual noise + distortion reveals that the distortion component (in isolation) is barely audible over the system noise - itself normally below audibility with typical loudspeakers.

So, it is entirely possible to design an amplifier whose distortion at any level below clipping is virtually unmeasurable. Marginally higher levels are commonplace, and it is thought by many that the typical distortion level in most well designed power amplifiers is inaudible under most listening conditions. There are (of course) others who deny this - either because they have done proper comparisons under controlled conditions, because they have hearing that is far more acute than most of us, or because they have been told that they *must* be able to hear the difference - if they can't, they must have 'tin ears'. Nothing like a bit of peer group pressure to influence one's perceptions.

Where does this leave Class-A? There is an emotional connection with the idea of a Class-A amp, and it has to be considered that sometimes there is simply a 'feel good' aspect to this - technicalities don't even enter into it. Despite my own ambivalence, I was still a bit disappointed in my decision not to use P36 for my own tweeters - and this in spite of the fact that I could hear no difference between the P36 and the high quality power opamp which I *am* using for my tweeters.

Because the transistors in a Class-A amplifier are never switched off, there is obviously no crossover distortion (after all, there is no crossover - where one transistor turns off, and the other supplies the load current). There is distortion though - it is caused by all the normal non-linearities in any active device, and in particular the wide current variation in the output device (in combination with elevated temperature). It is worth noting that crossover distortion is exactly the same as clipping distortion, but with a different phase with respect to the signal. Consequently, it contributes odd harmonics (as does clipping) - 3rd, 5th, 7th, etc.

If properly designed, a Class-A amplifier should be capable of a maximum open-loop

distortion of perhaps 5% at full power, reducing as the input signal (and hence output power) is lowered. This distortion is believed to be predominantly 2nd harmonic, which (in moderation) is far less intrusive than the odd-order distortion created by conventional push-pull Class-AB amplifiers, however this may not be the case. In contrast, most common Class-AB amps will have an open loop distortion of perhaps 10% to 15% at full power, although some will be much lower.

Such amps typically rely on global feedback to reduce this distortion, and usually have very high open loop gains. Another problem is that the open-loop gain is not constant with frequency, so the amount of feedback applied is reduced at the higher frequencies - not at all what is really needed. However, it *does not* mean that all such amplifiers are unlistenable - despite claims to the contrary.

For additional comment on Class-A, the "Death of Zen" (DoZ) article may be an interesting read.

Class-A Myth #1
A Class-A amp maintains the same current through the transistors, therefore ensuring that they remain in their most linear region at all times.

This is *not* the case at all - the current varies widely in the output device in the case of a current source amplifier, and it varies widely in *both* output transistors for other types of Class-A amp. While it is possible to make the current reasonably constant, it is neither practical nor sensible to do so.

Class Comparison

As often happens when writing, I suddenly decided that I just had to run a simulation on a pair of output stages. One is Class-AB (essentially the same as that used in Project 3A) and a Class-A emitter follower circuit. Both were operated with zero feedback, and the Class-AB stage was run at a quiescent current of 14mA vs. 2A for the Class-A circuit.

Rather than make this article longer than necessary, if you want to see the details see Class-A Part 2

Conclusion

Class-A is the most desirable of the amplifier configurations from a purist point of view, but is not suited to high power systems unless outrageous power dissipation is

acceptable (like between 825 to 1500 Watts of pure heat, to get 300 Watts of audio). However, if used for the high frequency amplifier in a tri-amplified system, it is possible to obtain the SPL you desire in your listening room, but without having to install a dedicated air-conditioning system to remove the heat generated.

When used for the frequency range of 3000Hz and above, comparatively little power will be needed, and the sonic benefits should be readily apparent - crystal clean highs, without any harsh distortion components. The distortion generated may be (but is not necessarily) predominantly 2nd harmonic, and will be greatest at high power levels where it is least likely to be audible. Bear in mind though, that a great many Class-AB amplifiers will be capable of performance that is just as good, and in a lot of cases, far better.

Class-A Myth #2

Class-A amps give predominantly 2nd order distortion.

They might, or they might not, depending entirely on the topology. A great many Class-A amps will produce distortion components that are almost identical to those produced by a Class-AB amp. This excludes clipping distortion, which should be avoided in *any* class of amplifier used for high quality audio.

An Alternative?

Where it is not feasible (economically or otherwise) to use a Class-A amp in the tweeter frequency range, a modified Class-AB amp could be used. The modification needed is to increase the quiescent current (to perhaps 1 Amp or so) so that the amplifier operates as Class-A for any signal below about 8 Watts - assuming a well behaved 8 ohm load such as a tweeter. Such a modification to an existing amp is quite simple for an experienced electronics engineer or service person, but will almost certainly require that the heatsinks be upgraded to prevent the destruction of the output devices. It is also probable that additional capacitors will be needed for the power supply - and possibly a regulator or capacitance multiplier circuit, too. Without these, the hum level may become intrusive, which rather negates the whole purpose of the exercise. Some basic experimentation is required for anyone thinking along these lines.

Bear in mind that you can say a fond farewell to any warranty which may exist on your amp - few manufacturers will accept that ripping their product to pieces and rebuilding it as something "new" is a perfectly reasonable thing to do.

Despite the cost of modifying an amp in this way, it is bound to be cheaper than buying

or building a Class-A amp from scratch - even more so if you have a perfectly good (but underpowered) amp just lying about waiting to be put to use. For not a lot of work and relatively few dollars, a potentially fine amplifier can be yours.

Warning

Please be aware that the above section is more in the line of "musings" than established fact with full testing. The theory is (more or less) sound, but one cannot predict the exact behaviour of any amp once modified, and I suggest that if any such mods are to be attempted, they should be done with "before and after" measurements to allow proper comparison. Operation at a higher than normal quiescent current may actually degrade performance with some amplifiers.

1.0 - Introduction

Although it is recognised that a power amplifier should never be subjected to (overload) clipping, it is equally well recognised that it will happen at some stage. This article will explain how different amplifiers have different characteristics in this area, and the explanations that follow may go some way to showing how some amps *can* sound very different from others when subjected to overload.

First, we need to know what overload clipping actually is. An amplifier is said to be clipping when the output signal attempts to exceed the supply voltage. Since the supply voltage defines the absolute maximum peak output voltage from the amp, the signal will

be clipped or 'cut off' if the input signal level is too high. For normal testing purposes, a sinewave is the most common test signal used, but this only tells part of the story.

A great deal of normal programme material is asymmetrical - it has peaks in one direction that are not duplicated in the other. Because of the signal processing used in the recording chain (including the microphone), the signal always has an effective long term DC level of zero volts, and no normal audio recorder or reproducer is expected to be able to handle a DC voltage. Short term deviations from the zero volts DC level are not uncommon, but can hardly be called 'DC' unless they are of long enough duration to cause a subsonic (in this case less than 1Hz) level shift.

Since it is very rare indeed that anything is recorded below about 16Hz, there is no apparent need for any reproducer to go any lower than that. The reality is that preamps and power amps will often have a -3dB frequency that is much lower than expected, with figures as low as 1Hz being common. I normally aim for around 7Hz in my designs, but even there you may find exceptions.

The following article applies to amplifiers used in any audio application - hi-fi, studio monitoring, professional sound reinforcement systems (live sound PA), or general purpose public address as used in buildings. Each application will present its own set of problems - the amplifier may be driving loudspeakers directly (multi-amping), or there may be transformers involved (electrostatic loudspeakers or building PA systems). In some cases tweeters and midrange drivers will be protected by series capacitance, while in other cases they may also be at risk from DC or very low frequency signals.

2.0 - Description

Within The Audio Pages, you will find several descriptions of amplifier overload, clipping recovery times, and various other associated topics (including Why do Tweeters Blow). This article concentrates on something very different, and a specific part of the topic that is not well covered elsewhere. In this case, it is the behaviour of the amplifier when clipping is asymmetrical - not because of the amplifier, but because of the applied signal.

Figure 2.1 shows the amplifier used for these simulations - there is a remarkable similarity to the P3A, however 'ideal' current sources were used where appropriate. This does not change anything in the simulations. Any amplifier from any manufacturer will do exactly the same given the test conditions described below. The behaviour described is not a function of the amplifier topology, only a function of the DC response. Valve (tube) amplifiers may generally be excluded - with reservations (see Conclusion

below).

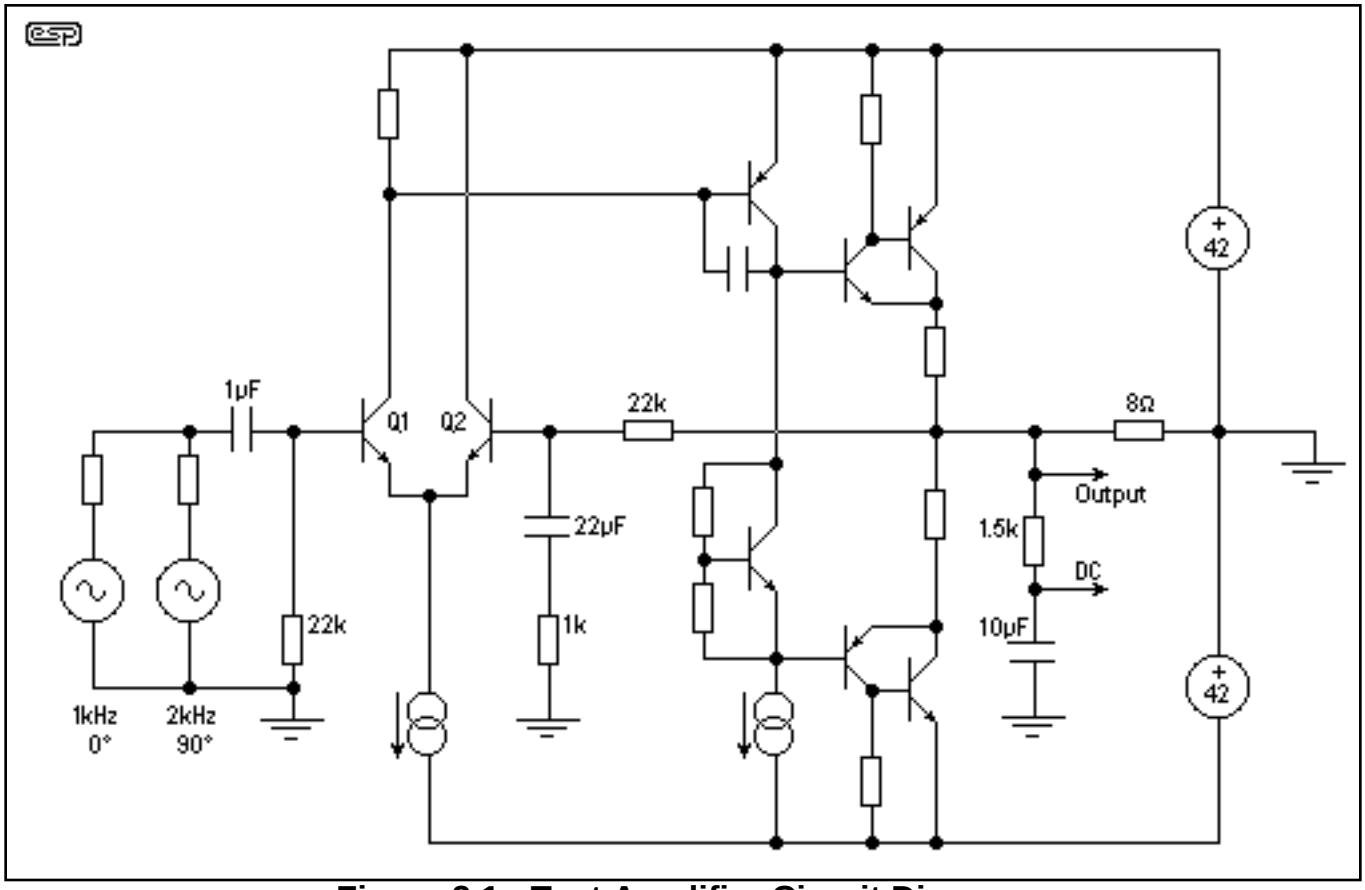

Figure 2.1 - Test Amplifier Circuit Diagram

The important parts of the above diagram are the input coupling cap and resistor, the feedback resistors and capacitor, and the final filter network used to isolate the DC component of the signal. It may also be said that the simulations that follow are by no means the 'worst case' ... any real signal may have far greater effect than that shown.

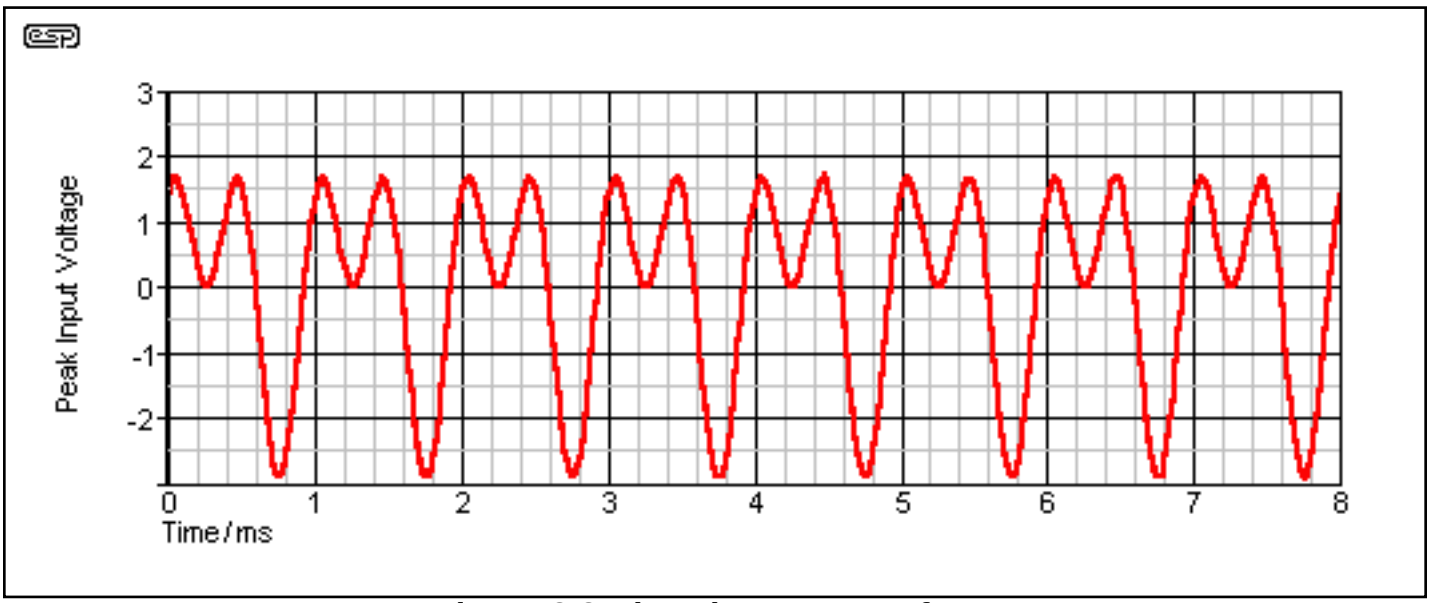

Figure 2.2 - (Raw) Input Waveform

The composite input signal is made up of a 3V peak-to-peak sinewave at 1kHz, added to a 2kHz 3V P-P sinewave whose phase is shifted by 90° to obtain an asymmetrical waveform that has a peak amplitude that is almost twice as great in the negative direction as in the positive direction. The DC component of this waveform is zero - the area of waveform above the zero volt line exactly equals that below, so the net DC must be zero (the simulator claims 3.15mV, but this is insignificant, and is simply the result of the simulator sampling rate).

The input waveform shown above is a bit nasty from the simulator's perspective, so a small delay was introduced to ensure that the signal started at exactly zero Volts. This can be seen in the displays below, where there is a 916.6us gap at the beginning to ensure that the input to the amplifier commenced at the 0V level. To do otherwise skews the results and makes it look a lot worse than it really is. It is also unrealistic, since no music signal can start from other than a zero reference voltage.

Before we continue, it is important to understand just *how* clipping the waveform can introduce a DC voltage. First, look at the basic waveform details (two complete cycles are shown), both before and after it is clipped ...

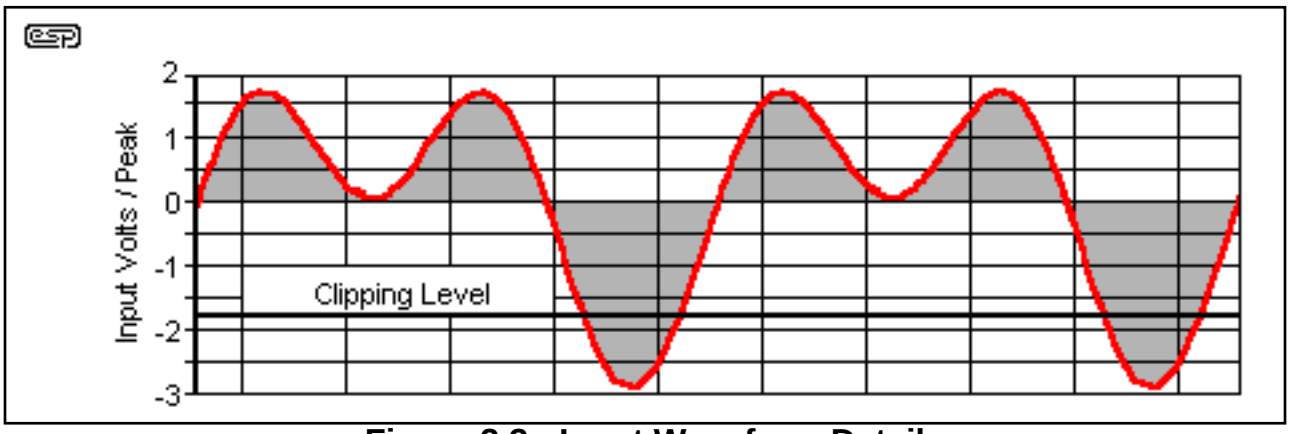

Figure 2.3 - Input Waveform Detail

The total shaded area shows that the area above the zero volt line is exactly equal to the area below, therefore, the signal is perfectly balanced and there is no DC at all. When the amplifier chops off (clips) the section below the line marked 'Clipping Level', the two areas are no longer the same - the area in the lower part of the waveform is smaller because some of it has been removed when the amplifier overloads. Since the upper (positive) section of the waveform now has more area than the lower (negative) section, the overall waveform has a positive bias - this is seen as a DC voltage. No tricks, no special effects, just plain old physics at its most basic level.

Note: - Although it may not *appear* to be the case that the areas above and below the zero volt line are equal, any apparent deviation is the result of conversion of the waveform to an image suitable for publication. Even so, you are welcome to count the pixels if you wish - you will find that the two sections are remarkably similar.

Any amplifier that has full gain at DC will present this instantaneous DC level to the loudspeaker, but it will be shown that an amp that does not extend to DC will eventually average out the DC component, reducing it to a subsonic signal with peak levels that are (hopefully) non-damaging to the loudspeaker. What is *not* shown is the recovery time (after the amplifier stops clipping), where it is understood that a non DC amplifier will produce a subsonic signal that has an equivalent amplitude but opposite polarity of that created when the clipping was present. I shall leave this as an exercise for the reader.

In all descriptions that follow, it is assumed that the amplifier is driving the loudspeaker directly (not using a passive crossover network). While the caps in a passive crossover will save the mid and tweeter drivers from being subjected to the DC, the woofer will still be affected, *regardless of the frequency that clips*.

2.1 - Test Results

Referring to the schematic above, the 1uF capacitor is the input cap. This ensures that any DC applied to the input cannot be amplified, and protects the speakers from DC introduced by the preamp or signal source. The -3dB frequency of the input cap and associated 22k resistor is 7.2Hz.

The 22uF cap is the feedback capacitor - when in place, the amp's gain will also be 3dB down at 7.2Hz. This capacitor ensures that the amplifier can have a maximum gain of unity for a DC input (including offset from the input long-tailed pair). With both capacitors in place, the -3dB frequency is 11Hz, and is about 1dB down at 20Hz.

Note that in the diagrams below, the charts only show the response obtained out to 20ms, but measurements were taken to 100ms of the waveform. The relatively slow rise of the DC component of the output is caused by the integrating filter (1.5k resistor and 10uF capacitor), but this was essential so that the DC levels could be seen easily. In all cases, the red trace shows the clipped output signal, and the green trace shows the DC component of the output. The clipping is easily seen - the bottom of the waveform is flat, and no longer looks like the input signal shown in Figure 2.2.

AC Coupled - When the amp is completely AC coupled (having the input cap and the

feedback cap installed), the clipping waveform shows that the peak DC voltage across the loudspeaker is 1.93V at 20ms, rapidly falling to 540mV at 100ms. While this is not especially desirable, it is considerably better than the alternatives that follow. The AC coupling throughout ensures that significant DC levels can never appear across the voicecoil for any appreciable period of time.

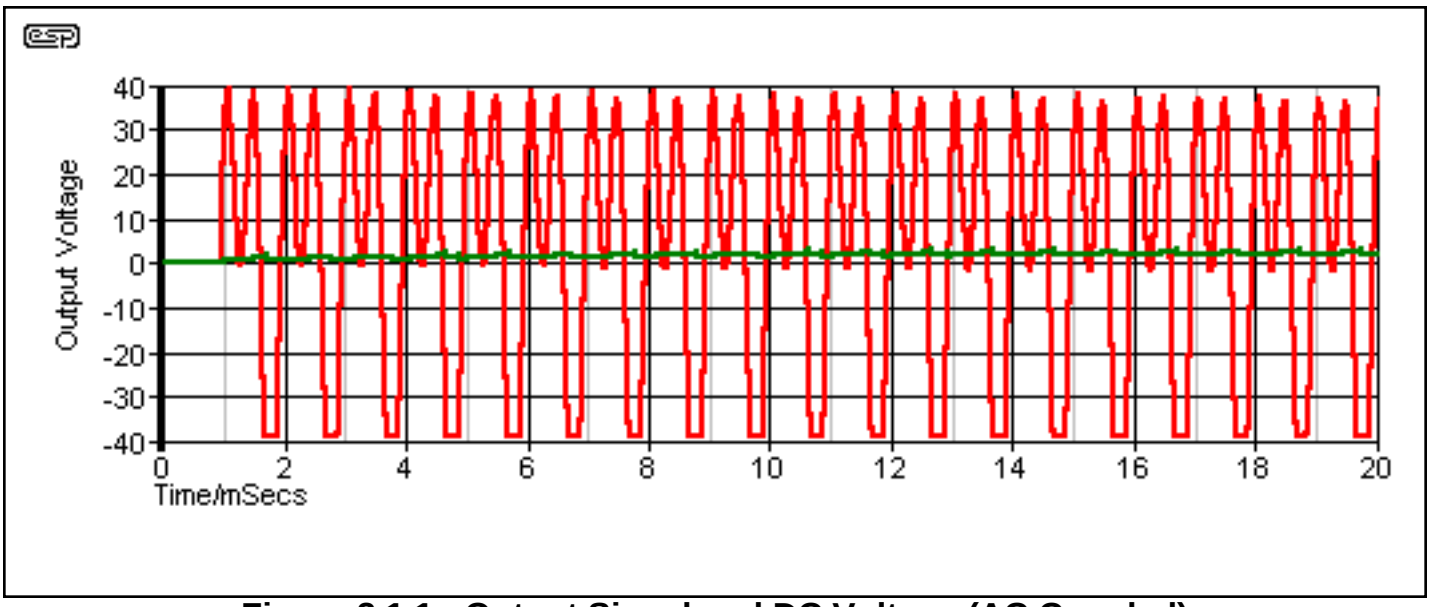

Figure 2.1.1 - Output Signal and DC Voltage (AC Coupled)

With the above, we can expect to see the cone move a little when the signal is first applied at a level sufficient to cause the degree of clipping shown. It will quickly settle back to normal, and the audible effect will be that of a slightly clipped signal only.

AC Coupled (Input Only) - Leaving the input capacitor in place and removing (shorting out) the feedback capacitor, the amplifier is now DC coupled from the input stage onwards. After 20ms, there is 2.7V DC output, rising to 3.8V at 100ms. Note that making the amplifier responsive to DC ensures that there *will* be DC applied to the loudspeaker if the amp is allowed to clip - even briefly.

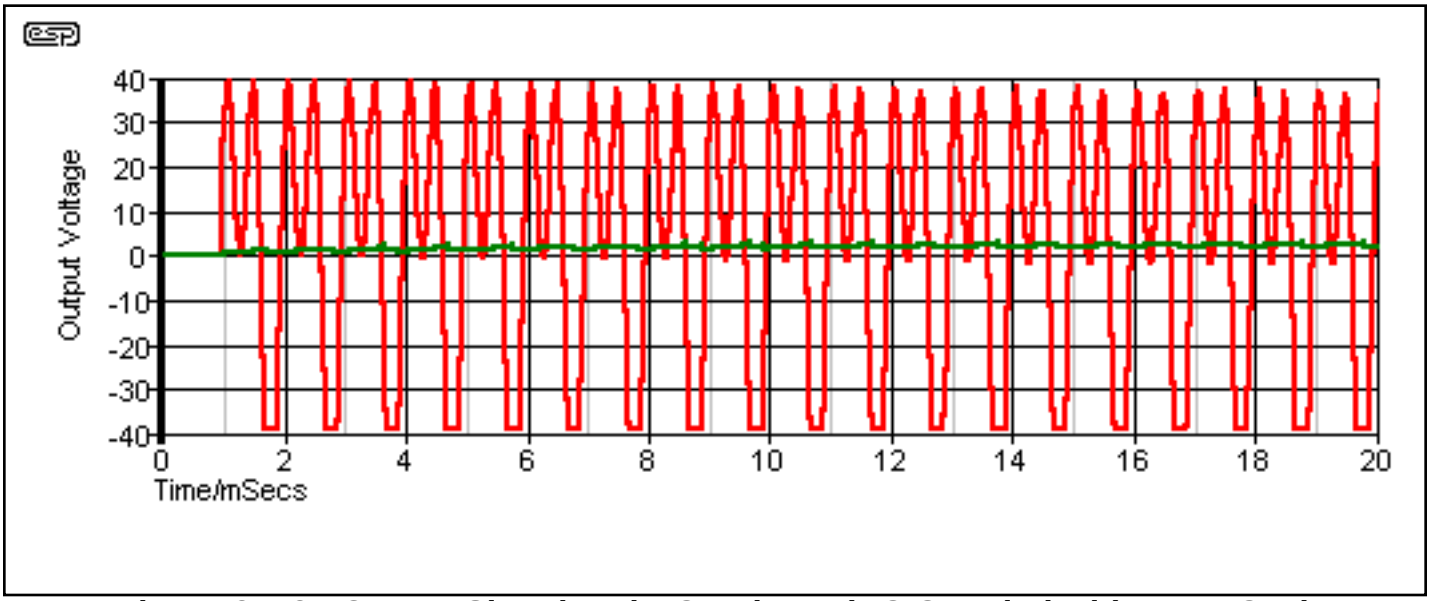

Figure 2.1.2 - Output Signal and DC Voltage (DC Coupled with Input Cap)

In this case, when the signal is applied and the amplifier clips, the cone will be seen to move (outwards if polarity is normal). While nearly 4V DC will cause a problem with a woofer, the effect with a direct coupled midrange (having relatively little cone excursion and using an active crossover) will be a disaster. You can expect the loudspeaker to distort badly - adding to the distortion already created by the amplifier. To explain the reason that using only an input cap will alleviate the problem marginally (compared to the fully DC coupled case) requires a brief explanation ...

When an amplifier clips, it is no longer a linear system for the duration of the clipping, and the feedback circuit is inoperable. The input stage is also no longer linear, and a small amount of rectification of the input signal takes place. *This changes the voltage at the base of the input transistor.* In the case shown above, the average voltage on the base of the input transistor (Q1) changed from around -32mV at idle, to -34mV after 20ms and -35mV after 100ms - nowhere near enough to correct the problem, but noticeable nonetheless. Be aware that this will not occur with all amp input stage topologies - some will never rectify the signal, regardless of input level or output distortion. As is to be expected, the average DC voltage at the base of the feedback transistor (Q2) follows that of the output, but attenuated by the ratio of the feedback resistors (voltage gain at all frequencies is 23).

DC Coupled - With a completely DC coupled amplifier (having neither the input cap nor the feedback cap), the situation is made even worse. The effective DC voltage presented to the loudspeaker load is 3.5V after 20ms, rising to 4.4V at 100ms. Although the voltage with this waveform will not get a great deal worse than measured, there are some waveforms that can easily impress up to 15V DC onto the voicecoil - this is likely to push the coil so far out of the gap that gross intermodulation distortion will occur in the

loudspeaker, adding to the harmonics generated by the amplifier clipping.

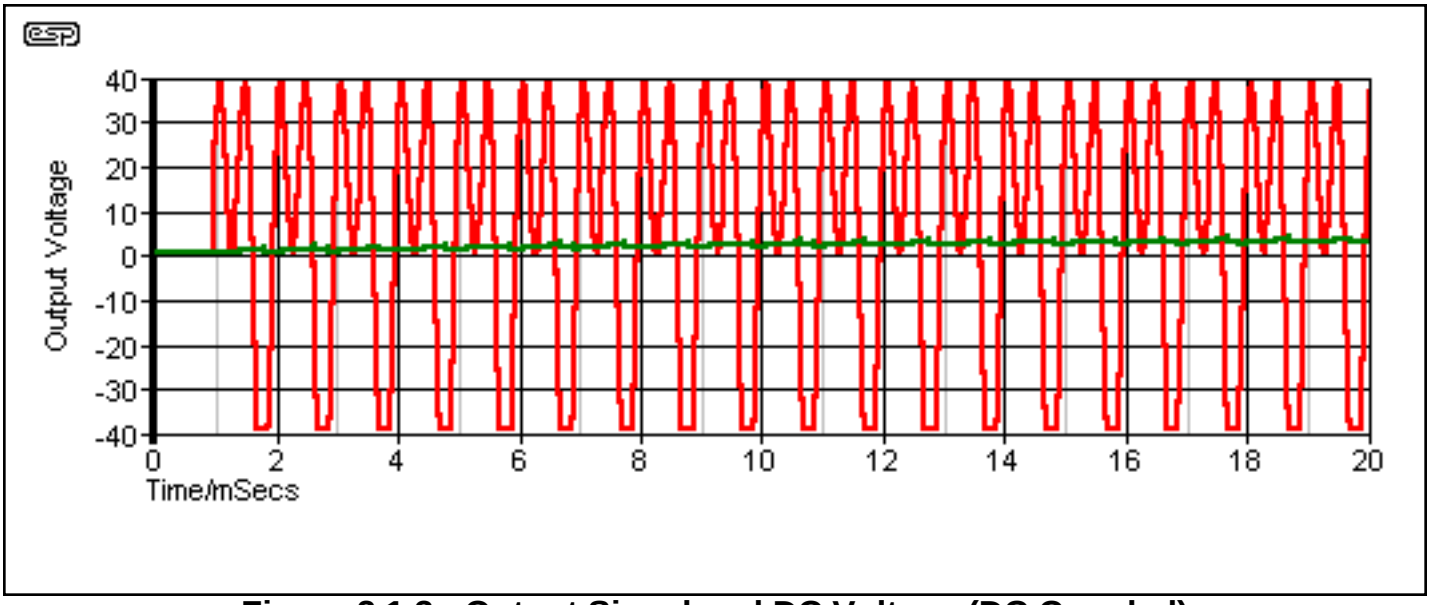

Figure 2.1.3 - Output Signal and DC Voltage (DC Coupled)

This is obviously the worst possible scenario - loudspeaker distortion will be very high indeed, and it is doubtful that even woofers (including long-throw subs) will be able to cope. This is especially true if the waveform is less 'friendly' than the one used for these simulations.

2.2 - Sources of Asymmetrical Waveforms

Most people probably tend to think that their music signal is relatively symmetrical, and this is usually true when averaged out over a long period (perhaps 30 seconds or more). However, there are a great many sources of asymmetry within the programme material itself, and these include ...

- Human voice (spoken or singing)
- Wind instruments (flute, horns, reed instruments, etc.)
- Plucked and struck stringed instruments (guitar, harp, piano, bass, etc.)

This list is not extensive, but covers the major 'culprits' - there are obviously many others such as drums of all kinds, synthesisers or other electronic sources, and not all notes or tones will be asymmetrical. In fact, any instrument may be symmetrical or asymmetrical depending on how it is played, the note being played, specific fingering techniques, etc. The averaging effects of a large orchestral ensemble will tend to create an overall symmetrical waveform in the long term, but there are many periods where a solo of any instrument will be not only highly asymmetrical, but made louder in the mix to even out

the sound level (compression).

Suffice to say that in any given piece of recorded music, it is almost a given that there will be periods of sufficient level and asymmetry to cause the problems indicated above if the amplifier is overdriven - the polarity of the asymmetry will vary as well, and often even within a relatively short period.

Any amplifier that is driven to even mild clipping will show the effects described, depending on whether it is AC or DC coupled. DC servo systems will not be fast enough to remove the DC component - these are usually made with rather long time constants to prevent the servo from interacting with the music material, and may actually make matters worse with some signals.

The signal I used for these simulations is relatively benign - there are a great many signals that could be used that would give far more dramatic results, but I elected to use a reasonably realistic signal without pushing the limits. In reality, the signal I used is reasonably typical, but of course there will be signals that are a great deal worse (either by accident or design).

2.3 - Other Issues

Apart from the possibility of the DC component causing gross loudspeaker distortion, in extreme cases it may also cause the amplifier's DC protection circuitry to operate. I have heard of some amplifiers that 'solve' this problem by setting a high detection threshold for their DC detection circuitry - it may be as high as 20V for a high powered amplifier. While this prevents 'false tripping' of the protection circuit, it also reduces the level of protection offered.

Given the right (or wrong) signal and sufficient clipping, there is the real risk that a loudspeaker driver may even be damaged. The voicecoil may be slammed into the rear polepiece of the magnetic circuit, suspensions may be stretched and the assembly's alignment compromised. This will lead to eventual driver failure.

While so far I have only mentioned conventional cone loudspeakers, the situation is made a great deal worse if there is a transformer used at the amplifier output - either to drive an Electrostatic Loudspeaker (ESL) or a 70V or 100V public address distribution system. In either of these cases, the DC that flows in the low resistance primary winding of the transformer may even cause amplifier failure, not to mention gross distortion (again) because of transformer core saturation.

3.0 - Conclusion

There is no doubt that a clipped asymmetrical waveform will generate a DC component in the output of an amplifier. There is equally no doubt (as evidenced above) that a fully DC coupled power amp is the worst possible case. Since there is no requirement whatsoever for an audio amplifier to reproduce DC, it follows that designs that are fully DC coupled are of no benefit to the listener, and indeed may cause far greater problems than they are supposed to 'solve' (according to those who insist that DC reproduction is somehow 'better').

Wherever possible, amplifiers should never be allowed to clip - this much is well known to anyone who is interested in quality reproduction. That it very likely will happen at some point is also accepted - parties in particular being the worst offenders. For those who use relatively small (i.e. low powered) amplifiers as a matter of course, the risk is greater, although the DC voltages so created are also reduced because of the lower overall supply voltage.

For those who prefer valve (tube) amplifiers, they are only partially immune from this problem. Since transformers cannot pass DC by their very nature, the DC cannot get to the voicecoil. There is still the real risk that distortion will increase dramatically if an asymmetrical waveform causes amp clipping, since it is now the output transformer that takes the burden of the DC ... this may cause core saturation. The problem will be worse with push-pull amplifiers, and their distortion could easily rise to the levels commonly found in single-ended designs.

To what extent have the effects described here influenced reviewers (who typically never use any instrumentation, and usually never know if the amp under test is clipping or not)? I have no idea, but it is not unreasonable to assume that some degree of clipping *must* be experienced from time to time, and that *will* affect the outcome of a subjective test ... but with absolutely no technical detail to indicate the actual cause of the problem should it exist. Reviewer-speak will obfuscate the real issue(s), and the lack of instrumentation leaves us in the dark.

Finally, it must be pointed out that this shows that clipping with real-world (speech or music) signals creates not only the harmonics that have been described in innumerable web pages, but also generates a subsonic signal that is potentially very damaging to drivers, but is never mentioned. This signal has the capability to cause driver damage at worst, or unwanted cone modulation and additional loudspeaker distortion at best -

neither can be considered a desirable outcome.

The moral of the story is to avoid clipping at all times - even momentary (supposedly inaudible) clipping will generate an unwanted low frequency or subsonic signal whose frequency will be completely unrelated to anything in the programme material.

4.0 - Acknowledgments & References

There is really only one primary reference that is pertinent to the facts here, and I was alerted to it by a contributor (who has also had some direct conversations with me on the subject). I considered the topic both interesting and important enough to put this information together, in the hope that disinformation and incorrect data elsewhere may be dispelled. The effect is real, is easily measured or simulated, and should be far better known than seems to be the case at present. To see the debate that started it all, go to ... alt.audio.pro.live-sound

To obtain an understanding of other effects that asymmetrical waveforms can influence (and also showing a waveform vastly more asymmetrical that the one I used here), see Allpass Networks in a speech chain by James L. Tonne.

1.0 - Introduction

Claims abound regarding how bad negative feedback is, how it ruins the sound, and how zero feedback amplifiers with comparatively vast amounts of distortion sound so much better with music. Entire papers have been written on the topic, new methods described to quantify the audibility of different harmonics, and new measurement techniques are suggested and described ad nauseum.

Of those papers, articles and semi-advertisements, many make completely incorrect assumptions as to how feedback actually functions in an amplifier, and some extrapolate these false assumptions to arrive at a completely non-sensical final outcome. Before continuing, we need to clear up one very important point ...

> Feedback does not - repeat *does not*- cause the signal to travel from the output, back into the inverting input, and continue through the amplifier several (or multiple) times. By not doing so, it does not (and can not) create additional harmonics that did not exist before the feedback was applied.

Feel free to re-read the last statement as many times as you need to. This is a claim that has been made on numerous occasions, and it is simply false. The whole idea of feedback is that it is as close as possible to instantaneous - feedback is applied to the input of an amplifier in direct proportion to the signal at the output, and for all intents and purposes at *exactly* the same time. (This means that the amplifier must be fast enough to keep up with the input signal at all times.)

Once you have grasped the logic of how feedback actually works (as opposed to the way some people think it works), you are a long way towards understanding that many of the evils attributed to feedback are due to a lack of understanding, and have nothing to do with feedback itself. It has been claimed that applying feedback can actually increase the levels of higher order harmonics [1], however, this claim does not stand up to scrutiny. It is reasonable to expect that measurement errors or flawed assumptions are almost certainly the cause of this 'problem', but some parts of the industry will never let the truth get in the way of a good story.

For the majority of the tests described, the effects were simulated rather than measured. There are some very good reasons for this, with the primary reason being that the simulator has access to 'ideal' amplifiers. These have infinite bandwidth, infinite input impedance, zero distortion and zero output impedance. Being perfect, they also contribute zero noise. This enables one to perform experiments that simply cannot be done in the real world, and provide a level of accuracy that is also unattainable using real circuits. Likewise, the signal sources have zero distortion, so resolution exceeds anything attainable using actual circuitry.

---

2 - What *Is* Distortion?

It is useful to understand what distortion is, and how it is produced. The generation of harmonics is not a weird function of a valve, transistor or MOSFET, but is a physics phenomenon that occurs whenever a waveform is not a pure sinewave. A pure tone contains only one frequency - the fundamental. By definition, this pure tone is a sinewave - no other waveform satisfies the criterion for purity. As soon as a sinewave is modified, the waveform that now exists is created by adding harmonics. Likewise, anything that adds harmonics changes the waveform - the two

are inextricably intertwined. Amplifying devices do not add harmonics per se! Amplifying devices modify the waveshape, and this *requires* that harmonics are added to create the 'new' waveform. The creation of harmonics is a physics requirement, and has nothing (directly) to do with the type of device that caused the modification to the waveform. Devices with high linearity modify the sinewave less than devices with lower linearity, so fewer harmonics are created in the process.

Because the sinewave is a pure tone, it has long been used as a measure of the amount of non-linearity for amplifying devices. Even very small wave shape modifications can cause a large amount of distortion (and hence harmonic generation), and it is for this reason that sinewave THD (total harmonic distortion) tests are still used. Despite many claims to the contrary, a sinewave is not an 'easy' test - quite the reverse. Less than 1% distortion of a sinewave is easily heard (depending on the exact type of distortion), while it may be completely inaudible with some music or barely audible with others. Any device that amplifies will also distort, and the purity or otherwise of the output signal shows non-linearities very clearly. Interpretation of the test results does take some background knowledge though, and simply quoting a percentage with no qualifying parameters is completely useless.

Strictly speaking, simply turning a sinewave on or off causes distortion, because a truly pure tone is not only without harmonics, but has existed (and will continue to exist) for eternity. While this is real, no-one will ever take it to that extreme.

Because of the nature of a non-linear device which modifies the waveshape and thus causes the creation of harmonics, it should be obvious that it is not the amplifying device that generates the harmonics directly - it *only* modifies the waveshape. The harmonics are the result of the modified waveform - nothing more. To explain how a device modifies the waveform it is necessary only to look at the device's transfer function, and understand the process of amplification.

Amplification is an (almost) instantaneous process. An amplifier does not 'see' a complex waveform any more than we can experience all of last week simultaneously. As the Compact Disk medium has demonstrated, time can be separated into discrete fragments, and digital data can be derived that describes the instantaneous voltage at that point in time. This process is repeated 44,100 times each second. Compared to an analogue amplifier, this is very slow. The analogue domain does not use time fragments - all processing is done on a continuous basis - *but*, the amplifier is only capable of processing one instantaneous voltage level at any one time. The input voltage is a moving target, and the output signal follows it as closely as possible.

If an amplifying device has a gain of 10 when its (instantaneous) input voltage is 100mV, the output voltage will be 1V. If the device is non-linear, then the gain may fall to 9.5 when the input voltage is 1V, so the output will be 9.5V instead of 10V. This is distortion! That's it! The amplifying device does nothing more than change its gain slightly depending on the amplitude of voltage or current it has to deal with at any value of input voltage.

2.1 - How a Transistor Causes Distortion

Let's look at a common bipolar transistor as an example. The primary (but by no means only) form of distortion is caused by the internal emitter resistance of the transistor. Figure 1 shows a simple single transistor amplifier. A bias resistor is shown - it must be pointed out that this biasing method is never used in practice, because it is too dependent on device gain, temperature and supply voltage. Proper biasing that allows for thermal effects, device parameter spread, etc. is beyond the scope of this article.

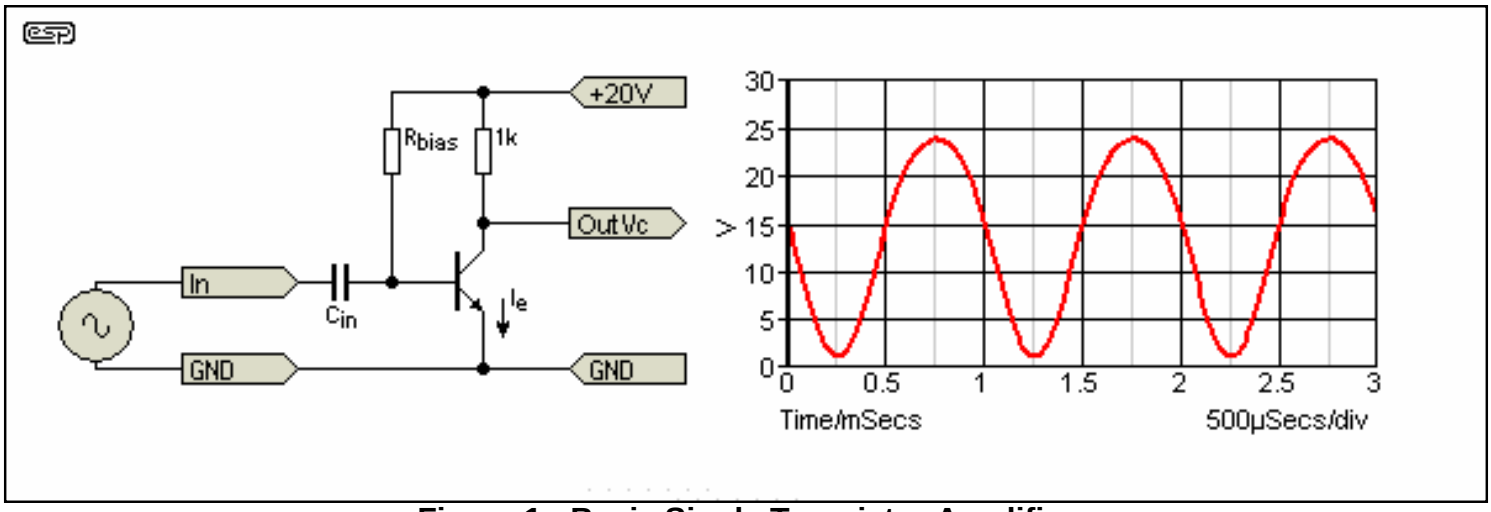

Figure 1 - Basic Single Transistor Amplifier

This is a very basic amplifier, but it embodies all the issues that face other amplifying devices as well - valves, JFETs and MOSFETs all have similar non-linearities, but for different reasons. It just happens that with a transistor it is easy to describe in simple terms. The output waveform is also shown, and distortion measures 12%, being second (-18.5dB), third (-52dB) and fourth (-56dB) harmonics. All others are over 90dB below the fundamental. It is generally taken that ...

re = 26 / Ie (mA) where re is the internal emitter resistance and Ie is the emitter current

The gain is determined by the ratio of the collector resistance to the emitter resistance, and is approximately ...

Av = Rc / (Re + re) where Av is voltage amplification, Rc is collector resistance, Re is external emitter resistance, and re as above

Re (the external emitter resistance) has not been included in the circuit of Figure 1, which has a gain of about 390. As we shall see, this varies over the output voltage range, so the measured value gives a false impression because of waveform modifications. Table 1 shows how much the circuit of Figure 1 will vary the emitter current and hence the (theoretical) gain, depending on signal level. The base current has been ignored, but this also has an influence - albeit rather small.

Vc (Volts)	Ie (mA)	re (Ohms)	Voltage Gain
29	1	26	38
25	5	5.20	192
21	9	2.89	346
17	3	2.00	500
13	17	1.53	654
9	21	1.24	807
5	25	1.04	962
1	29	0.89	1115

Table 1 - Gain Variation of Figure 1 Circuit

You can see from the table how the waveform of Figure 1 comes about. When the collector voltage is high, the gain is lower, and the waveform is flattened. When the collector voltage is low, the gain is much higher, so the waveform becomes elongated. As is obvious, the gain varies over a wide range, and any waveform applied to the base must become distorted. Transistors show a logarithmic response when the base to emitter junction is driven from a voltage source, and table 1 shows this effect quite clearly.

Because the transfer function is non-linear, it must alter the wave shape. If the wave shape is altered, harmonics are produced. To reduce distortion (of all forms), the application of negative feedback will make the amplifier more linear, and this results in fewer harmonics. There is no mystery and no magic. It doesn't matter if the feedback is global (applied around a complete circuit) or local (applied to each device individually). In general, global feedback gives better results than local feedback, but only if the amplifier has high open loop gain (i.e. gain without feedback).

Prior to adding feedback, it is advantageous to improve the circuit's linearity by other means if possible. Since the gain of a transistor varies widely with emitter current, maintaining a constant current (via the collector) will help. Since transistors are current controlled, using a variable current for the input will also help - distortion can be halved by this alone, but voltage gain is reduced. In the case of the above circuit, using a 15mA constant current source instead of the 1k resistor increases the voltage gain to 3227, and reduces distortion to 4% - using current input (via a series resistor) reduces gain, but also reduces distortion even further.

The additional gain from the use of a current source load allows us to apply feedback - if the gain is set at 400 (close enough to the 390 measured before), distortion is reduced to 0.7%. The second harmonic is now -43dB, the third is -70dB and fourth is at -95dB (all with respect to the fundamental). Compare these figures with those obtained for the circuit as shown - no comparison! This is covered in more detail in Section 6.

Alternatively, *Re* (the external emitter resistance) can be added to create 'local feedback'. By

adding an external resistor, we actually do nothing more than (partially) swamp the variation of *re* with emitter current. While this makes the circuit more linear, it is not really feedback at all - the correct term is degeneration. Gain variation (and hence distortion) is reduced because *Re* + *re* is much greater than just *re* alone and base current is also more linear, but one of the benefits that feedback (as opposed to emitter degeneration) gives is reduced output impedance. Emitter, cathode or source degeneration does not lower output impedance.

2.2 - Historical Perspective

There is a great deal of information that was compiled a long time ago that seems to have been forgotten, dismissed, or simply neglected. Of particular interest is the section on distortion in the Radiotron Designer's Handbook [2]. Since some (many) of the detractors of negative feedback advocate single ended triode operation, one would expect that they would have examined what was considered 'high fidelity' back in 1957, rather than claim that amplifiers that were considered low fidelity back then represent high fidelity today. This is not a tenable position!

Of some interest is a table of harmonics based on a fundamental of C - taken for convenience as 250Hz. The table is reproduced below. It shows the musical relationship of each harmonic up to the 25th with respect to the fundamental, based on the natural or just musical scale (as opposed to the equally tempered scale that is used for most instrument tuning).

Harmonic	Frequency	Note	Comment
1st	250	C	Fundamental
2nd	500	C^1	
3rd	750	G	
4th	1000	C^2	
5th	1250	E	
6th	1500	G	
7th	1750	-	Dissonant
8th	2000	C^3	
9th	2250	D	
10th	2500	E	
11th	2750	-	Dissonant
12th	3000	G	
13th	3250	-	Dissonant
14th	3500	-	Dissonant
15th	3750	B	
16th	4000	C^4	
17th	4250	-	Dissonant

18th	4500	D	
19th	4750	-	Dissonant
20th	5000	E	
21st	5250	-	Dissonant
22nd	5500	-	Dissonant
23rd	5750	-	Dissonant
24th	6000	G	
25th	6250	G#	Dissonant

Table 2 - Harmonic Distortion on the Musical Scale

Obviously, harmonic distortion that extends to the 7th or beyond is to be avoided. It is (or was) well known to guitar amp manufacturers that the seventh harmonic should not be reproduced if possible (even during overdrive conditions) because of just this issue - discordant (or dissonant) harmonics simply don't sound nice.

Another table shows the levels of distortion that were considered objectionable, tolerable and perceptible for various frequency limits and triode or pentode valves. This table is also reproduced, but I have only included the 15kHz results - other bandwidths were listed, but no-one would consider a bandwidth of 3750Hz acceptable these days.

Source	**Mode**	**Distortion**	**Comments**
Music	Triode	2.5%	Objectionable
	Pentode	2.0%	
Speech	Triode	4.4%	
	Pentode	3.0%	
Music	Triode	1.8%	Tolerable
	Pentode	1.35%	
Speech	Triode	2.8%	
	Pentode	1.9%	
Music	Triode	0.75%	Perceptible
	Pentode	0.7%	
Speech	Triode	0.9%	
	Pentode	0.9%	

Table 3 - Comparative Distortion Tests (Olson)

These figures are interesting compared to amplifiers of today. Both triode and pentode amplifiers used in the test had an output of 3W, and were conducted in a 'typical' listening environment. While modern (competent) transistor amps will invariably beat the distortion criteria by a wide margin (at any level or frequency), modern SET amps seem to be considerably worse than one would hope, many having distortion that rates as objectionable -

and this table was compiled was a very long time ago indeed.

For those who have access to the complete text of the Designer's Handbook (or at least Chapter 14 which concentrates on fidelity and distortion) I strongly recommend that it be read in its entirety. There is a great deal more to it than I have the space to reproduce here, and the fundamental principles have not really changed, despite the passing of the decades since it was written.

There is an informative section covering intermodulation distortion, in which it is pointed out that there is no direct correlation between THD and IMD. It is also pointed out that no actual amplifier has *only* second or third harmonic distortion - every form of distortion is accompanied by multiple harmonics, although either second or third harmonics can be the most dominant.

3.0 - Principle of Negative Feedback

Negative feedback (or just feedback) has been used for many years to linearise amplifiers. Between 1935 and 1937, Harold Black of AT&T received three U.S. patents relating to his work on the problem of reducing distortion in amplifiers by means of negative feedback. The invention caused little controversy for many years, but eventually this happy situation had to end - at least in the hi-fi industry. Feedback is used extensively in medical, military, aerospace and industrial applications and seems not to cause any problems there, despite its bad reputation amongst some audiophiles.

Although many of the early attempts were less than perfect, it must be understood that the results without the feedback would have been many times worse. Negative feedback cannot make a dreadful amplifier sound good, but may make it sound acceptable. There is no possibility that the use of feedback will make a good amplifier sound bad. Not only are distortion components reduced, but negative feedback also increases the input impedance, reduces output impedance, and linearises frequency response. It is not a panacea, but it does come very close.

So, let us examine what feedback really does. Figure 2 shows the basics of a gain block - in this case, an operational amplifier (opamp). It may be comprised of any number of devices, and the active components can be valves (tubes), transistors, FETs, MOSFETs or any combination thereof. The gain block will be assumed to have infinite gain and infinite bandwidth for the initial analysis - we all know this is not possible, but it makes understanding the principle easier.

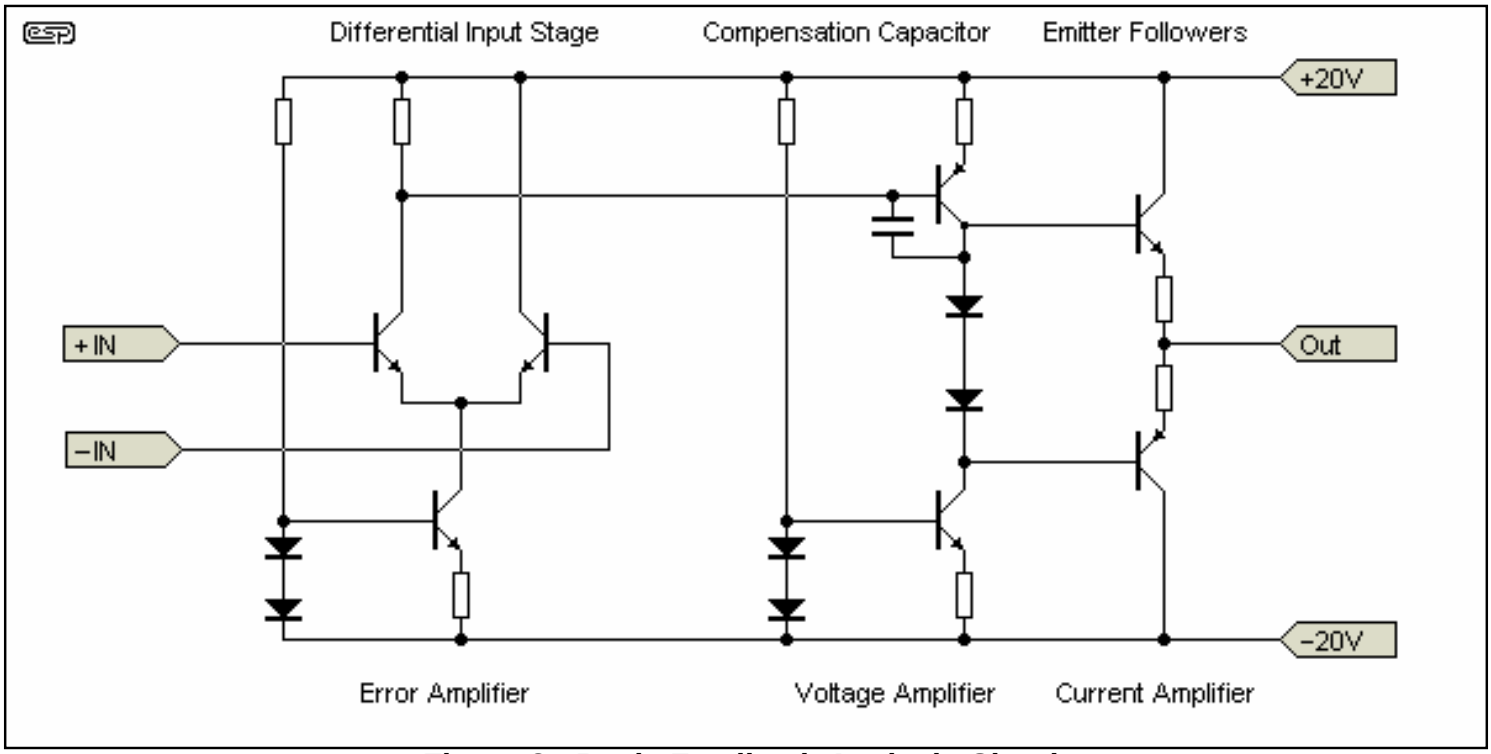

Figure 2 - Basic Feedback Analysis Circuit

An amplifier (power amplifier of conventional topology, opamp, etc), consists of three discrete stages. These are ...

1. Error amplifier (commonly referred to as the input stage)
2. Voltage amplifier stage (VAS)
3. Current amplifier (output stage)

Each of these may be as simple or complex as desired or needed, and each can use a different technology. The functions of each stage are (or will become) self explanatory, and a quick look at any of the project amplifiers (e.g. P101, P3A, etc.) will show that the same basic stages are used in most amplifiers.

If you have read the article Designing With Opamps, you will know the two rules of opamps (a typical semiconductor power amplifier may be thought of as an opamp for all intents and purposes). These rules are ...

1. An opamp will attempt to make both inputs exactly the same voltage (via the feedback path)
2. If it cannot do so, the output will assume the polarity of the most positive input

In any linear circuit, rule #2 is inapplicable unless there is a fault or overload condition, so only rule #1 needs be considered for this discussion. As shown below, a voltage of 1V is applied to the non-inverting input - the normal input for an audio amplifier. I will state at the outset that only one thing is important - the value of the voltage presented. We need not concern ourselves with frequency - indeed, time is utterly inconsequential.

Referring to the practical circuit shown in Figure 9, in order to fulfil rule #1, the amplifier's output voltage must be exactly 11V. This figure is simply derived from the voltage divider formula ...

$V_{out} = V_{in} * (R1 / R2 + 1)$ Where V_{out} is the voltage at the -ve input and V_{in} is the voltage at the amplifier output

Therefore, at the inverting input we should measure ...

$V_{-in} = 11 / (10k / 1k + 1) = 11 / 11 = 1V$

The first rule is satisfied, and the system is stable. The error amplifier is the critical element here. If the input voltage changes, the error amplifier simply detects that its two inputs are no longer the same, so commands the VAS to correct the output until equilibrium is restored. This is *not* an iterative process, which is to say that the amplifier does not keep feeding the input signal (meaning a significant part of the input waveform) into the inverting input to be re-amplified, re-distorted and re-compared. This is where some of those who criticise negative feedback have made their first error.

The output of the amplifier simply keeps changing in the appropriate direction until the error amp detects that the voltages are again identical, at which point the output of the error amp ideally just stops where it is, and so does the rest of the chain. In reality, there will be a small amount of instantaneous correction as the two voltages approach equality, but this *must* happen much faster than the input signal can change with normal programme material.

The fact that the correction is usually done well before the input voltage has even changed significantly clearly means that no part of the feedback signal is fed through the amplifier over and over again - that just doesn't happen. In our ideal device, the change is instant, in a real device it is possible to measure the time it takes for the correction to be made. For an audio amplifier, the correction must be completed faster than the highest frequency of interest can change - how much faster is open to some conjecture, and that will be looked at later in this article.

All amplifying devices have some distortion. Desirable though it may be, a distortion free amplifier doesn't exist - other than in a simulator. Some opamps come very close (with feedback), but inherent non-linearities within the amplification chain are inevitable. Without feedback, the distortion components tend to be low order (i.e. second, third, fourth, etc., with diminishing amplitudes as the order increases. The application of negative feedback reduces the amplitude of these harmonics (hence the term harmonic distortion), in direct proportion to the amount of feedback applied.

A common claim is that, because the feedback signal is re-amplified, the distortion components

are subjected to additional distortion. This supposedly creates high order harmonics that did not exist as a result of the original distortion mechanism in the amplifier. Since the feedback acts as an ultra-high-speed servo system, it is difficult to imagine why it is assumed that high-order harmonics are 'generated'. They are not generated at all, but simply become more easily measured because all the lower harmonic clutter is removed (in part at least).

Also notable is that *any* signal that is created within the feedback loop (most commonly noise) is also cancelled by global feedback. Because this generates signals that did not exist at the input, the error amplifier 'sees' any such extraneous signal as a deviation from the input signal, and cancels it to the best of its abilities. Note that input device noise is *not* cancelled, because the error amplifier cannot differentiate between noise it has created and the input signal.

That this works was amply demonstrated many years ago when the only cheap opamp was the venerable uA741 and a few others of similar noise performance. These are (still) notoriously noisy, so many designers added an external input stage using low noise transistors. This addition reduced the noise to acceptable levels, even for sensitive high-gain amplifiers as used for phono preamps and tape head amplifiers. The external transistors formed the error amplifier, and being low noise types were able to cancel out much of the opamp's internally generated noise - the additional gain also improved distortion performance.

This ability of the feedback loop to cancel internally generated signals (be it noise or distortion products) is so critical to your understanding of feedback that I have included a circuit and simulation results. These probably show more clearly than any other method how feedback works to remove anything that is not in the original input signal, by using the error amplifier to correct the output by applying an 'anti-distortion' component to the amplification stages within the feedback loop.

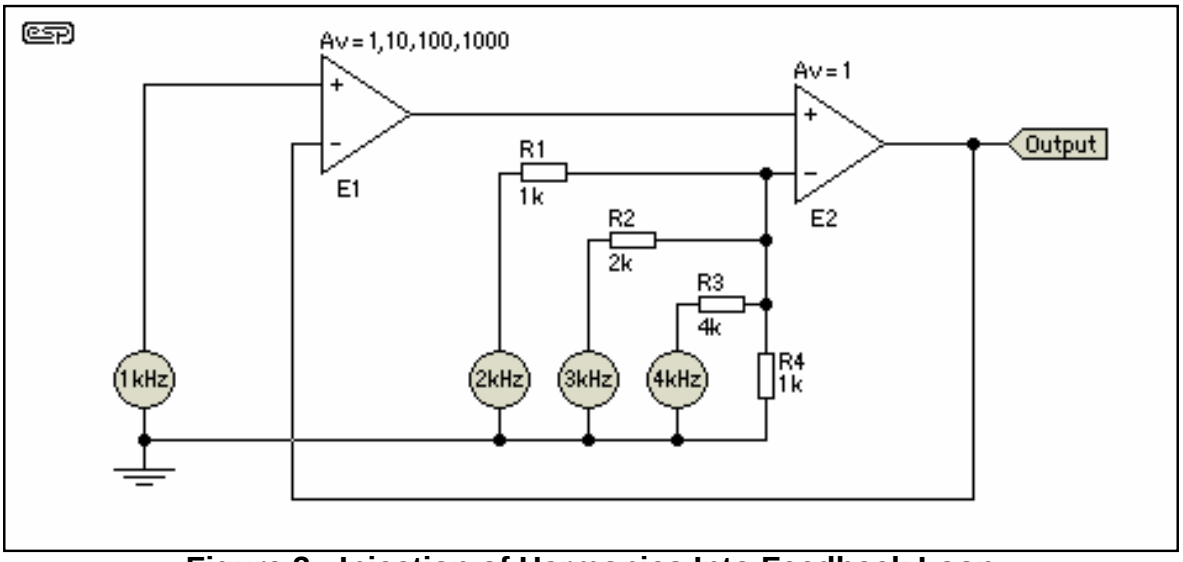

Figure 3 - Injection of Harmonics Into Feedback Loop

All signal sources have the frequency indicated, and all are set for an output of 1V peak (707mV RMS). Because of the simulator, there is no concern with frequency drift, so the distortion

waveform will remain the same - this test can be run easily with real opamps, but attempting any harmonic relationship is pointless because the frequencies will drift. If you have access to synchronised oscillators it's not a problem, but I don't, and I doubt many others will either.

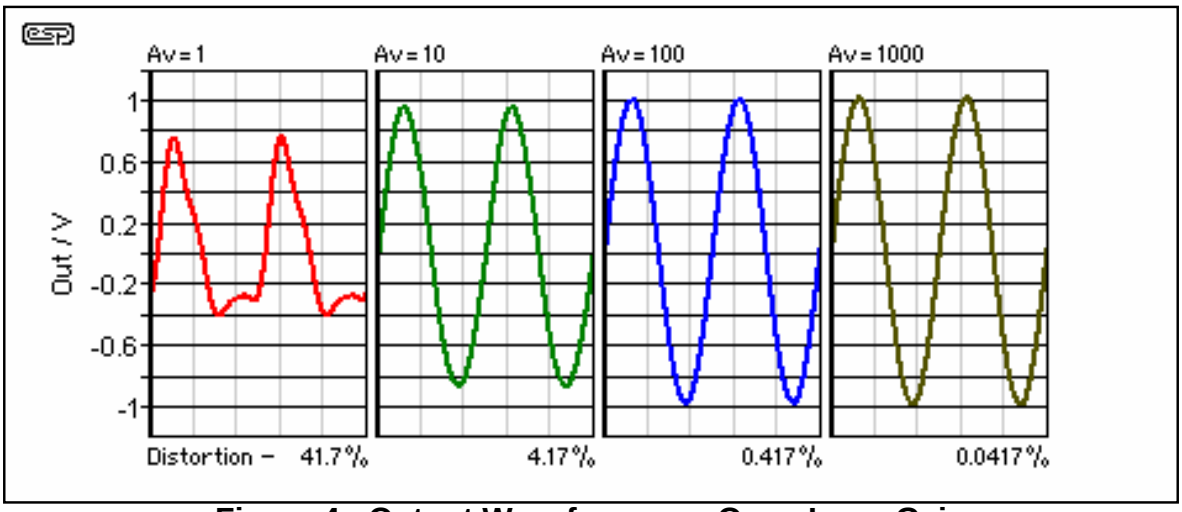

Figure 4 - Output Waveforms vs. Open Loop Gain

The first waveform is with E1 set for unity gain. There is some degeneration, but no feedback. If the feedback loop is disconnected, the waveform remains the same, but at a higher amplitude. As gain is increased (only the gain of the first stage (error amplifier) is changed), the distortion is reduced in direct proportion to the error amplifier's gain. There is no point reproducing a spectrum for this test, as the relationships are fixed by the 2, 3 and 4kHz signal sources. Only the total amplitude of the 'harmonics' is reduced with respect to the fundamental.

Although the circuit shown is configured as a unity gain buffer, adding feedback resistors to give the circuit gain makes no difference to its ability to remove the injected harmonics. To verify this, the error amp was set to a gain of 10, and the gain of the whole stage was increased to 10 by means of a 9k resistor from output to inverting input, and 1k from inverting input to ground. There was a significant gain error (Av = 5 rather than 10 as set by the resistors), but the rejection of the extraneous signals was just as effective.

Likewise when the error amp's gain was 100 (Av = 9.09) and 1000 (Av = 9.9). This is normal behaviour for an opamp - the open loop gain ideally needs to be 1,000 times greater than the required gain to achieve gain accuracy of 0.1%. While interesting and useful to know, that is not relevant to this article.

The above circuit will work with opamps too. Voltage controlled voltage sources are convenient in the simulator because their gain can be changed where one has no control over the open loop gain of an opamp, and some changes are needed to make a 'real' opamp work. However, the same distortion reduction is clearly evident.

3.1 - Oh No, Not a Water Analogy!

Sorry, but yes . A negative feedback system may be thought of as a servo, but that won't help anyone who is not familiar with servos. A toilet cistern is another matter - everyone has seen one, although not everyone has looked inside. I encourage you to do so . The cistern is a good example of a simple negative feedback system. Unlike an amplifier (which is bipolar - it can generate positive and negative output voltages), a cistern is more like a regulated power supply - these also use negative feedback to maintain a stable voltage.

When water is let out of a cistern, the water level falls, and this in turn opens a valve. The water is replaced until such time as the level is restored to its original preset level. If water is allowed to escape at a low (but variable) rate, the float valve (ball cock) will regulate the water level perfectly, maintaining the same level even as you allow more or less water to escape. This is a simple example of negative feedback at work in your bathroom. For expedience, I have neglected the uncertainties of the mechanical linkages and valves (as well as the inertia of the water itself), but you knew that already.

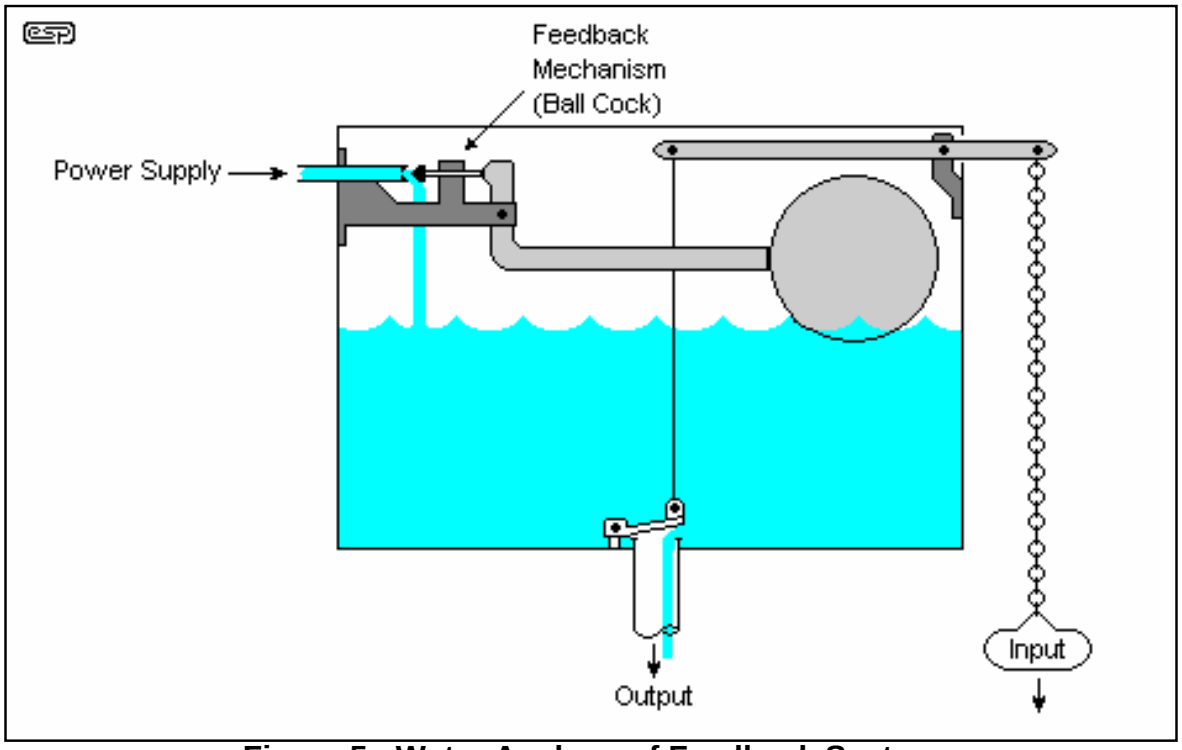

Figure 5 - Water Analogy of Feedback System

Should the water be allowed to escape faster than it can be replenished, the system is in an overload condition. This is no different from an amplifier where the input signal changes faster than the output - the system cannot keep up, so the output is 'distorted'. I am unsure if this will help, but if it does improve your understanding of negative feedback, then it was worth it.

For those in Australia, be aware that the above analogy cannot be used because our water reserves are too small to allow the luxury of playing with water. We will just have to imagine that it works .

4.0 - Distortion Analysis

So, having established that the output signal is not re-amplified over and over again instantly removes one of the criticisms of negative feedback - that it creates frequencies that didn't exist before feedback was added. Since there is no re-amplification of the signal, there can be no new frequencies created, other than the distortion of the waveform caused by device non-linearity. Figure 6 shows a simulation circuit, using a diode to create distortion [3]. The distorted signal is enclosed within the feedback loop (Feedback) of a pair of VCVS (voltage controlled voltage sources - 'perfect' amplifiers in the world of the simulator). A second circuit (Open Loop) applies the same distortion, but simply amplifies the distorted signal to obtain the same RMS voltage. C1 and C2 provide DC blocking to remove the diode's forward voltage.

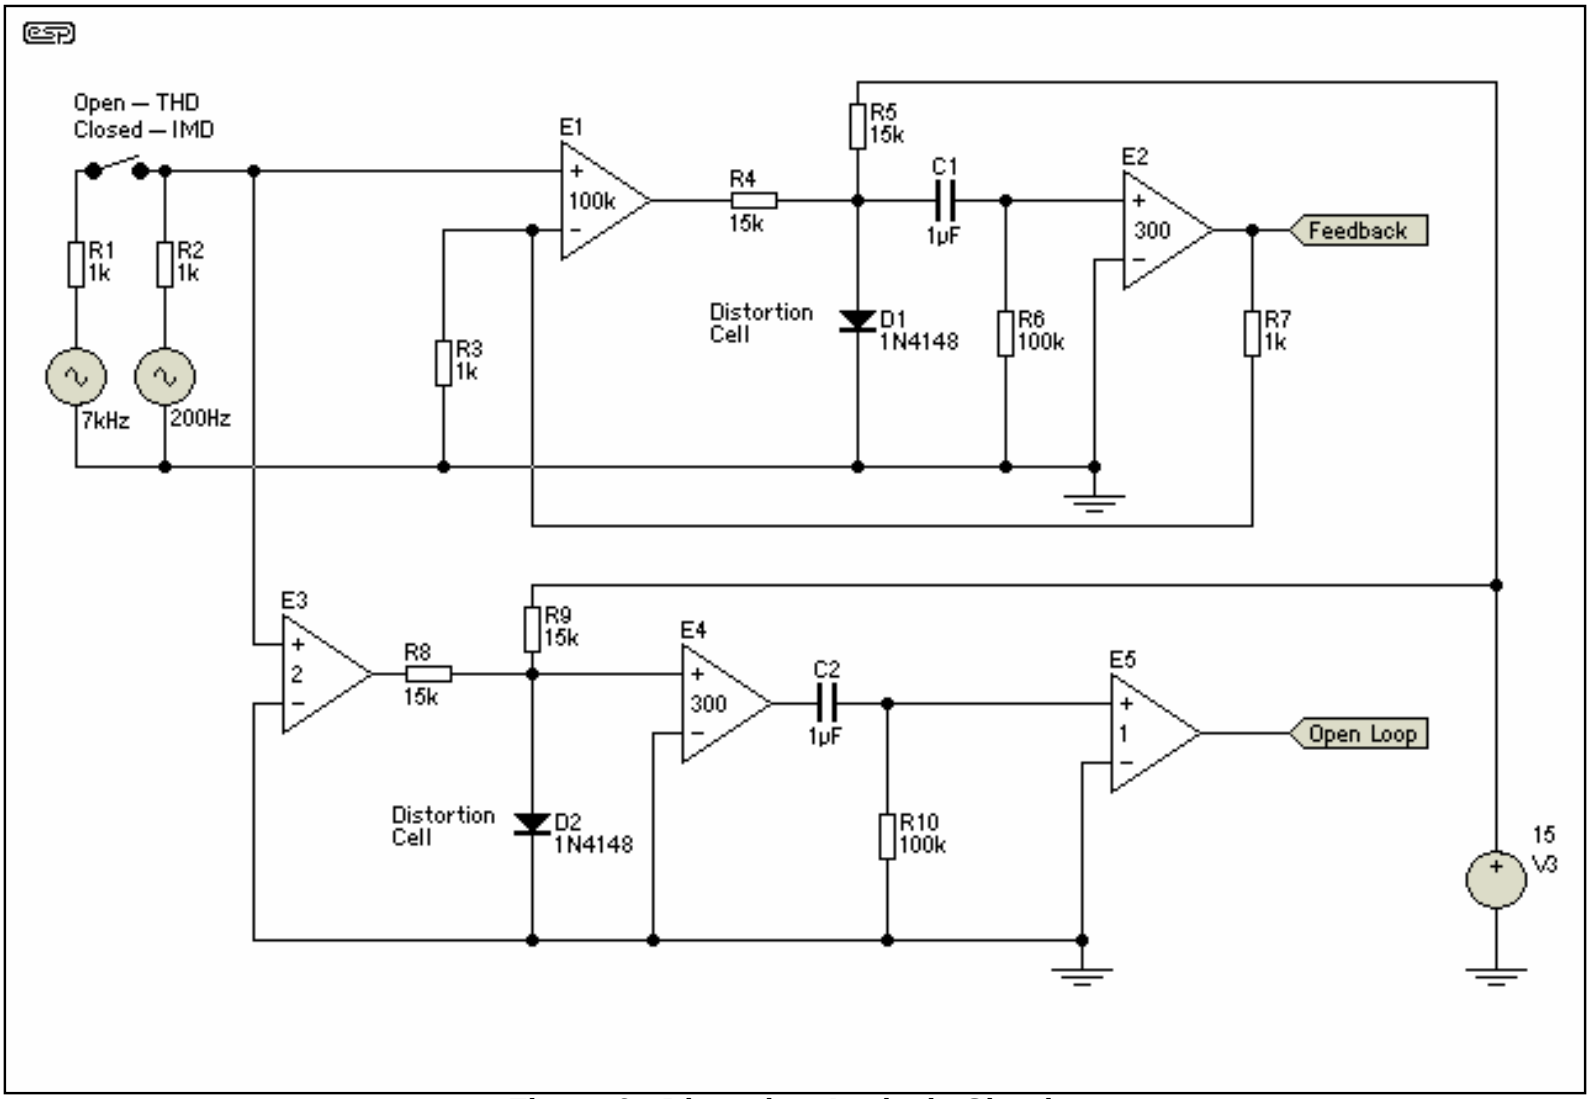

Figure 6 - Distortion Analysis Circuits

The applied input signal is 2V peak at 200Hz + 500mV peak at 7kHz, so we can see both harmonic and intermodulation products as generated by the non-linear element - a forward biased diode, passing ~15mA. This attenuates the signal greatly, and applies a controlled amount of distortion, measuring at 8.5% for a single frequency. In each case (feedback and open loop) the input voltage to the distortion cell was maintained at as close as practicable to

the same level, although quite wide variations do not cause significant changes to the distortion level.

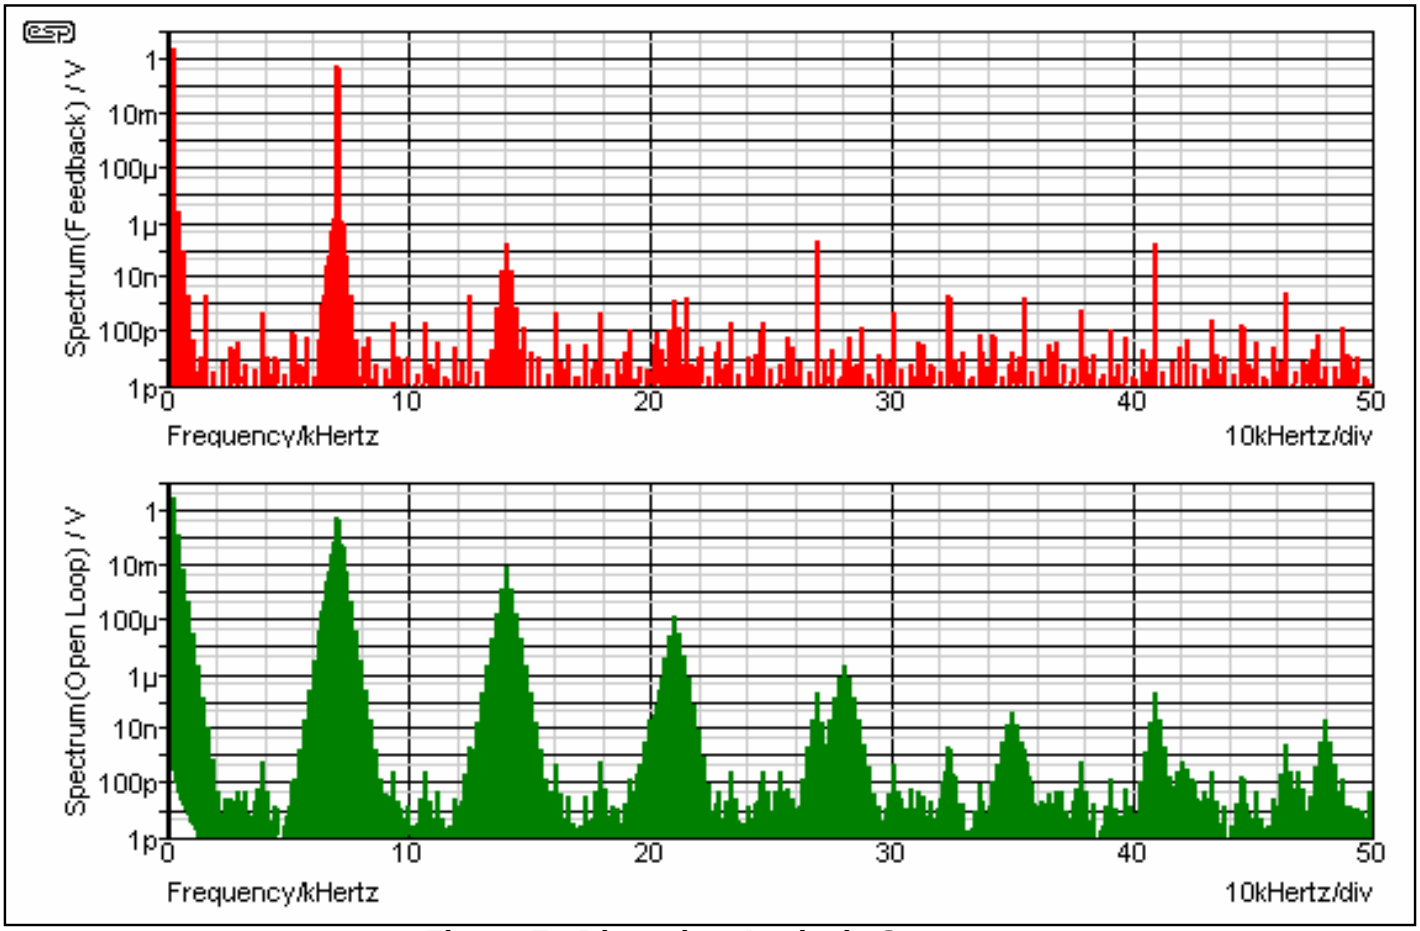

Figure 7 - Distortion Analysis Spectra

Looking closely at the FFT analysis of both the feedback and open loop circuits shows clearly that the distortion is reduced by the application of negative feedback. There is no evidence that any individual harmonic frequency is at a greater amplitude when feedback is applied, but you can see some signals that are not affected either way - these are simulation artefacts, and should be ignored. Note that the base level of 1pV is -240dBV - this can never be achieved in reality, so you can ignore any value below 1uV (-120dBV). Even this is rather adventurous, and 10uV is more realistic at -100dBV.

Note the peaks at and around 14kHz, 21kHz, 28kHz and 35kHz. These are highly affected by feedback because they are harmonics and intermodulation products of the 200Hz and 7kHz input frequencies, and are virtually eliminated by applying feedback.

The spikes at 26.92kHz and 40.92kHz are not affected, because these are artefacts of the sampling rate (a simulator works in a manner similar to any digital system, and uses sampling to convert the 'analogue' signal into digital for processing).

For reference, I have also included a spectrum analysis for a single 1kHz sinewave. This makes the picture clearer, and is the way THD is measured using spectrum analysis. The harmonics

are seen clearly, and it is notable that a circuit that one may assume would produce only even harmonics also produces odd harmonics. There is a school of 'thought' that is convinced that single-ended triode amplifiers (for example) produce only even ('nice') harmonics, while yucky push-pull amps produce only odd harmonics. This is not the case. While it is true that push-pull amps do indeed cancel the even harmonics, if the first claim were true, a push pull amp using triodes would cancel the even harmonics (which they do), leaving no distortion at all at the output (which they don't). Even-order harmonic distortion in isolation does not happen - it is invariably accompanied by odd-order harmonics, as demonstrated by the open loop response shown below. Taking the 'even order distortion only' argument to extremes, in order to obtain *only* even order harmonic distortion, the first harmonic (the fundamental) cannot be present because it is an odd number! While a bridge rectifier can achieve this, the sound is unlikely to gain wide acceptance .

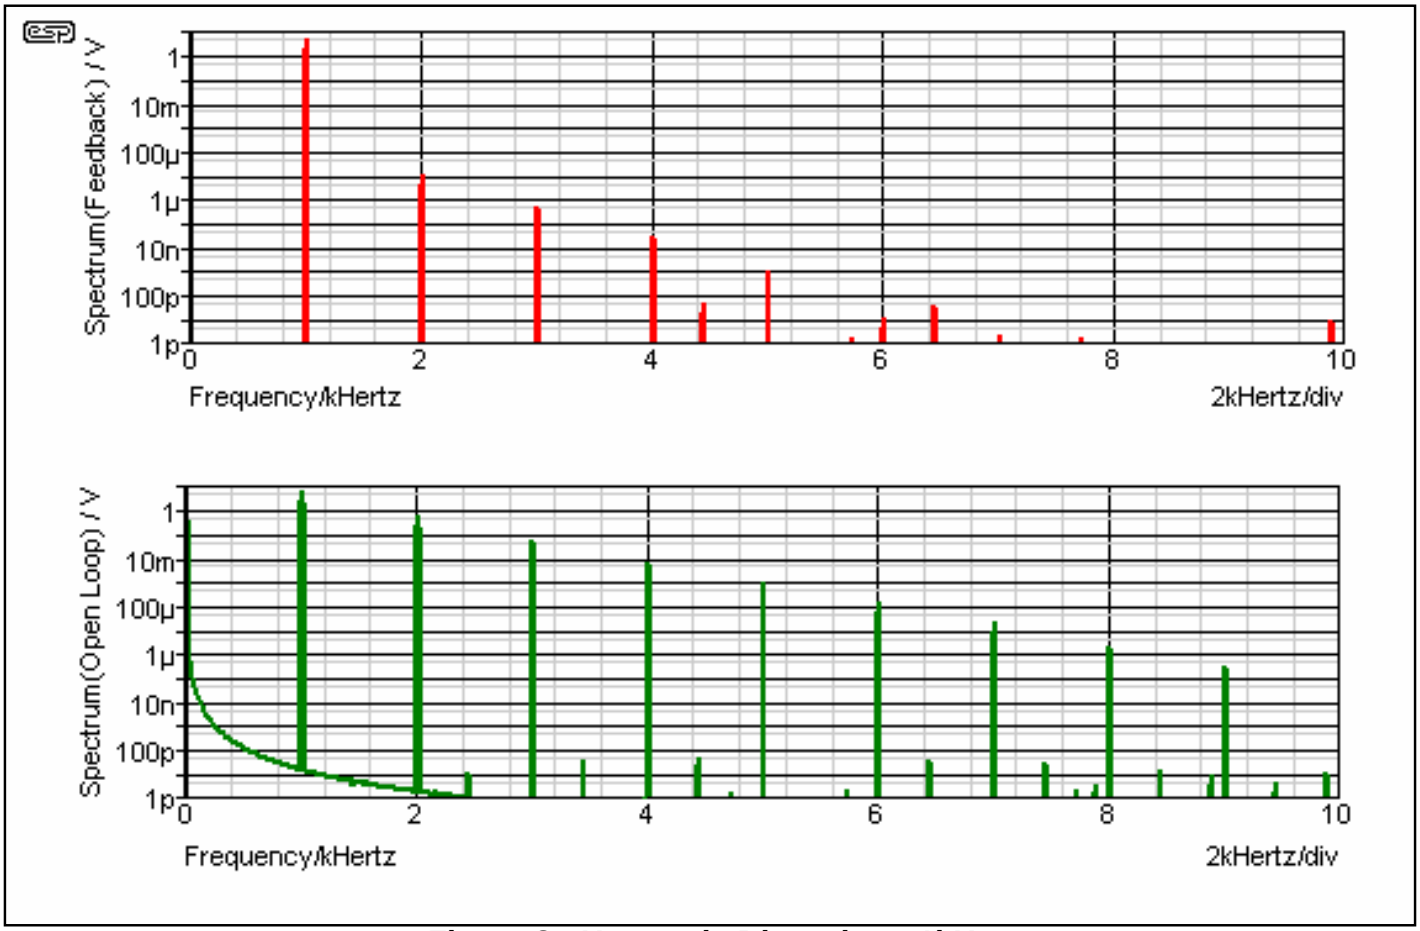

Figure 8 - Harmonic Distortion - 1kHz

Note that the open loop distortion products show diminishing amounts of both odd and even harmonics. Only those up to the seventh harmonic (7kHz) are relevant - all others are more than 100dB below the fundamental. When feedback is applied, *all* of the distortion products are greater than 114dB below the fundamental. Also, note that not *one* distortion product is at a greater level than in the open loop circuit. The spectra shown only extend to 10kHz because there are no significant harmonics above that frequency. Reducing the gain of E1 reduces the feedback ratio and increases the level of the harmonics as one would expect. Changing from 100k to 10k (20dB) increases the amplitude of the harmonics by 20dB. If E1 is reduced to a gain

of 1k, the second harmonic is increased to -74dB with respect to the fundamental. This effect is quite linear over a significant range.

As with the intermodulation test above, there are artefacts of the simulation and FFT process. The small peaks at 4.44kHz and 6.44kHz are not related to the 1kHz input signal, but are so far below the noise floor that it wouldn't matter if they were real. These signals exist in both cases (and at the same amplitude).

5.0 - Examining the Feedback Loop

Having looked at some examples using ideal amplifying devices with no real-world limitations, it is now time to examine real circuits. Unlike their simulated counterparts, real amplifiers have finite bandwidth and slew rate (maximum rate of change), finite input and output impedances, and are not free of distortion. For the audio frequency range, this makes very little difference, despite claims that these limitations lead to Transient Intermodulation Distortion or 'TIM' - now pretty much universally discredited, but still quoted by some [4].

An amplifier simply needs to be somewhat faster than needed for the highest frequency of interest. Just as in the explanation given above, real amplifiers don't care if the input is AC, DC, or a mixture of multiple frequencies. The only things of interest are the instantaneous voltage level and the highest frequency of interest (and its relative amplitude). The latter determines how quickly the output must change to prevent it from losing control.

One major limitation in any amplifier is propagation delay - how long it takes for a signal applied to the input to reach the output. Propagation delay depends on actual semiconductor delays, as well as phase shift introduced by the dominant pole capacitor. This component is almost invariably needed to maintain stability, because the amplifier must have less than unity gain when the total phase shift through the amp is 180°, otherwise it will oscillate.

Without the dominant pole compensation, propagation delays will be sufficient to cause a 180° phase shift while the amp still has significant gain. For example, if an amplifier has a propagation delay of 1us, this causes the phase to be reversed at 500kHz, so the amp will oscillate strongly unless the gain is reduced to slightly less than unity for any frequency of 500kHz or above.

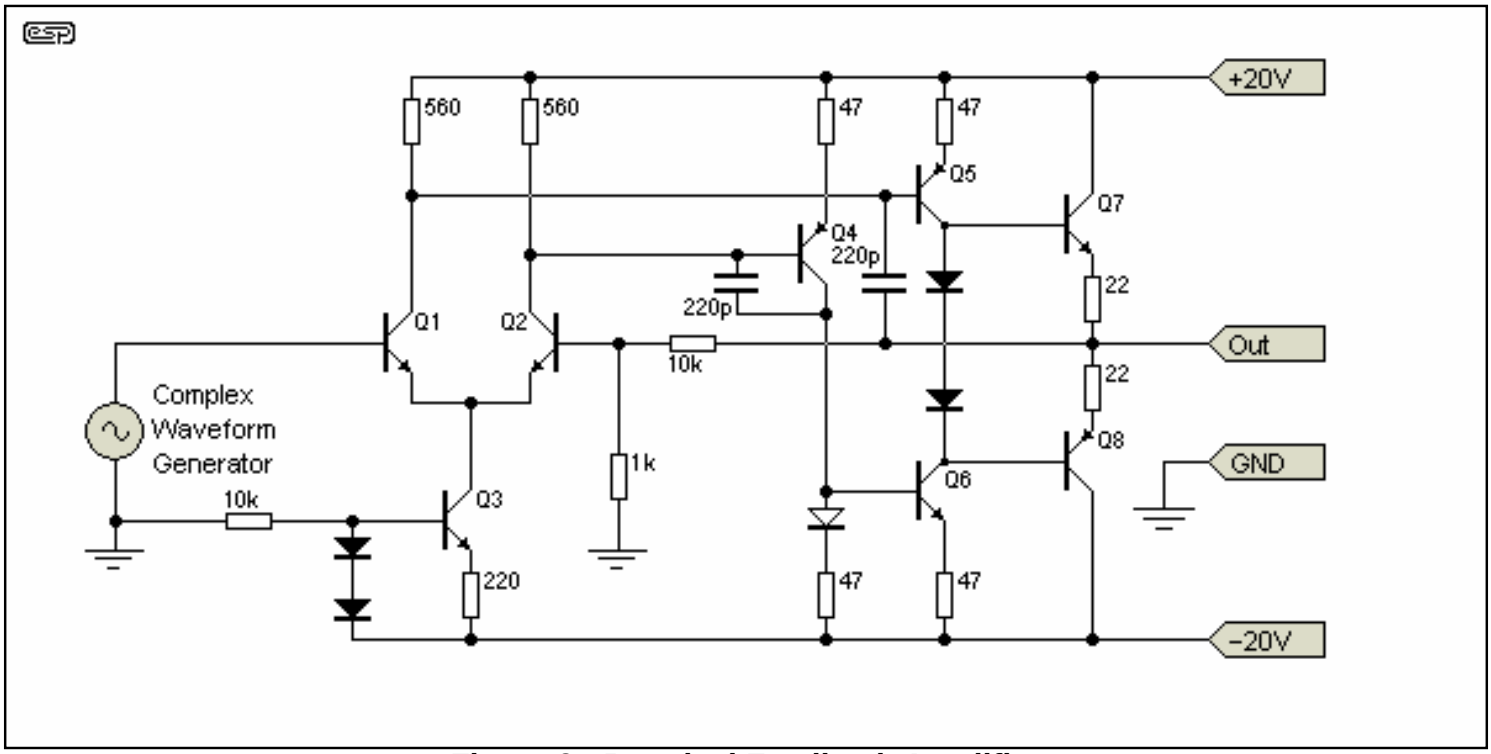

Figure 9 - Practical Feedback Amplifier

In order to obtain approximately equal slew rate for positive and negative going signals, the circuit of Figure 6 was used. Q1, Q2 and Q3 form the error amplifier, Q4, Q5 and Q6 make up the VAS, and Q7, Q8 is the current amplifier. Open loop gain is 20,000 (86dB), and the HF compensation caps (220pF) cause the open loop frequency response to be 3dB down at 2.4kHz. As is typical with such circuits, there is less feedback available at high frequencies because of the requirement for the dominant pole capacitors. They are not needed for open loop operation, but all linear (audio) applications will use the amplifier as a closed loop (feedback) circuit.

At an output voltage of 1kHz / 3.7V RMS, open loop distortion is 2.3%. Input impedance is about 7k, with output impedance at about 200 ohms. The distortion components are low order as expected, with only second and third harmonics at significant levels. The fourth harmonic is at -85dB relative to the fundamental.

Adding feedback, but maintaining the output at the same voltage, things change much as we would expect. Distortion at 1kHz now measures 0.0014%, and only the fundamental is above -98dB (the level of the second harmonic with feedback). What happened to all the high order harmonics 'generated' by the addition of feedback? As fully expected from previous tests, they simply don't appear - *all* harmonics are suppressed to much the same degree, but with some dependence on the open loop gain (and hence feedback ratio). In this case, closed loop voltage gain is 11 times.

With feedback, frequency response is -3dB at 4.3MHz (no, I don't really believe that either), input impedance a more respectable 5.8MΩ at low frequencies, falling to a bit under 1M at 20kHz. Output impedance is well under 1 ohm. Apart from the rather optimistic frequency

response reported by the simulator, the figures are pretty much what I would expect.

The slew rate is 11.5V/us positive and 18V/us negative - not exactly equal, but it will have to do. The maximum slew rate for a sinewave is determined by ...

$$\text{Slew Rate} = (2 * \pi * V_{peak} * f) / 10^6 \text{V/us}$$

So, it we want to get 10V RMS output at 100kHz, the required slew rate is ...

$$V_{peak} = V_{RMS} * 1.414 = 10 * 1.414 = 14.14\text{V}$$
$$\text{Slew Rate} = (2 * \pi * 14.14 * 100\text{k}) / 10^6 = 8.9 \text{ V/us}$$

Despite the gain rolloff after 2kHz and the relatively low slew rate for the desired frequency (it's not even double that needed for a positive going signal), the distortion measures 0.038%, and no harmonic exceeds a level of -70dB (with respect to the output of 10V RMS). The fifth harmonic is at -85dB. Remember that this is for a frequency of 100kHz.

5.1 - TIM/TID - Transient Intermodulation Distortion

The concept of TIM (Transient InterModulation distortion) was first proposed in the 1970s by Otala, and although it created a stir for a while, most designers realised fairly quickly that it does not happen in any sensibly designed amplifier. The 'dark side' of the industry seized upon TIM as their 'proof' that feedback was bad, and the debate has raged ever since. Some supposedly objective works on the topic have glaring errors, or have completely ignored other factors [4], such as amplifier output impedance and its effect on the response of a loudspeaker. It is notable that almost without exception, driving a speaker with higher than normal impedance sounds 'better'. Frequency response is less linear, damping factor is (much) lower, but somehow it sounds really good - at least in the short term. However, it is a grave error not to eliminate this variable from a test, because the sound difference is usually unmistakable.

According to the theory, when an amplifier has feedback around it, the delays between the input and output changes will be such that *huge* amounts of TIM will be produced. Naturally, a sinewave will never show the effect (at any frequency), and traditional measurement techniques will be useless for identification of this mysterious distortion mechanism. A useful test is to apply a squarewave at (say) 1kHz, with a sinewave superimposed upon it. This test will certainly let you know if there is a problem, but although I have used the test many times on amplifiers that should have vast amounts of TIM, no problems have ever been seen.

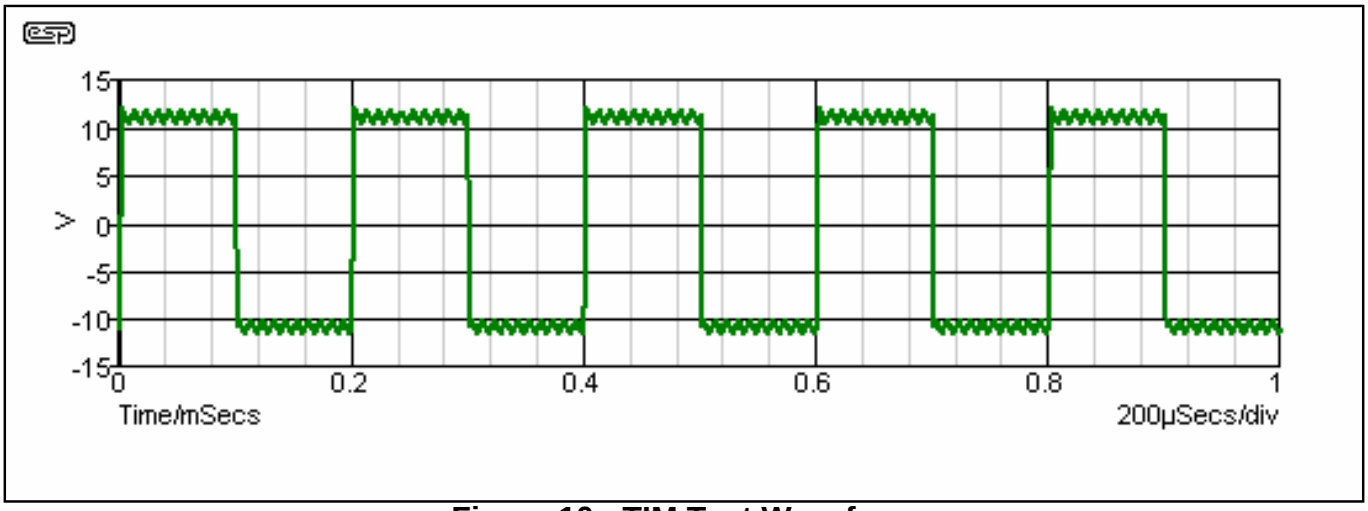

Figure 10 - TIM Test Waveform

Figure 10 shows the output waveform of the Figure 9 amplifier, which consists of a 10kHz squarewave whose slew rate is limited by the amplifier, with a 100kHz sinewave superimposed. This combined signal forces the amplifier into slew rate limiting, where the output cannot keep up with the input. The rise and fall times for the input squarewave are set at 1ns - many times faster than the amplifier can accommodate. Regardless of that, the sinewave shows very little modification - certainly there is a small section that is simply not reproduced at all, but this is with input frequencies and rise times that *do not occur in any type of music !*

Although a CD is capable of full output level at 20kHz (a slew rate of 5V/us for a 100W / 8 ohm amplifier), such a signal will *never* occur in music. This is a good thing, because tweeters cannot take that much power anyway. An examination of the maximum level of any music signal vs. frequency will show that the level at 20kHz is at least 10dB below that in the mid band - 10W for the amplifier above, or a slew rate of 1.6V/us. No sensible designer will ever limit an amplifier to that extent, but allowing 5V/us is easy, and will let the amplifier match the maximum rate of change of the CD source. In case you were wondering, vinyl can't hope to match a CD for output level at high frequencies, because at the first playing with the best cartridge and stylus available the high amplitude high frequency groves would be damaged forever. That vinyl can reach higher frequencies than CD is not disputed, but the level is very low. Fortunately, very high frequencies are never present in music at very high amplitudes.

As for claims that local feedback is 'good' and global feedback is 'bad' this is generally false. Global feedback around a competently designed amplifier will generally give much better results than multiple local feedback loops. Remember that waveform modification causes distortion, so a number of low gain stages with local feedback will generate additive distortion because *each stage applies its own amount of modification to the signal*! This is real, and the exact opposite of what may be claimed by local feedback proponents.

An amplifier with a single gain block and one global feedback loop will, provided it has reasonably good open loop linearity, simultaneously remove a significant amount of distortion from all stages at once, and there is no additive effect due to cascaded stages. This point is

rarely (if ever) mentioned.

6.0 - Amplification Circuit Delay

It is obvious that nothing in life is instantaneous. When a signal is applied to the input of an amplifier, there is a delay before the amplifier can react to the change, and this is determined by the speed of the devices used. Logic circuits typically have nanosecond delays from input to output, and this is also the order of delay one can expect before an amplifier as shown in Figure 7 will react to a change of input. According to the simulator, it takes about 5ns for the amp to respond to the fact that the input has changed - this is still using the very fast squarewave as an input. The output then swings in the appropriate direction at its maximum slew rate until the voltage at the inverting input again equals that at the non-inverting input. Once the voltages are equal, it takes about 220ns for the output to stabilise, settling so that the two input voltages are exactly the same. These times are very short - it takes the output 1.3us to change from +11V to -11V, so the 'reaction' time is close to negligible. It would be pointless to try to reproduce all the waveforms, so I suggest that you download the simulations. The files are in SIMetrix format, and are ready to run.

However, the above was all done with a signal that is much faster than the amplifier can handle, and it is more useful to examine what happens when the input slew rate is limited to something sensible. By adding a filter to the squarewave signal, the rise time can be limited to a somewhat more realistic value. A 32kHz, 24dB/octave filter was used, and this limits the output signal from the amplifier to 1.85V/us - well within its range, but still a great deal faster than any real music signal will create. Everything is now within the linear capability of the amplifier. The output is delayed by 46ns compared to the input, but this is inconsequential. Of more importance is how the amplifier reacts to the combined sine and square wave signal. It is not immediately apparent from the output, but in fact the sinewave is almost completely unaffected - the portion that would otherwise be cut off due to slew rate limiting now simply 'rides' the slope of the squarewave - if compared (after correcting for the level difference), the input and output are virtually identical - there is no evidence whatsoever of anything that could be classified as transient distortion - even with a 100kHz signal.

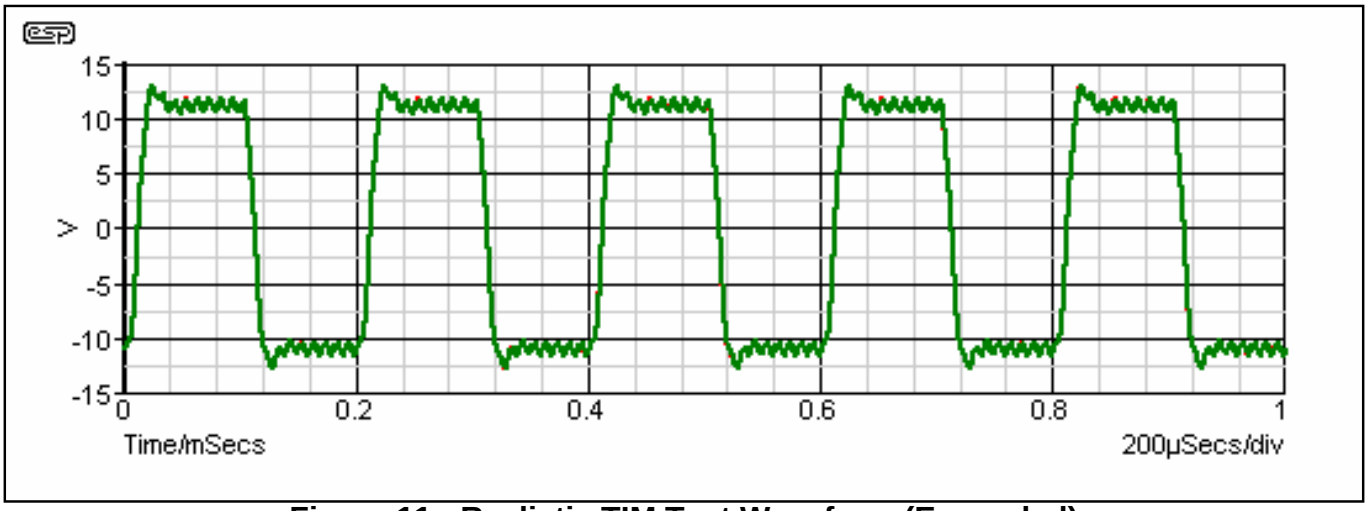

Figure 11 - Realistic TIM Test Waveform (Expanded)

There are two graphs in Figure 11 - green is the scaled input (increased in level to match the output) and red is the output signal. They are perfectly overlaid, indicating that the difference between them is very small indeed. Differences can be seen if the graph is expanded far enough, but the resolution of any oscilloscope will be such that the two waveforms will appear identical. The simulator can resolve details that are imperceptible with real test equipment. It is worth pointing out that the ESP sound impairment monitor (SIM) will detect the difference in real time using real world signals. Even the modified waveform of Figure 9 does not represent *any* signal that can be recorded or produced by any musical instrument (or combinations thereof).

Once the combined input signal is made sensible, the difference between the input and output signals can be seen, and it is primarily the result of the time delay (mainly phase shift) through the amplifier circuit. By using the SIM technique (measuring the difference voltage between the two inputs), all that remains is a residual signal that correlates with the gain of the amplifier at the frequencies used. The residual signal contains no non-linearities whatsoever, and is shown in Figure 12. The input stimulus this time is a 5kHz squarewave, filtered at 24dB/octave with a filter having a -3dB frequency of 32kHz. Superimposed on this is the same 100kHz signal used for the previous tests. The signal shown is the difference between the inverting and non-inverting inputs of the amplifier. Some of the signal shown is the result of the amplifier's error correction stage (the long-tailed pair) and VAS over-reacting slightly, and is also affected by the amplifier's total propagation delay and phase shift.

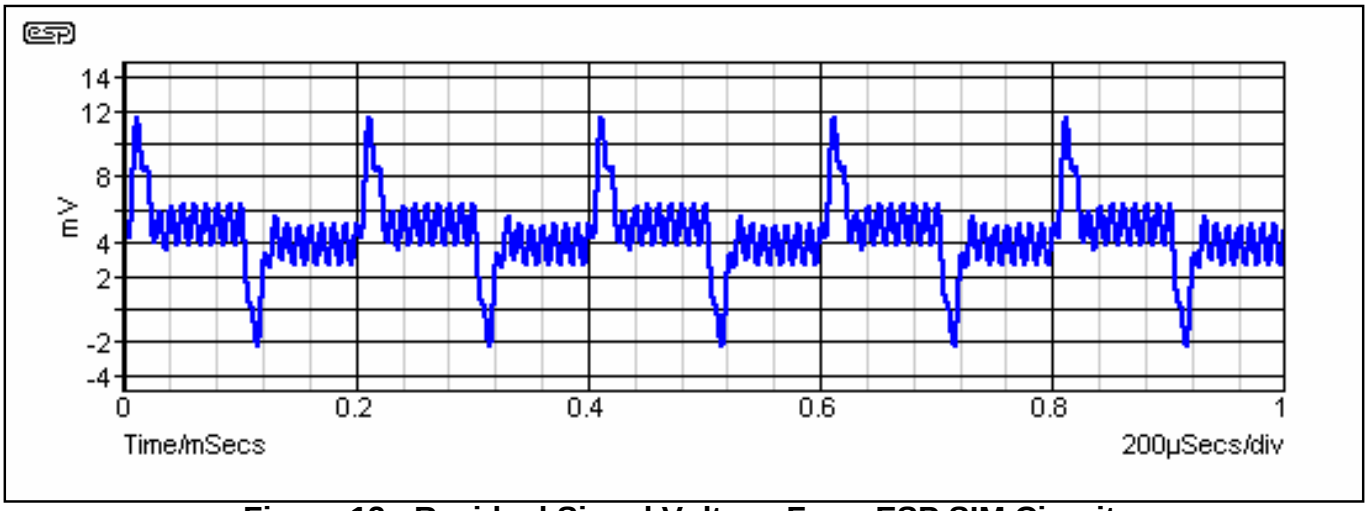

Figure 12 - Residual Signal Voltage From ESP SIM Circuit.

The important point here is that the amplifier *must* be maintained within its linear range. All amplifiers, including 'zero feedback' designs, can be forced outside their linear range. The whole idea of an amplifying circuit is that it should be linear, so no test signal should be used that dramatically exceeds the parameters of those of a normal source (such as music). To do so highlights 'problems' that do not exist in reality, so their inclusion is pointless at best, and grossly misleading at worst. The test signal used to obtain the above waveform is still a savage test - far more so than any music signal will produce, and deliberately much closer to the amplifier circuit's own limitations.

One can also measure the difference between an amplified version of the input signal, and that passing through the real circuit. In this case, the error signal is ~58dB down from the amplifier output, but is mainly the result of phase shift and very small gain errors - it is not a non-linear (distortion) component. At the upper test frequency of 100kHz, the amplifier has an open loop gain of only 470. With a design gain of 11 and an open loop gain of 470, the *actual* gain works out to be about 10.75 - this (as well as phase shift and DC offset) will always cause some error. It is important to understand that this is simply a small gain error, and does not contribute towards non-linear distortion.

These same tests have been performed (using test equipment, not the simulator) on various amplifiers shown in the project pages, with very similar results to those described above. There remains no evidence that any sensibly designed amplifier cannot keep up with recorded music, regardless of genre. The most common real amplifier fault one is likely to encounter in the listening room is clipping. Since clipping forces an amplifier out of its linear region, the main concern is how long the amp takes to recover from the overload.

This is a test I always perform, and a well behaved amp should recover almost instantly. The simulated circuit of Figure 7 recovers in less than 500ns for both positive and negative peaks, clipped with an input signal +4.5dB above the maximum level at 10kHz. Normal maximum level is 1.75V, and the input was driven with 3V (both are peak input levels). Recovery from clipping is not substantially affected by the input level. The recovery time is substantially less than the

sampling rate of a CD (44.1kHz = 22.675us), so the loss of information is only a fraction of one sample. Most amplifiers *should* recover in a few microseconds. If they do not, then there is a problem with the design.

7.0 - Local vs. Global Feedback

There is a constant argument regarding the benefits of local rather than global feedback. The following two circuits show an essentially similar design, but one uses two stages with only local feedback, while the other has been optimised for global feedback. The value of the feedback resistor was adjusted to give identical overall gain, in this case 40 (32dB). Conventional transistor current sources were used in the second circuit, the only difference being the use of a voltage source instead of a pair of diodes. The difference is minimal.

The strange resistor values in the global feedback circuit were a matter of expedience, and were used to set the gain and collector currents so that both circuits were run with the same current and collector voltage. Normally, one would not go to so much trouble, but for this experiment it was important to eliminate as many variables as possible.

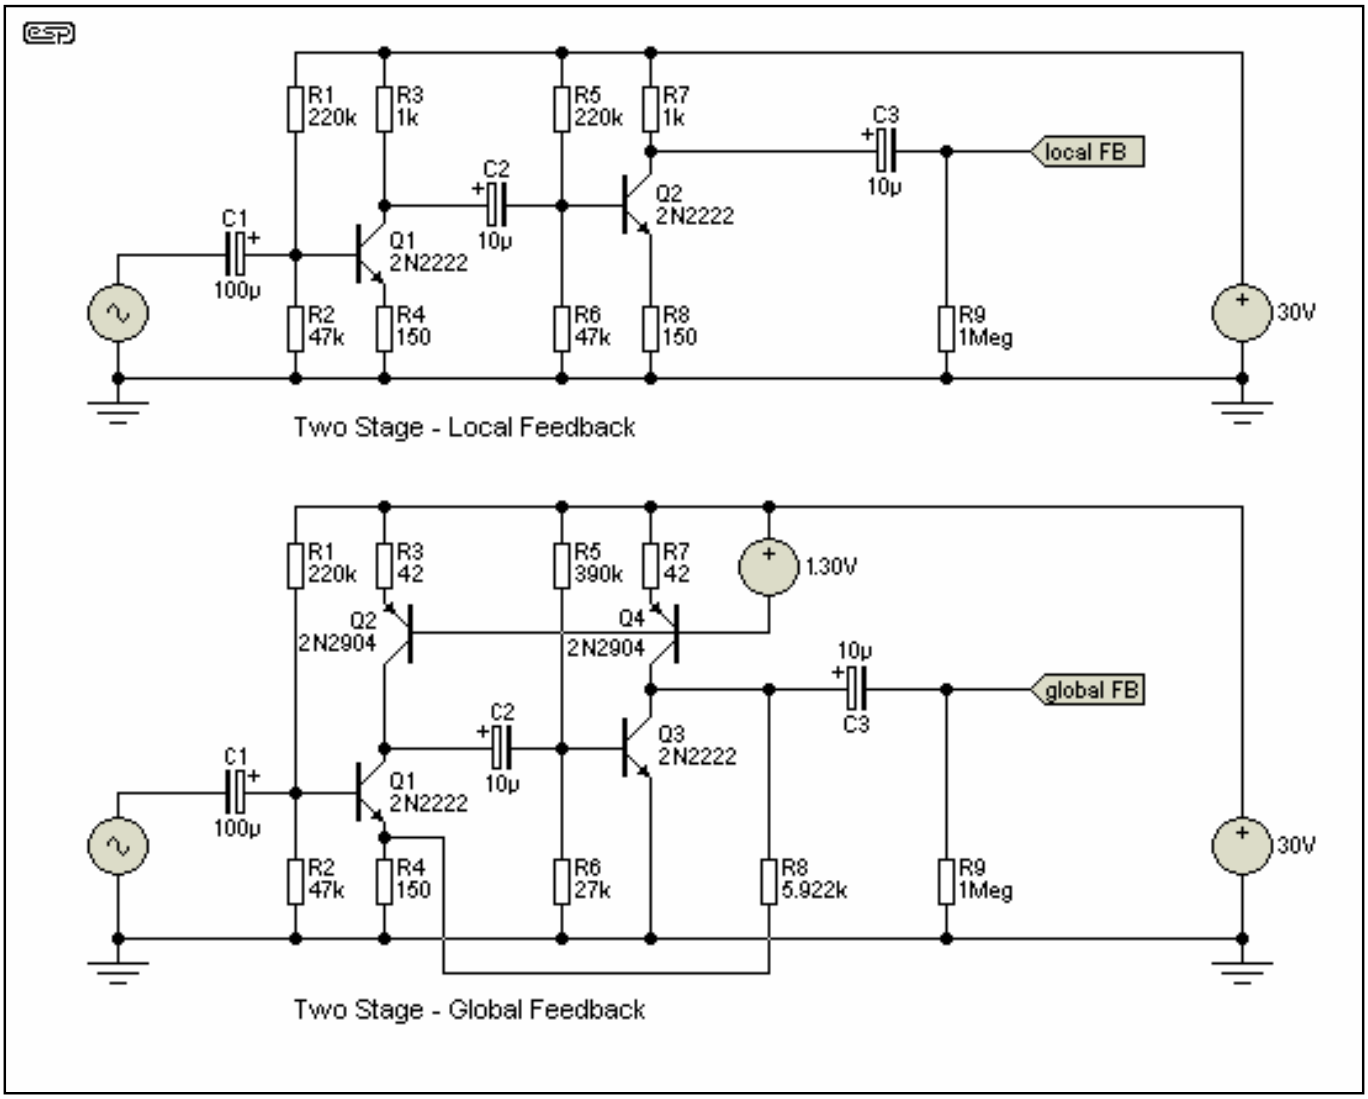

Figure 13 - Test Circuits for Local & Global Feedback

There are some quite surprising results. The global feedback circuit has less than half the distortion of the local feedback version (0.035% vs. 0.082%), but there are many other advantages as well. Input impedance is higher, output impedance lower, and global feedback makes the circuit faster and with better frequency response. The full listing is shown in Table 4, and it is obvious that global feedback is superior to local feedback in every respect.

Parameter	Local FB	Global FB
Distortion	0.082%	0.035%
Input Impedance	17kΩ	37kΩ
Output Impedance	1kΩ	<26Ω
-3dB Bandwidth	10.4MHz	24.7MHz
Open Loop Gain	40	286,000
Rise Time	28.8ns	11.9ns
Fall Time	32.3ns	10.6ns

Table 4 - Local vs. Global Feedback

One would think that there *must* be a down side. Something so simple can't possibly be that much better without a sacrifice. Can it? Yes, it can. Figure 12 shows the spectrum of the two circuits. As you can see, global feedback reduces all the harmonics, and the 'nasty' third harmonic is reduced far more effectively by global feedback than local. Not what you might expect, but there it is.

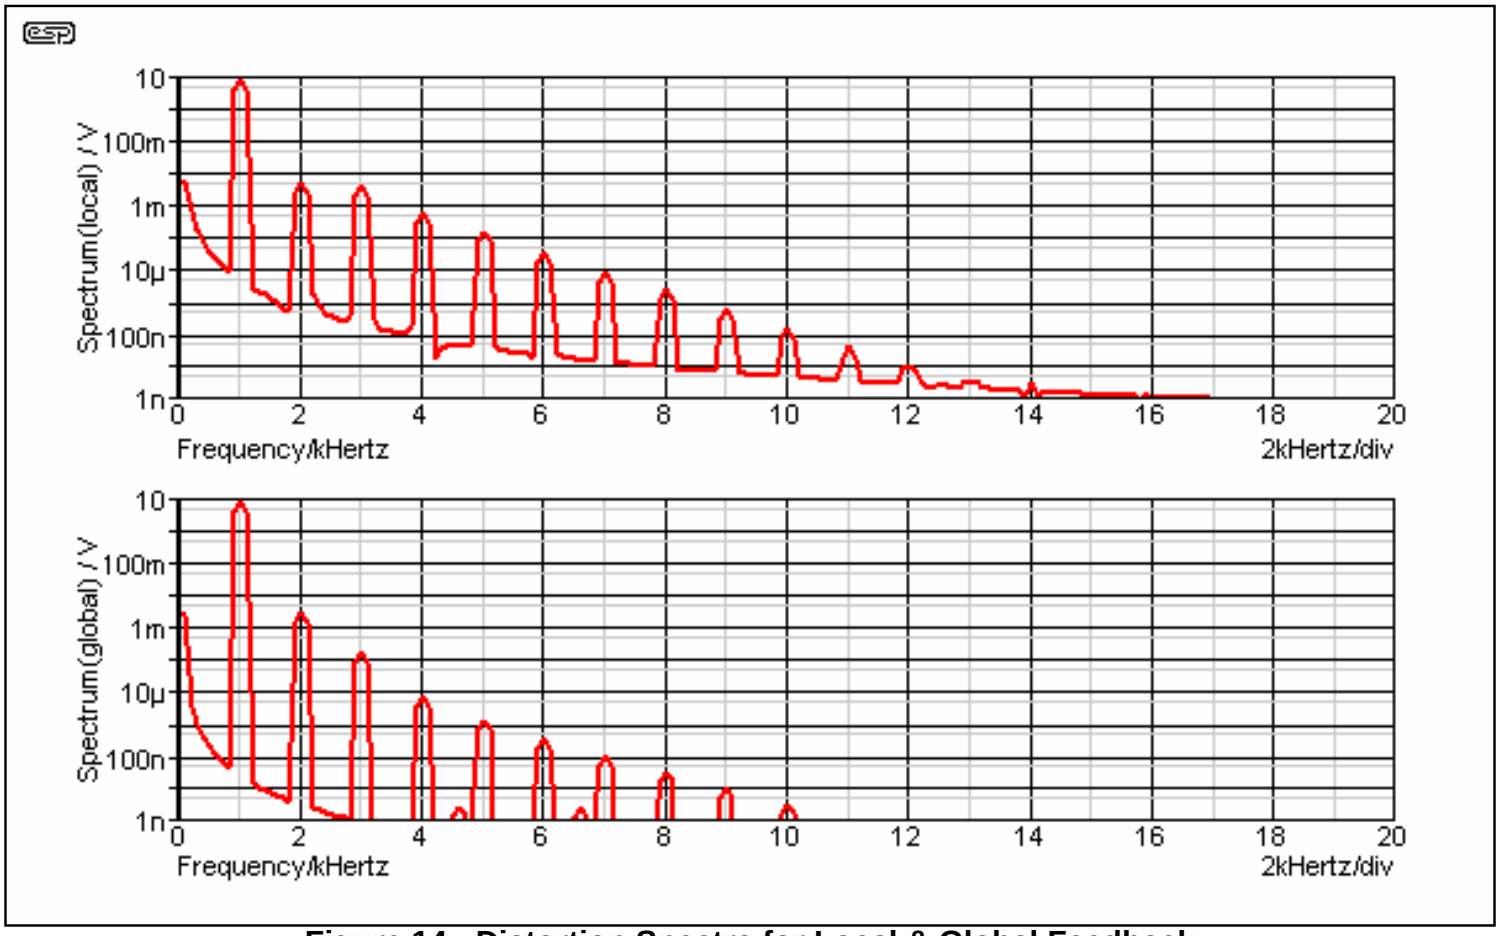

Figure 14 - Distortion Spectra for Local & Global Feedback

On the basis of this, global feedback wins on all counts. If you were to build the two circuits, you would find that the overall situation will not change, although some of the parameters will. This is due to component tolerance, but will not affect the final outcome.

It is notable that global feedback works best when there is lots of it. The claims that global feedback should be used in moderation are just silly, and have never considered the reality of good circuit design. The higher the open loop gain the better, but eventually you will run into stability issues, so some form of frequency compensation becomes essential.

Designing for stability and high open loop gain can be a challenge at times - especially for power amplifier circuits. However, when it is done (and done properly), there is no doubt that global feedback lives up to all the claims for it, with virtually no down side at all.

Well, there *is* a down side, but we have to look for it and know what we are looking for. Because nearly all opamp style amplifiers require a dominant pole capacitor to prevent oscillation, this causes a loss of open loop gain as frequency increases. Less open loop gain means less feedback, so upper harmonics are not attenuated as well as low order harmonics.

This could lead one to imagine that the application of feedback has indeed increased the level of the high order distortion components, but in fact it has done no such thing. What *has*

happened is that the feedback at higher frequencies is insufficient to reduce the upper harmonics as effectively as those at lower frequencies. Their amplitudes have been reduced, but not by as much as the low order harmonics. High order distortion products can therefore be seen extending out well past the audio band, at a similar level to the lower order components. For example, we may find that the tenth harmonic is reduced to perhaps -80dB, but the eleventh is only at -81dB, the twelfth at perhaps -81.5dB and so on.

Examining the spectrum may show that the relative levels of all subsequent harmonics remain at much the same level, well beyond the audio band. In this respect, the addition of feedback can easily be blamed for all the upper harmonics. The problem really lies with the gain of the amplifier, which rolls off the frequency response too early.

This effect can be seen plainly with crossover distortion on an unbiased P101 MOSFET power amp. At 1kHz, there is virtually no visible crossover distortion, even when the output stage has zero quiescent current. At 10kHz, the distortion is clearly visible on the oscilloscope, even though it is not audible with a single tone (the 3rd harmonic being at 30kHz). Needless to say there is zero visible (and almost zero measurable) crossover distortion at 10kHz once the amp is biased correctly, but this highlights the open loop gain issue. At 10kHz there isn't enough feedback to be able to correct the crossover distortion, but there is more than sufficient at 1kHz.

The solution is simple enough - make sure the amp is as linear as possible before feedback is added (which in the above case means setting the bias current correctly). While there is no doubt that a wider open loop bandwidth is beneficial, this must never be at the expense of amplifier stability. A small amount of distortion at the uppermost frequency range is far better than an amp with marginal stability - oscillating amplifiers definitely don't sound very nice at all.

8.0 - Conclusion

Read any articles about distortion you may come across (including this!) with care. Like death and taxes, distortion is inevitable, however it can be minimised with careful design and a proper understanding of how feedback can be used most effectively to ensure that distortion doesn't spoil your listening experience.

Loudspeakers contribute far more distortion than the vast majority of amplifiers, but some forms of distortion can be very intrusive - especially crossover distortion in transistorised amps. Fortunately, it is a simple matter to design an amp using sensible circuitry and modern transistors where crossover distortion is (for all intents and purposes) non-existent. Total harmonic distortion figures of well below 0.1% at any normal power level from a few milliwatts to several hundred Watts are easy to obtain. The distortion of most modern amps will contain only a few low order harmonics at all power levels up to the onset of clipping.

Of far more concern is the addition of distortion to the recording, either deliberately or by

accident. Nothing that you do in your home system can eliminate that - once a signal is distorted, you are basically stuck with it.

To avoid the use of global feedback based on so-called 'research' is most unwise. As demonstrated above (and by many others), correctly used, global feedback is as close to a panacea as we are ever likely to find. The idea of any hi-fi system is to reproduce the source material as faithfully as possible, and to deliberately add distortion to everything you hear (due to amplifier deficiencies) because it sounds 'nice' is simply not high fidelity. If that is what you want to hear then there is no problem with that, but by adding so much additional material (by way of harmonics and intermodulation) you have a tailored sound system, not a hi-fi.

Harmonic distortion and intermodulation are linked together, so much so that it is virtually impossible to have one without the other. By ensuring that each element in the amplification chain is as linear as possible, you minimise both THD and IMD, both of which are easily demonstrable. This is a far better option than trying to minimise TIM, the very existence of which has been called into question countless times since it was 'discovered'.

Finally, I have included a pair of simple circuits that can be used to create distortion. Testing these using my workshop speaker system, the distortion of a 400Hz sinewave was (just) audible at < 0.5%. This same level would be inaudible on most music, being primarily low order as seen on the residual of my distortion meter. It is probable that had I used headphones or a better speaker system, low order distortion would be found to be audible at lower levels, but this simple test shows just how revealing a sinewave really is. While those trying to 'prove a point' will claim that a sinewave test is too simple and reveals little, this is obviously *not* the case. As noted above in Section 2, a sinewave is not an easy test at all, and anyone who claims otherwise is seriously mistaken.

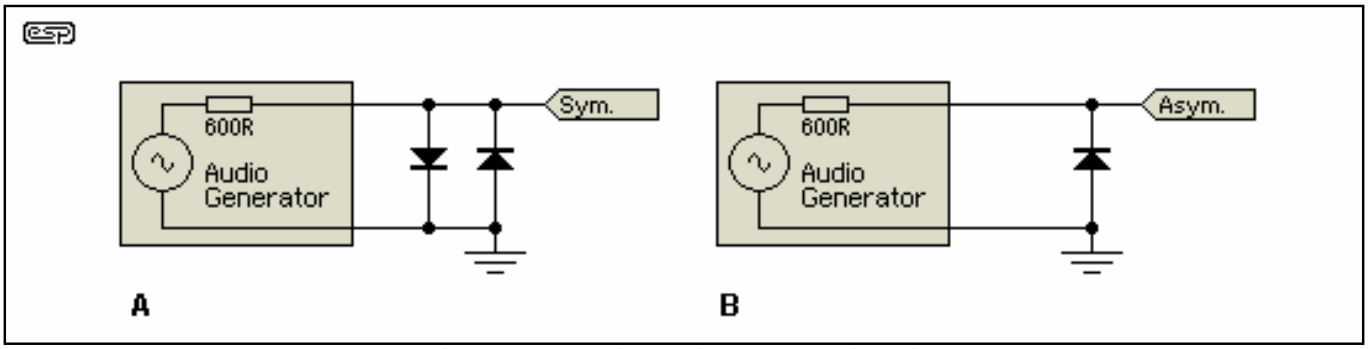

Figure 15 - Distortion Test Circuits

The circuits shown will need to be carefully tweaked to suit your test equipment and amplifier, so consider them to be more of a general idea than a definitive test circuit. The amount of distortion for both A (symmetrical) and B (Asymmetrical) is adjusted by varying the input level, and no attempt has been made to level match the distorted and undistorted signals. The distortion itself is sufficiently prominent that full blind AB testing is not needed to get a general idea, but would be essential for a scientific study. The day after I did these tests, a friend came to my place, and I repeated the test with him. The distortion meter was disabled so we had no

visual cue, and we arrived at almost exactly the same result with both test circuits.

Be aware that you may find that you can't hear any distortion until it is greater than the 0.5% I measured. Try moving around (even a few centimetres or so will be enough). Why? When listening to a steady tone, standing waves and reflections can combine to make a single frequency much louder than it should be, or almost inaudible. This effectively changes the distortion spectrum, making it sound much greater or less than the actual value. While this effect may have contributed to my hearing only 0.5% distortion on a sinewave, I did move around to make sure that the distortion was audible in more than one position. I neglected to measure the sound level when the test was done, but it would have been around 75dB SPL - any louder becomes very irritating.

For around 0.5% distortion measured and using an asymmetrical diode clipping circuit (B), the harmonic levels will be pretty close to the following (note that all harmonics are referenced to the level of the fundamental, all voltages are peak) ...

Fundamental 400Hz	448mV	0dB (reference)
2nd harmonic	1.35mV	-50dB
3rd	942uV	-53dB
4th	599uV	-57dB
5th	348uV	-62dB
6th	167uV	-68dB
7th	68uV	-76dB

It is probable that only the first few harmonics would have been audible, since those above the fifth are approaching my hearing threshold. Even this may be wishful thinking - anything above the third is well below the ambient noise floor.

Sine waves are too simple to use as a test? We think not!

Guitar Amplifiers

IN THE STUDIO and on stage, instrument amplifiers are vitally important to the musician. Specialised equipment is a necessity, and the instruments themselves are becoming more and more demanding of the amplifier-speaker combination with which they are used,. The size and power ratings of such systems has grown considerably in recent years; it is not ,uncommon to find instrument amps today, which are more complex and larger than a band's entire PA system of a few years ago. As one of the most controversial pieces of amplification ever produced, we shall first take a look at the guitar amplifier, which has evolved from a general purpose "as long as it works" device, to a sophisticated piece of equipment - at least in the professional sector, where the so-called "universal" amplifier is no longer relevant.

Most guitarists will say that, with a given amplifier, a certain volume level is required to obtain the right sound. While this is to a point psychological, there are very good technical reasons to support this statement. The "right sound' usually means a fairly high level of harmonic distortion, both from amplifiers and speakers - distortion which gives much needed assistance to an electric guitar by providing the missing harmonics and increased sustain. A certain amount of sustain is obtained by acoustic feedback, particularly with semi-acoustic guitars, however the majority is the result of the amp being driven into "clipping", or distortion. This has the effect of maintaining the level at a (more or less) constant level for much longer than would normally be the case (Figure 1).

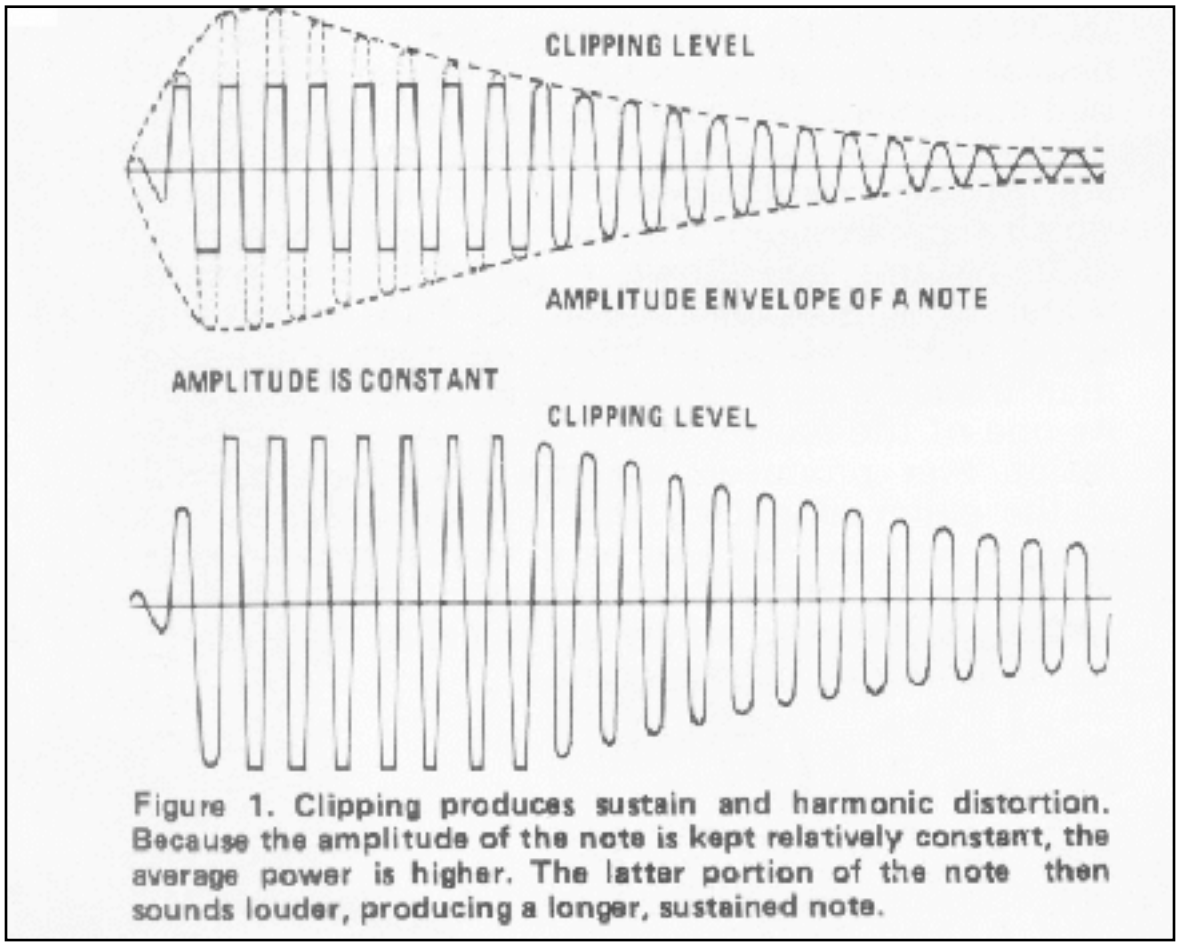

Figure 1. Clipping produces sustain and harmonic distortion. Because the amplitude of the note is kept relatively constant, the average power is higher. The latter portion of the note then sounds louder, producing a longer, sustained note.

If an amplifier is overdriven, the sound produced is usually considered objectionable, so special measures must be taken to obtain the desired characteristics.

Firstly, there is the bandwidth restriction of the speaker cabinet. For the low-end this may be achieved by using an open-back box, to allow bass cancellation, or to contain the speakers in an enclosure of limited internal capacity. High-end roll-off is usually a characteristic of the speakers themselves: speakers - without "whizzer" cones or aluminium domes will generally sound smoother because of their limited high frequency response. A broad peak in the speaker's response at 2kHz to 4kHz adds "presence" and bite, and the response should roll off beyond that point. It is preferable that frequencies above about 7kHz are not reproduced at all,

as this will exclude the 7th harmonic (which is discordant) of all strings of the guitar. Damping or venting of guitar speaker enclosures is usually avoided like the plague because damping will lower colouration, a desirable feature in musical instrument amplification. Without colouration all plucked string instruments, for example, would sound much the same.

- **Vented boxes are avoided because they emphasise (or allow to be reproduced) the lower frequencies - these are usually not desired, since they tend to muddy the sound. This is especially true for "heavy metal" playing styles, since severe amp overdrive is commonly used to achieve the sound, and even small amounts of low frequency material (such as string handling) will cause large amounts of bass "waffle".**
- **The majority of guitar speaker boxes (as noted above) are either open backed, or are relatively small sealed enclosures. There are naturally exceptions, but even 20 years after this article was first written, are still uncommon.**

Additional bandwidth restrictions are usually designed into the output transformer of valve amplifiers. Transistor amplifiers usually do not have an output transformer, so this method of filtering is precluded. The effect of all this manipulation of response is to "clean up" the distorted output waveform of the overdriven amplifier - the sound will become less harsh, and the transition from overdriven to "clean" becomes less apparent.

In fact in a valve amp the clean or "no distortion" state exists only when there is no input. Distortion is present even at low levels, and increases with the input signal.

The above situation is in contrast with the majority of transistor amps, which generally have very low distortion up to the point of clipping, after which distortion rises rapidly. Maximum distortion is the same as for a valve amp - i.e. a square wave, but the transition is such as to be very noticeable; this can be objectionable when the guitarist is playing clean but for the odd note or chord which overdrives the amp, causing a marked change in tonality (Figure 2).

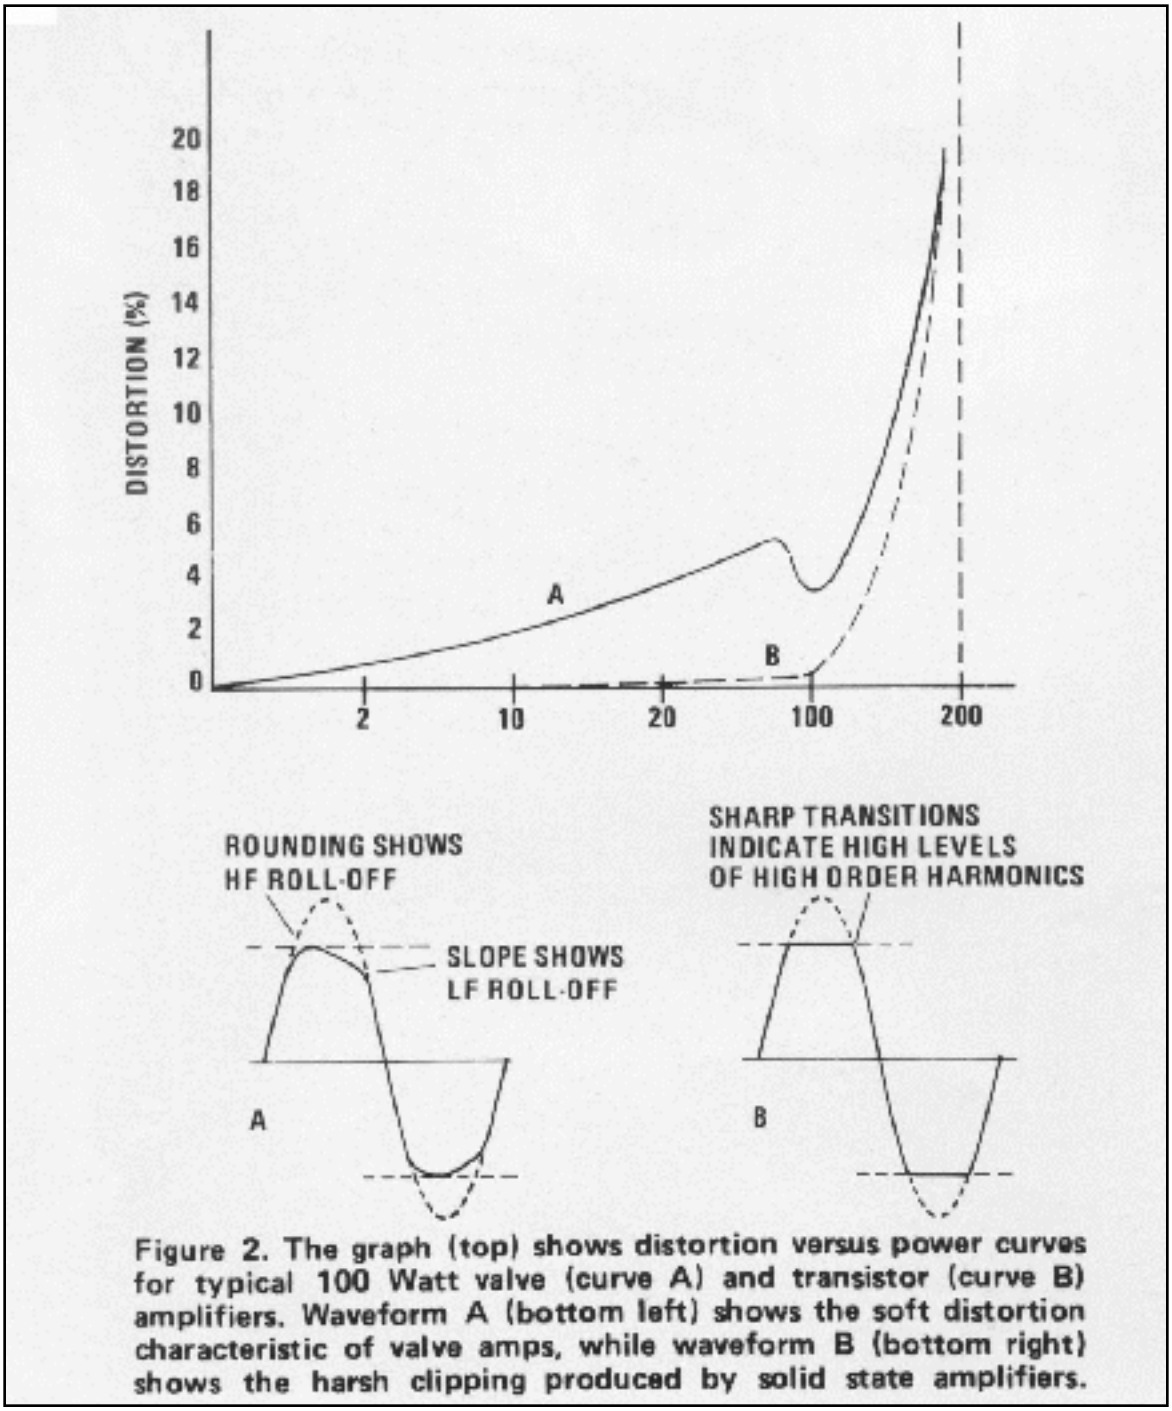

Figure 2. The graph (top) shows distortion versus power curves for typical 100 Watt valve (curve A) and transistor (curve B) amplifiers. Waveform A (bottom left) shows the soft distortion characteristic of valve amps, while waveform B (bottom right) shows the harsh clipping produced by solid state amplifiers.

Output impedance and "dynamic output" are other major contributors to the sound of a guitar amp. Output impedance, in this instance, has nothing to do with speaker "ohmage", but is the actual source impedance of the amplifier, as seen by the speaker. In a valve amp, the source impedance may be as high as 200 ohms for a nominal 8 ohm output. This allows the speaker freedom to exhibit its own natural resonances, plus the colouration provided by the enclosure itself. A low output impedance on the other hand, will repress colouration by damping the speaker, in much the same way as would fibreglass in the cabinet. This tends to make the amp sound flat and lifeless, lacking the subtle colouration and tonality which makes a fine musical instrument - and after all, a guitar amplifier is as much a musical instrument as the guitar itself. Transistor amps usually have a low source impedance, typically less that 1 Ohm.

- **It should be noted that the power rating for guitar amps is (very) commonly quoted at 10% distortion. This means the amp is typically about 80W at the onset of clipping (usually taken as the "real" maximum power level). This is justified on the basis that few guitarists will operate their amps with no distortion at all. This assumption is not necessarily valid, but has prevailed for a very long time, so is unlikely to change now.**
- **The source impedance of valve amplifiers is generally lower than that quoted above, and in fact it will generally match the speaker impedance (assuming no feedback is applied). I appear to have goofed in the original article.**
- **From the very first guitar amplifiers I ever built using transistor output stages, I used current feedback to increase the output impedance of the amp. This restores much of the "valve sound", and provides a simple but effective method of providing short-term short circuit protection (for example while plugging 6.5mm phone jacks into their sockets while the amp is on). This technique has now been adopted by nearly all guitar amp manufacturers. Regrettably, this technique does little to improve dynamic output. Output impedance of my amps was typically 200 Ohms.**

Dynamic output in this context means the ability of an amplifier to deliver power to the load (the loudspeaker). Because of the high source impedance and low efficiency of valves, output transformer and the power supply, a valve amp is capable of developing approximately 75% of its rate power into double its rated impedance, and up to 50% of rated power into four times rated load. This means the amp can provide relatively constant power regardless of the variations of impedance with frequency which are a characteristic of speaker loads.

In contrast, a transistor amp can usually deliver only 55% or so of its rated power into double rated load, and about 30% into four times rated load. These variations may not appear to amount to very much, but they do make a big difference in terms of spectral balance and dynamic performance. Such is the difference in fact (and this also applies to valve hi-fi amps, bass amps, etc) that a 100 watt valve amp will generally sound as loud as a 150 watt transistor amp.

The technical reader with an understanding of dB and the logarithmic response of the human ear may be sceptical about the foregoing paragraph, but differences of 1dB are audible when one has a suitable point of reference; in musical groups, where the balance of instruments is critical, such differences are very noticeable.

Powering Up

The level of sound produced by a guitar amp is usually way out of proportion to the quoted power rating. For example, a 100 watt guitar amplifier played normally (for a rock guitarist) will produce an average sound pressure level of about 120 dB at 1 metre. Try that with your hi-fi and you will most likely have speaker cones (and/or your neighbour's projectiles) all over the listening room floor. The reason is quite simple. Because the amp is being overdriven, peak

limiting will occur - clipping of the output waveform - which reduces the peak to-average power ratio of the program material. The peak to average ratio of a guitar signal is about 20 dB; that is, the peak level as a note or chord is struck will be 100 times higher than the overall average level. An overdriven amplifier may reduce this ratio to 2:1 (3 dB) or less, and as a result the average power is higher.

A further power increase results from the fact that a severely clipped waveform will approach a square wave, which has twice the power of a sinewave of the same amplitude. The result is a 100 watt amplifier delivering an average power of perhaps 170 watts short term (i.e. maximum level indicated on a VU meter), and up to 130 watts averaged over a 5 to 10 second period.

Compare this with an undistorted amp handling program with a peak-to-average ratio of 100:1 (20dB). The long term average power will be in the order of 2 to 5 watts with peaks of 100 watts. With mild distortion, say less than 15%, the average power climbs rapidly to around 25 watts; increase the distortion further and the power climbs again until, with maximum overdrive, a 100 watt amp will be delivering 200 watts!

- **An important point was raised by a reader, who said that the above explanation only applies if the power supply remains at a constant voltage with the increased load. This is very true, and in reality, most don't, so the maximum power is limited by the capabilities of the supply. Valve amps are usually worse in this respect than transistor amps, and the maximum power at full clipping may only be 150% of the rated power.**
- **Despite this, the average SPL (Sound Pressure Level) is maintained at a high level, and the effect is that it sounds louder than one might imagine it should. This is similar to using compression (as done with ads on TV). The maximum SPL is not increased, but because everything is at maximum, it appears to be louder than it really is.**

So loud, in fact, are many popular guitar amps, that guitarists are now experimenting with methods of obtaining "the sound" at lower power levels. There has been a trend for some time now towards smaller amps and/or some provision for simulating amplifier overload. The latter is best achieved by using a master volume control and some form of clipping circuit, which should ideally be placed (electrically) between the tone controls and the power stage. A clipping circuit placed before the tone controls will not sound like amp overload because of the large amount of treble boost built into guitar amps. A clipping circuit so placed will produce only the dreaded fuzz box sound, once much loved but now generally disdained because of its harsh unnatural sound.

- **Having said that, there seems to be a resurgence of old analogue technologies in all areas of electronic music, and this includes the lowly fuzz box. There have also been moves to try to emulate the asymmetrical clipping characteristics of valves (some dating back many years).**
- **One of the most innovative (and complex) attempts to recreate the valve sound with solid state electronics is the Vox AC30 Simulator - a contributed article on the ESP Project Pages.**

The addition of a graphic equaliser set, now incorporated in many brands such as the Zoom (above), greatly expands the tonal variation possibilities of an amplifier.

Bass Amplifiers

Many of the requirements for guitar amps also apply to bass amplifiers, in particular those factors relating to colouration and harmonic distortion provided the latter is not obtained from amp overload. A high output impedance and high dynamic output are also desirable features.

One of the major differences is the power requirements. Whereas a guitar amp will usually be overdriven, a bass amp should not be; the sound will become muddy and indistinct, lacking punch and definition. Bass is, by its very nature, difficult to reproduce. The open E string for example, has a fundamental frequency of 41.2 Hz, a difficult frequency to reproduce even given ideal circumstances, let alone at high power and with enclosures which must be able to be moved around! As a result, few bass systems have appreciable output below about 80Hz - and this includes the large "W" bins used for PA systems. Up to four times as much power may be needed at 40Hz to match the acoustic output at 400Hz (Figure 3).

Because it is undesirable to drive a bass amp into distortion, and the bass should be able to equal the guitar in volume, much more power is required for bass than for guitar. In fact if we assume a guitar amp rated at 100 watts and operating at an average power of 130 watts, and assume a bare minimum bass peak-to-average signal ratio of 10:1 (10 dB), our bass amp

would need to be at least 1000 watts to match the guitar amp without producing audible distortion! A certain amount of clipping of transients is permissible, and in a well designed system will not be audible because of the masking effect of the rest of the band. It will, however, be very audible on a bass solo if the same volume is used.

Harmonic distortion in the bass region is usually very high, especially in the speakers. Some are capable of a total harmonic distortion approaching 100%! This "impossible" distortion level is caused by speaker "doubling" - the result of a combination of speaker-cone breakup, voice coils which actually leave the magnetic gap and poorly designed enclosures. The main faults in enclosures are truncated horns, excessive horn flare rates, badly vented cabinets, and poor internal bracing of cabinets which are often simply too small for the speaker. Intermodulation distortion arises from the large excursions of a speaker cone at bass frequencies which cause the voice coil to partially leave the magnetic gap. When this occurs, efficiency is lost and distortion appears at the peaks of the waveform. Any superimposed high frequencies (harmonics) will also be distorted.

- **It must be noted that many of these problems have been reduced with modern loudspeaker drivers, whose excursion is often prodigious. Linear cone travel of +/-10mm or more is not uncommon now, and there are many very efficient speakers that are specifically designed for use in small enclosures. Coupled with the very high powers that are common today, it is possible to make a bass amp that will faithfully reproduce down to 30Hz in a cabinet that is still portable.**

It should now be apparent that a 200 watt bass amp, typical of many systems, is quite inadequate for a reasonably loud rock band, and in fact is often barely adequate for a club band; it will usually be pushed so hard that it will be clipping for up to 60% of the time. If we now connect the above amplifier to a speaker system whose efficiency, especially at the lower frequencies, is not very high, add equalisation to provide a measure of bass boost, then the amp overload problem becomes even worse.

The obvious solution is to use more speakers in larger enclosures - and more of them - driven by even more powerful amplifiers. An effective alternative is bi-amping; an electronic cross-over separates amp-speaker combinations which may be more easily optimised for the frequency range being covered. This approach has been used with some success, and although it is more costly it will eventually become a standard technique. The advantages of a bi-amped system are lower intermodulation distortion, and greater acoustic output for the same total power as a conventional amp/speaker combination.

Unfortunately there are many trade-offs which must be made, both for financial and physical reasons, and many of the better combinations are precluded by prejudice. For example, the average. bass players' opinion of 300mm (12") speakers is not printable.

A variation on bi-amping is to use separate amps and speakers for a stereo bass guitar. In this

arrangement the bass and treble pick-ups on the instrument are brought out separately and fed to separate amps. This technique has been around for many years but as few instruments are wired for stereo, most bass players have not had the opportunity to experiment with it. Any two pick-up bass can be easily modified however, and it is a trick well worth trying.

Keyboard Amps

A modem keyboard setup is probably the most complex and expensive item in any band, with the possible exception of the main PA system.

The basic requirements, at least insofar as the bass and midrange are concerned, are much the same as for bass amplifiers. Power requirements are of the same order, and similar problems involving loss of definition may occur due to insufficient power, poor enclosure design and a lack of understanding of the demands which are placed on a keyboard system. These include the extreme dynamic range (if pianos, the vast pitch range of synthesisers, and the special difficulties presented by such instruments as string ensembles, Mellotrons and Leslie type organ speaker cabinets (which are usually not loud enough unless miked).

- **Mellotron?? I'm not going to even try to explain this one (you wouldn't believe me unless you were there). Try a web search, you might well be surprised.**

The majority of intelligence and energy of keyboards is in the mid-range, the band of frequencies from about 180Hz to 1200Hz (Roughly F3 to D6) that cover the fundamental frequencies of the most used section of any keyboard instrument. If this section is not treated with the respect it deserves, it will be difficult to obtain a good, clean sound from the majority of instruments.

Obviously, the power required will depend on the volume at which the musician intends to play, but 100 watts would have been a minimum for all but the quietest bands. In a rock band this may have to be increased to around 1000 watts, with 450 watts on bass, 450 watts on midrange and 100 watts for treble.

An exclusively mid-range enclosure should not use speakers larger than 300mm (12') if a good transient response is to be obtained, and a flat frequency response is desirable.

Bass Boost	**Power**
Ref. 440 Hz Level	Ref. 10OW @ 440 H z

0dB	100 W
1dB	126 W
2dB	158 W
3dB	200 W
4dB	250 W
5dB	316 W
6dB	400 W
12dB	1600 W

Figure 3. The right column shows the power equivalent to the bass boost in the left column, referenced to 100 watts at 440 Hz (A above middle C).

Horn loading is an excellent way of achieving high efficiency, and if properly designed will provide low distortion, good frequency response and excellent transient response. The bass enclosure should not be horn loaded, because a horn which will work properly down to the lowest frequencies will be too large. Instead a reasonable sized vented enclosure should be used.

- **A better alternative today would be to use a sealed and equalised enclosure (see the EAS subwoofer project on the ESP Project Pages). This will give the best transient response, but requires much more power. On the positive side, the box will be very much smaller that would otherwise be possible.**

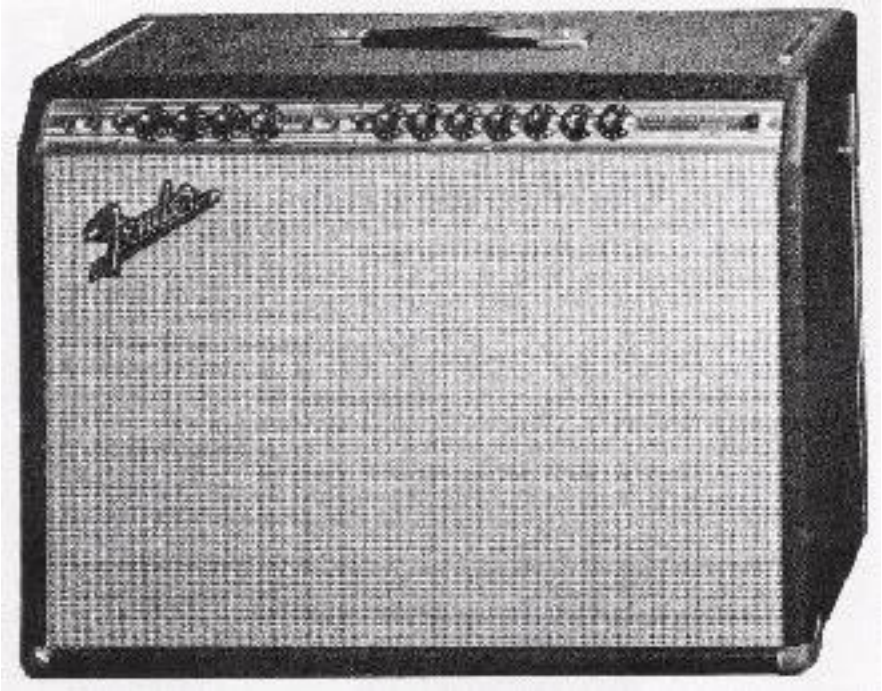
The high frequency end of the spectrum needs careful design, and must be protected from high power at high frequencies which the synthesiser, in particular, is capable of producing. (A synthesiser is the only instrument able to develop the same power at 20kHz as at 40Hz). Some form of protection for the high frequency drivers is therefore desirable, and becomes essential if H.F. horns are used. Such protection will also assist the musician in retaining his/her hearing (although from personal experience I can assure the reader that hearing retention is unlikely).

Passive crossovers are not recommended for high power keyboard systems except at the top end, from horns to "ring-radiators", where they will provide the most cost-effective solution without loss of performance. In general, though, their excessive power loss and the difficulty of optimising the crossover points makes them undesirable. A large keyboard system, then, is basically a very large hi-fi, with colouration being something to be avoided. It is not, or should not, be an extension of the instrument because of the number of different instruments which must be accommodated. Any colouration which is introduced should therefore be controlled by the musician.

Odds and Ends

Equalisation circuits are used in nearly all forms of amplification, and some have become very sophisticated. The old faithful bass and treble controls still exist, but the majority of mixers and amplifiers now have additional controls. Midrange and "bright" have been with us for some time, as has the presence control and graphic equalisers and semi parametric EQ are now being more widely used.

The range of effects available is enormous and growing; the echo, reverb and tremolo of yesteryear have been joined by esoteric devices like automatic double tracking ("ADT") digital delays, phasing, flanging, chorus, true vibrato (frequency modulation), peak limiters, compressors, harmonisers etc and etc.



The simplicity of an amp like the classic Fender Twin Reverb (above) still appeals to many musicians. The Twin Reverb is used by both rock and jazz guitarists, and is also popular with electric piano players.

More important now than ever before are leads and terminations. Cannon type connectors are replacing 6.5mm jacks on most equipment, and guitarists are changing over to Cannons because of their greater reliability. Heavy duty, low loss cables are being widely used, providing less noise and lower failure rate than standard cable, which responds poorly to having a 200kg rack of power amps wheeled over it.

- **Although there was (at the time of writing) a tendency for guitarists to use cannon ("XLR") connectors, this movement has seemingly died. This is a shame, since they are far more robust and reliable than 6.5mm jacks. There are, however, a number of professional locking 6.5mm phone plugs and jacks available, that did not exist when the article was written.**

Well, there you have it. If some of the points made here prove contentious, so much the better, for it will stimulate discussion and debate, both of which go towards a greater understanding of the problems of instrument and amplification. With a better knowledge of the needs of musicians, the technical persons amongst us will be better able to analyse the difficulties encountered by players, be able to pinpoint and maybe even eliminate them. On the other hand, a little technical knowledge will assist the musician in describing his problems, and will be very helpful to the technician or engineer who is expected to solve them, often without even knowing what they may be.

Rod Elliott has many years experience in audio electronics, especially in the pro-audio field. He was a partner in Bumett-Elliott Audio Developments, and has undertaken original design and development work on many different types of equipment. He has written reviews for international publications, as well as technical reports for many instrument-amplifier manufacturers. Rod's current activities (apart from writing for us) include running a four-track recording studio called 'Fly-By-Night, a part-time business, SKAManufacturing, and a full-time business, Elliott Sound Products. Rod also lectures in electronics for the School of Electronics and the Academy of Sound Recording Engineers.

Introduction

This is another of Phil Allison's contributions, and discusses specific experience that Phil has had with short circuit protection circuits in power amplifiers. These are commonly called VI Limiters, since they limit current (I) based on the voltage (V) across the power transistors.

As Phil will explain, not all manufacturers get these circuits right, and the sonic artefacts can be extremely unpleasant. In extreme cases, the very circuit designed (?) to protect the output stage can do exactly the opposite, and cause the amplifier to fail, and / or damage tweeters into the bargain. Have I ever mentioned in these pages that I don't like protection circuits? Hmmm, I thought so :-)

Testing Amplifiers To Their Limits (By Phil Allison)

Virtually any power amplifier would be quickly destroyed by a short on the output if there were no internal limit on the output current. This is because the power supply can deliver a short term power level much greater than the capacity of the transistors used in the output stage. The answer is some form of output current limiting to prevent damage under short circuit or near short condition on the speaker terminals. Many schemes have been used to protect the output devices in an amplifier, from fuses and current trips in the power supply to elaborate electronic circuits.

The most common technique used is known as "VI limiting". A pair of NPN and PNP transistors is connected across the drive signal to the output devices and fed from a resistor

network that senses both the voltage across and the current through them. When the combination of V and I, which is the power dissipation, is more than what can be handled safely then the protection transistors conduct the drive signal away just enough to prevent output transistor failure (see Figure 1).

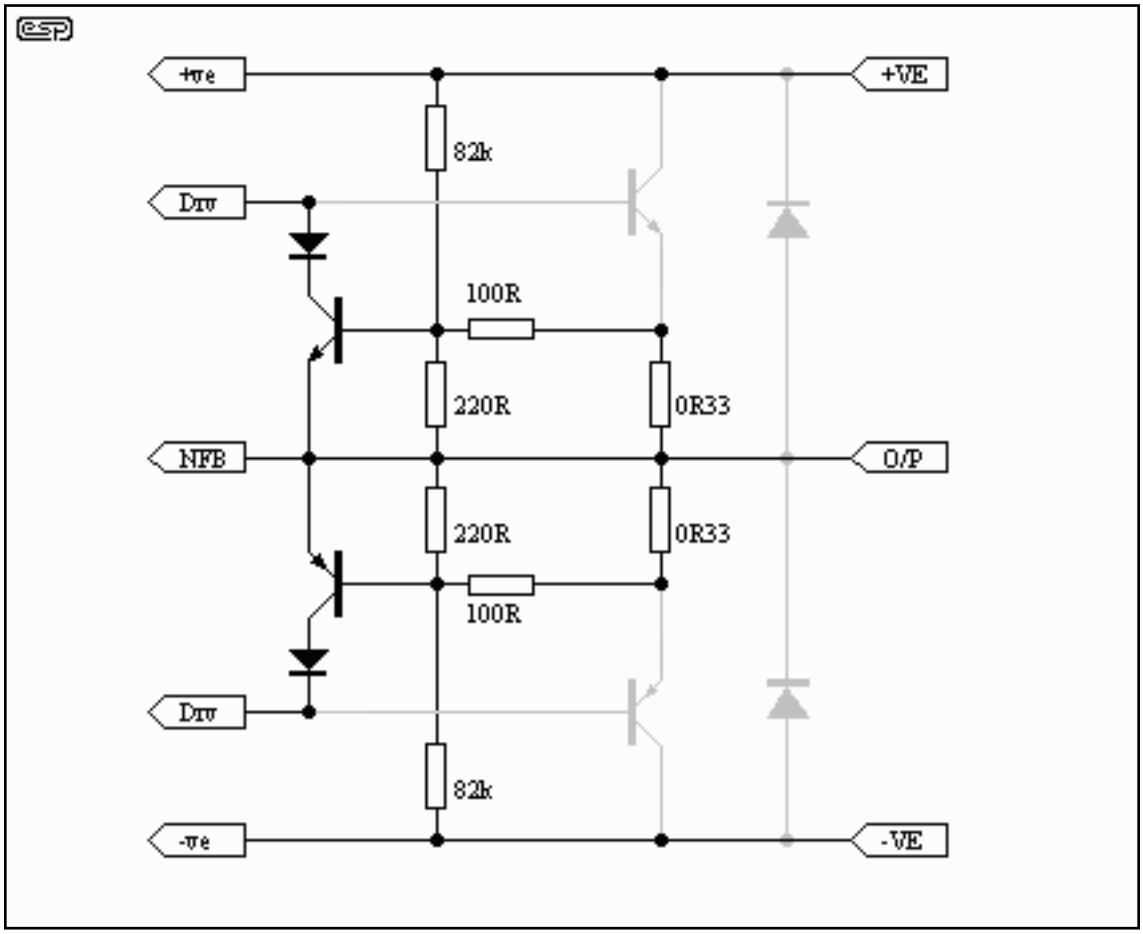

Figure 1 - Basic VI Limiter Circuit

The output transistors are shown in representative form, coloured grey, and may be darlington, compound pairs, or any combination thereof. The remainder of the amplifier is not shown, since this is largely irrelevant to the operation of the protection circuit. The diodes shown in grey are sometimes included (see Editorial Comment).

You may wonder why amplifiers need to deliver any current into a short circuit, after all surely this is a fault situation. True enough, provided all the amplifier ever had to do was drive pure resistors. The problem becomes more obvious when you consider that amplifiers have to drive loudspeakers. Real loudspeakers are a "reactive load", that is their impedance changes with frequency.

For example, a nominal 8 ohm 12 inch driver in a sealed enclosure will have a bass resonance at some low frequency and around that same frequency an impedance peak of 20 ohms or more. At frequencies above 1 to 2 kHz the impedance rises doubling each octave due to the inductance of the voice coil. Systems having tuned ports result in double impedance peaks in

the low frequency range only dropping to the "nominal" value at two points, in the middle of the peaks and at 250 Hz where the figure is often measured. An impedance that rises with increasing frequency is inductive and the opposite capacitive. While a loudspeaker's low frequency impedance peaks are caused mechanically, by the back EMF generated by the moving voice coil, they look to the amplifier exactly as if tuned circuits had been connected. An equivalent electrical circuit can be derived and contains large inductances in parallel with large capacitances. This is in addition to any passive crossover network that may be installed. The amplifier is required to drive this complex load at any frequency and level without distortion. Figure 2 shows the equivalent circuit of a single driver in a sealed enclosure.

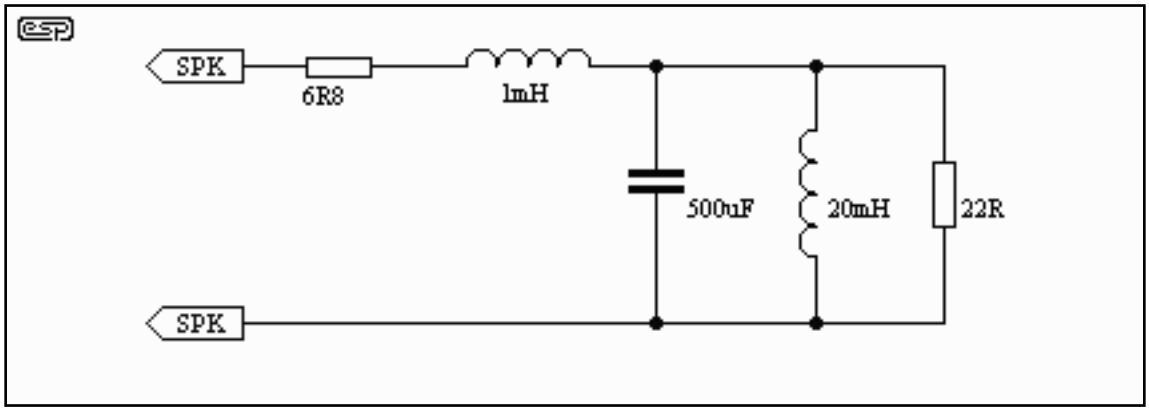

Figure 2 - Equivalent Circuit Of A Typical Loudspeaker Driver

Figure 3 shows the impedance versus frequency for the simulated speaker, and as can be seen, it looks very similar to the impedance response curve you see with many real loudspeakers. This (of course) is the whole point of the exercise.

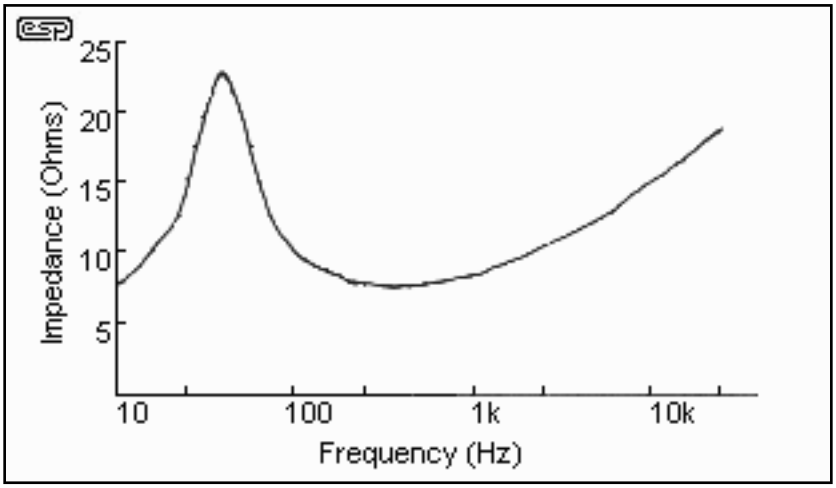

Figure 3 - Impedance Curve Of Simulated Loudspeaker

This can be built using the component values specified in Figure 2, or you may want to experiment further. Attempting to make the simulation "look" like a real loudspeaker system, including crossover networks and additional drivers is possible, but becomes quite complex. Since all speakers are different, this approach is neither suggested nor recommended, due to the cost of trying to re-create simulated versions of even a small number of systems.

Out of Phase Current

A load impedance that is inductive or capacitive has one important characteristic, the current and voltage are "out of phase". Having a current and voltage phase shift means zero volts and zero amps no longer coincide. The amplifier has to produce high current when its output voltage is zero. Also, it will have to produce negative current when the output voltage is positive.

An amplifier which limits heavily into a short circuit can do neither of these things. The amount of out of phase current a good amplifier should be able to deliver is a moot point. Amplifier makers want speaker makers to tame their designs to make life easier for them. Speaker makers reject any restrictions and often produce systems that only the best amplifiers can drive without VI limiting. The market has to sort out which combinations don't work together. This is not a happy situation but it is reality. Amplifier makers take for granted a few facts about speakers. Systems are mostly nominal 8 ohm or 4 ohm and their impedance does not go much below this value as it is close to the DC resistance of the driver(s) involved.

The assumption based on experience and used by many amplifier designers is that the phase angle will at worst be no more than 45 degrees and then be at an impedance that is about 40% higher than the nominal value. For most loudspeaker systems this assumption would be true. The above situation can be simulated by a load impedance formed by a power resistor of 4 or 8 ohms in series with an air cored inductor of about 5 to 10 millihenrys. At the frequency where the phase angle is 45 degrees the load will be either 5.6 ohms or 11.2 ohms (see note 2). Any good amplifier should be able to drive this combination at full level and any frequency without problems. However, even some well known ones don't.

What's the Problem?

If the VI limiting circuit prevents current from reaching the value needed to drive a load at a particular frequency then an unexpected thing happens. The stored energy takes over from the amplifier and dumps a large spike of voltage and current back into the output stage, twice each cycle. Each spike is equal to or more than the amplifier supply voltage and starts around the zero crossing of the wave form lasting about half a millisecond (Figure 4). Such spikes of possibly over 100 volts sound very nasty. They usually don't damage the bass driver but other speaker components (like piezo horns) and even an amplifier has been known to quickly fail because of them.

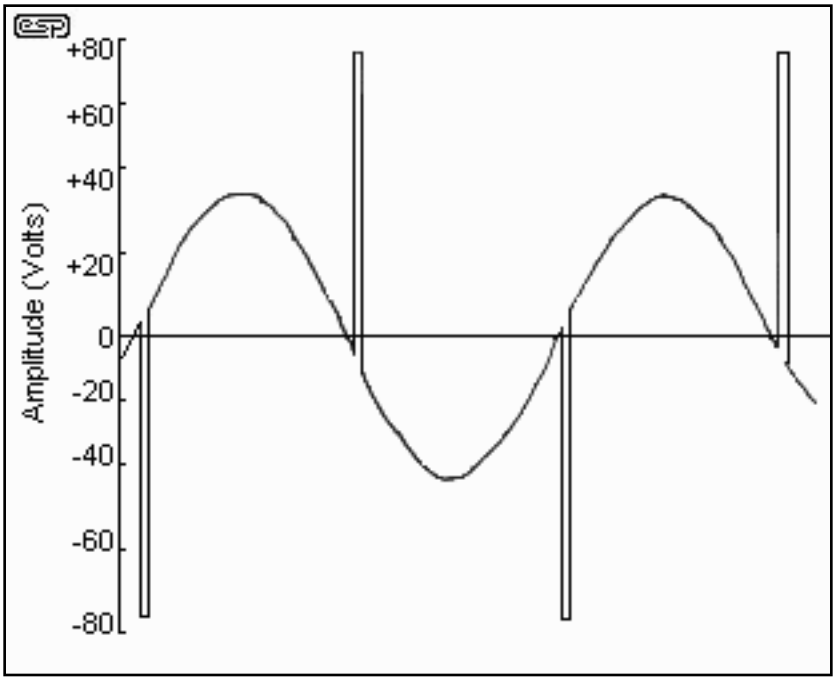

Figure 4 - Voltage Spikes Caused By VI Limiter

Why don't amplifier makers get it right?

Mostly they do. The release in the late 1970s of Hitachi's Power Mosfets eliminated the need for VI limiting allowing most MOSFET amplifiers to have only a simple peak current limit set by zener diodes across the MOSFET gate drive and rely on supply rail fuses to open when the amp was shorted. These amps can drive any known loudspeaker (See note 1). Amplifiers using bi-polar output transistors, even the likes of Motorola's best, are at higher risk of failure and fuses don't blow fast enough. Cost restrictions set a limit to how many output devices can be used, and sometimes the need to prevent output stage overheating and device failures when shorted produces a design which is unable to drive nominal 4 ohm loudspeakers. Another reason for not getting it right is that there is no industry standard for reactive load testing. Resistive load tests are all that are normally done or specified. Similarly speaker makers don't fully specify their products either.

How much out of phase current do amplifiers need?

It depends on the loudspeaker, but the more the better. A first class amplifier is one that can deliver the same current at zero volts as it does at maximum output reducing only when the output swings to the opposite polarity. Such an amplifier rated at 800 watts into 4 ohms would have a short circuit current of at least +/- 20 amps. A lower current capability is often considered acceptable as it will satisfy the majority of loudspeakers, a level of 50% of the maximum output current available at zero volts reducing to zero at full opposite supply. This takes into account the 40% higher impedance expected at the frequency of a 45 degree phase angle and the fact that current is 71% of maximum at zero volts.

Testing the Amplifier

To find what a particular amplifier can deliver in the way of out of phase current requires a couple of bench tests. Neither is complicated or out of the reach of the average technician.

Only a few low cost items are needed - a high power air cored 5 mH inductor (see Note 3) and a 0.1 ohm 10 watt resistor as well as the usual 4 and 8 ohm dummy load resistors.

Test 1
Connect the 5 mH inductor in series with the dummy load and the amplifier with the oscilloscope connected across the amplifier output as usual. Set the sine wave generator at about 250 Hz and using the 8 ohm load gradually increase the level until either spikes are seen or clipping occurs. If there is no problem switch the load to 4 ohms and the generator to 127 Hz and repeat the above. The generator can be swept from 50 Hz to 500 Hz to investigate further for any spiking though if there is no problem at either of the test frequencies then there will usually be no problem at any other. Note the power level at which any spiking occurs.

Test 2
Connect the 0.1 ohm resistor to the amplifier and the oscilloscope leads directly to the resistor. Set the generator to 250 Hz and switch to square wave. Couple the signal into the amplifier input through a capacitor of about 2.2 nF (0.0022 uF). This creates a series of spikes of low average power that does not stress the amplifier. Increase the input level until clipping of the spikes is visible and note the oscilloscope reading in each polarity. Multiply by 10 to get the answer in amps. This test reveals the current available at zero volts and should be compared with the rated output current into 4 or 8 ohms derived from the power output specification. If the positive and negative current readings are asymmetrical or very high there may be a fault with the VI limiting circuit itself or the amplifier is NOT short circuit proof.

Conclusion

A load using a resistor equal to the rated impedance and an inductor in series driven at 45% phase angle allows a simple pass or fail test for an amplifier depending on whether any spikes on the sinewave are heard or seen on a oscilloscope screen. The amount of current available into a short circuit is also a useful guide. It should be 50% of the peak current output into the rated load. Amplifiers that fail these tests may be put on "restricted duties" and used only with 8 ohm nominal loads or speakers that are known as easy to drive. Modification of the VI circuit is always possible but you have to know exactly what you are doing as the output stage may be rendered vulnerable.

Notes:

1. The Perreaux 8000B MOSFET, rated at 800 watts 4 ohms, has a maximum peak current of 60 amps at any output voltage. There are 5 power mosfets in parallel with

zener diode limiting to about 12 amps each.

2. The formula for the frequency for 45 degree phase angle in an RL network is the same as for the -3dB frequency point ... namely $f_{45°} = R / 2 * \pi * L$ For example, for 4 ohms and 5 mH, the frequency is 127 Hz.
3. Any inductor used for testing should be air cored to prevent saturation distortion and should have low resistance. If the resistance is other than negligible, adjust the resistor value to compensate.

Editorial Comment (By Rod Elliott)

Some amplifier circuits show diodes connected between the output and the +ve and -ve power rails - these are shown in grey in Figure 1. The purpose of these should now be obvious - they will "catch" the spikes generated under the conditions Phil has explained. These will (hopefully) prevent the destruction of output transistors by shunting the excess voltage and current back into the power supply which simply absorbs the energy. The diodes prevent the amplifier's output voltage from ever exceeding the supply by more than 0.65 volt or so, and therefore prevent reverse biasing of the transistors under fault conditions.

Needless to say, this provides zero sonic benefit, since the spikes will still occur, but they will now be limited to a little over the amplifier's supply voltage. The amp will probably not self destruct, but it will sound just as horrible when driven beyond its current limits.

High power amplifiers (i.e. anything over about 400W) nearly always use MOSFETs rather than bipolar transistors, and this is especially true of professional units for sound reinforcement. There are very good reasons for this, as Phil has explained.

The ability to drive virtually any load without the need for VI limiter protection is one of the all time great advantages of power MOSFETs. Naturally, the requirement that there are sufficient output devices to handle the load still exists, but MOSFETs are far more tolerant of fault conditions than bipolar transistors, and are not subject to a most undesirable problem known as "second breakdown".

This occurs in bipolar transistors when a small section of the silicon die becomes hotter than the rest due to an overload condition, or where the devices are too small for the job. This increases the gain in that small section, and it therefore does even more of the work, causing it to get hotter still. Thus a repeating the cycle is started, which results in device destruction. This happens very fast (in as little as a few tens of milliseconds), and it is virtually impossible to protect the device once second breakdown has started. The VI limiters are designed to prevent the device(s) from ever exceeding the manufacturer limits where second breakdown is known to occur.

As Phil has shown, some attempts at achieving that goal are somewhat less than a complete success.

- 1 Introduction
- 2 Soft Clip Circuit
- 2 Amp Power Reduction
- 4 Conclusion

---

1 - Introduction

There seems to be something really nice about the idea of soft clipping. Rather than have the amplifier clip any wayward peaks with the traditional square-edged characteristics typical of solid state amplifiers, wouldn't it be nice if they did much the same as a valve amp? A comparison of the two forms of clipping is shown in Figure 1, and you can see that the valve amp's clipping behaviour is more 'civilised' (if any form of clipping can be considered civilised, that is).

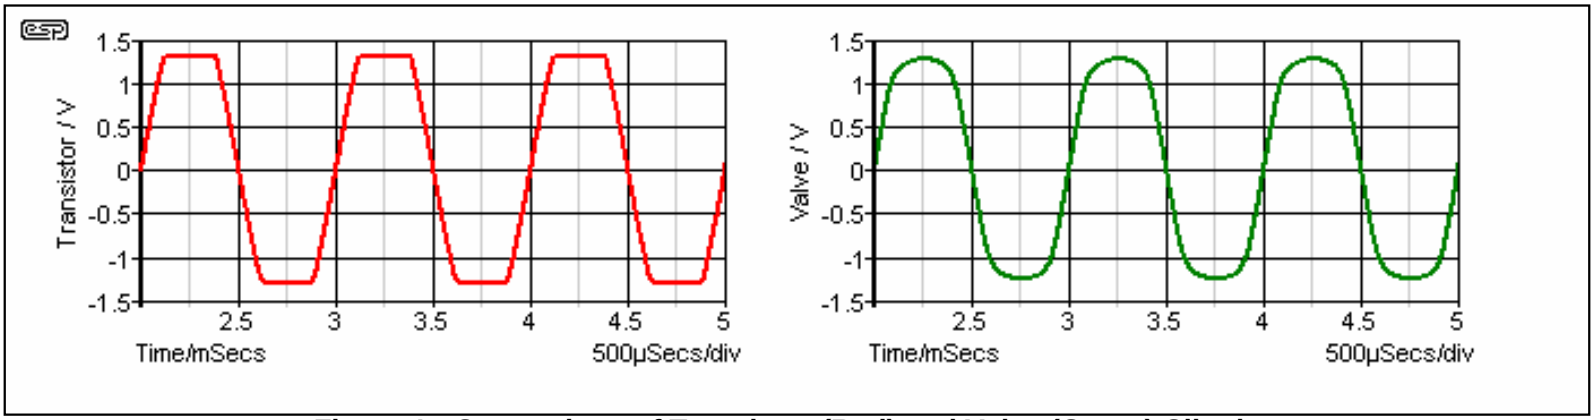

Figure 1 - Comparison of Transistor (Red) and Valve (Green) Clipping

The 'soft' characteristic (Green) shown in Figure 1 has few high order harmonics. The harmonic content is predominantly third harmonic, with a smaller amount of fifth, and lesser amounts of each additional

higher odd-order harmonic. Because the waveform is symmetrical, even order harmonics are typically at vanishingly small amplitudes. Figure 2 shows the harmonic structure of each waveform. Note that the hard clipping produces high levels of eleventh, fifteenth and nineteenth harmonics compared to the soft clip circuit. However, both signals will sound objectionable with the amount of clipping shown.

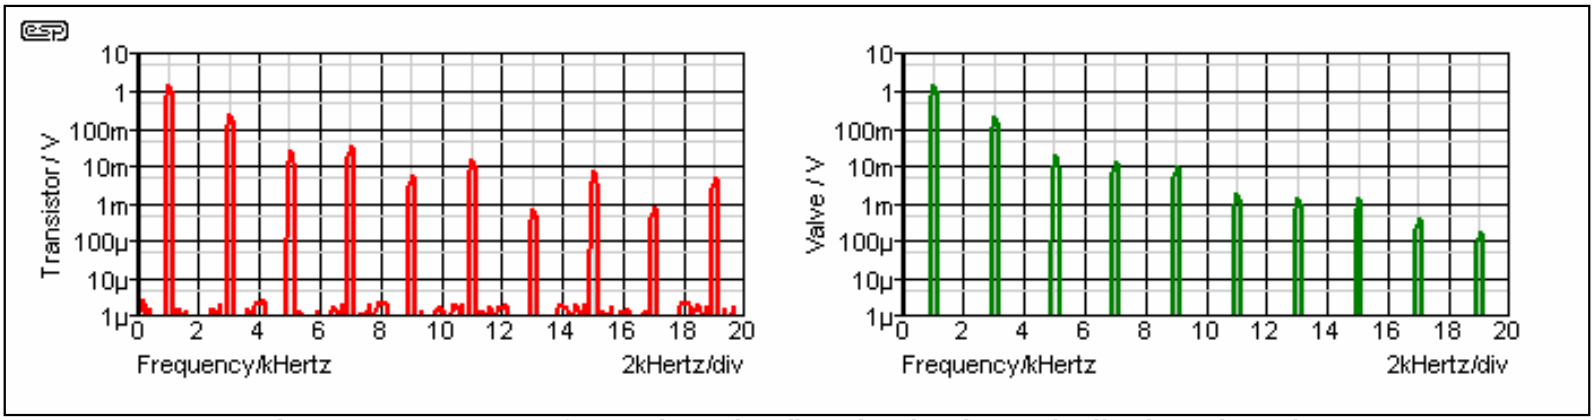

Figure 2 - Spectrum of Transistor (Red) and Valve (Green) Clipping Distortion

Note that the ragged looking transistor spectrum at low levels may appear to be 'bad', but all such signal levels are at about 1uV, so are around 120dB below the amplitude of the fundamental. The spectrum tells part of the story, but the harmonic distortion also needs to be examined. The soft clipped valve-like distortion measures 14.6%, while the transistor circuit gives 17.6% by comparison. In each case, the amplitude of the original (unclipped) waveform was identical, at 2V peak (1.414V RMS). The primary reason for the higher measure distortion of the hard clipped waveform is that the harmonics extend to well over 100kHz at levels exceeding -80dB, while the soft clipped harmonics are below that level by 23kHz.

---

2 - Soft Clip Circuit

Apart from the obvious solution of using a valve output stage (hardly a simple modification to an existing circuit), the easiest way to make a circuit that clips 'softly' is to use diodes. The above simulations were done using diodes, and reality is very close indeed to what is observed in a simulation. There is nothing new about diode clipping circuits - they have been the mainstay of guitar distortion pedals (fuzz boxes) for many years. The deliberate use of this technique for a hi-fi amplifier is less common, and as will be shown below, this is as it should be.

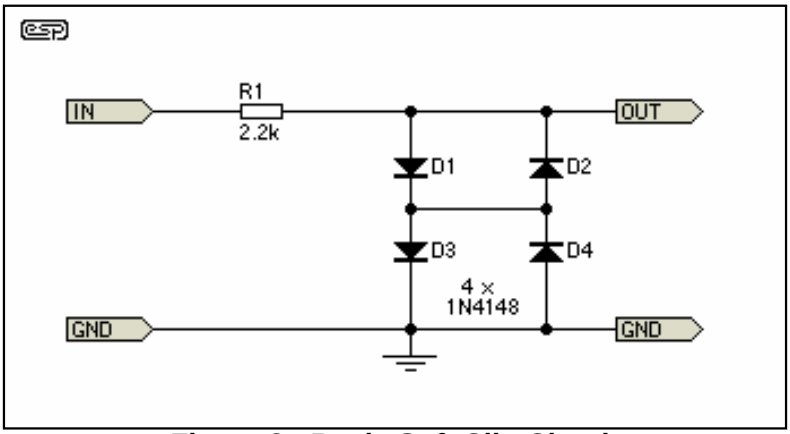

Figure 3 - Basic Soft Clip Circuit

Figure 3 shows the basic schematic of a soft clip circuit. By using diodes, the relatively soft knee of the diode conduction curve provides exactly the waveform that we need. There is an inevitable cost though, and to understand why, we need to examine the conduction characteristics of a diode. It is commonly taken that conventional silicon diodes conduct at 0.65V, although the actual figure varies depending on the type of diode and the current.

The value of R1 is surprisingly very important. If it is too high, there will be considerable distortion at even relatively low levels because of the inherently non-linear resistance of the diodes. If R1 is too small, performance at lower levels is improved, but the source amplifier (preamp, CD player, etc.) may be forced into premature clipping because of the loading. As shown, 2.2k is a reasonable compromise, but if you are willing to include an opamp that can drive low impedances (such as the NE5532 or OPA2134 dual devices), you can reduce R1 to about 680 ohms without having to worry about hard clipping from the preamp.

In Figure 4, it is obvious that not only do the diodes start to conduct at well below the nominal voltage, but they have significant internal resistance as well. It is these very characteristics that give us a soft clipping waveform, and also give us greatly increased distortion as we approach the clipping voltage. The sharpness (or otherwise) of the clipped waveform depends on the signal source impedance and the diode characteristics, and manipulation of the impedance (but maintaining the same diodes) has a very significant effect on the final waveform.

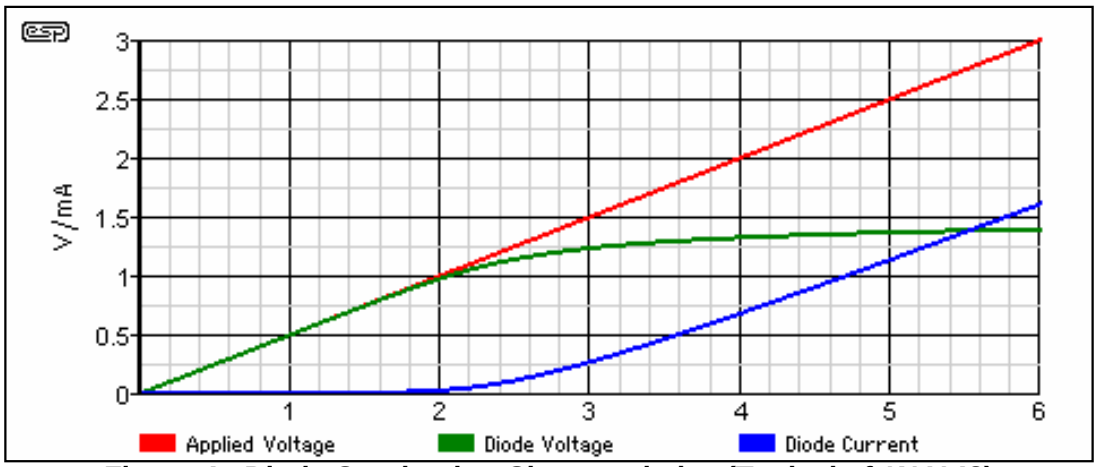

Figure 4 - Diode Conduction Characteristics (Typical of 1N4148)

The supply voltage is applied using a ramp waveform, and the diodes (two in series) are fed using a 1k resistor. As the voltage increases, there is virtually no diode current until the voltage has reached about 1V. At this voltage, diode current starts to flow, and the voltage across the diodes deviates from the applied voltage. As the supply voltage increases further, diode current also increases, and the voltage across the diodes starts to flatten out. You can see that it is not completely flat even at the extremity. The voltage continues to increase at a rate determined by the diode's internal (dynamic) resistance - in the case of the simulated 1N4148 pair used, this can be calculated to be (based on the variation across a defined area of the curve where the curve has flattened out) ...

Voltage change = 3.5mV
Current Change = 21.3uA
R = V / I = 3.5mV / 21.3uA = 112Ω

This is for the pair, so each diode has a dynamic resistance of 56 ohms. Note that you cannot simply use the voltage across the diodes and the current through them to obtain this figure, because of the diode's internal voltage drop. You will get an incorrect figure (that is much too high) if you do that. The point is that the dynamic resistance changes, depending on current. To see this effect properly, Table 1 shows the dynamic resistance (impedance) at each numbered point along the horizontal (X) axis of Figure 4.

Point	ΔVoltage	ΔCurrent	ΔResistance
1	50mV	171nA	292k
2	34mV	7.7uA	4.4k
3	11.4mV	18uA	633
4	5.55mV	21uA	264
5	3.50mV	21.3uA	164
6	2.44mV	21.6uA	112

Table 1 - Variable Dynamic Resistance of 2 x 1N4148

Much as simulations allow the easy determination of things that are very hard to measure, there is nothing like measurement to demonstrate the effects in the real world (as opposed to the cyber-world of the simulator). Accordingly, Table 2 shows a comparison between measured and simulated results, with each using the same basic parameters.

V_{in}	V_{out}	Measured THD	Simulated THD
1	830m	8.9%	7.1%
800m	740m	4.5%	3.0%
700m	670m	2.2%	1.46%
600m	587m	0.81%	0.57%
500m	500m	0.28%	0.19%
400m	400m	0.076%	0.06%
300m	300m	0.036%	0.018%

Table 2 - Measured vs. Simulated Distortion

The simulator under-estimates the distortion, and although it is (probably) more accurate, the measured results are ultimately what really counts. My audio oscillator has a residual distortion of 0.015% at 1kHz, and this needs to be factored in at low measured figures. One thing that is inescapable is that the distortion is increased at all levels. Even reducing the input to 50mV, the simulator still shows a measurable distortion ... although few amplifiers could even hope to get down to the 0.0002% level the simulator indicated.

The value of R1 (as noted above) has a great influence on the circuit's performance. Table 3 shows the simulated distortion levels for a range of voltages and series resistance. Be aware that very few opamps can drive significant levels into low impedances, so this limits the minimum value to around 680 ohms with high drive opamps, and about 1.5k or so with most others.

V_{in}	680 Ohms	1.2k	2.2k
1	4.90%	5.92%	7.08%

800m	1.44%	2.11%	3.00%
700m	0.57%	0.92%	1.46%
600m	0.19%	0.33%	0.57%
500m	0.06%	0.11%	0.19%
400m	0.019%	0.033%	0.060%
300m	0.006%	0.010%	0.018%

Table 3 - Simulated Distortion vs Source Resistance and Voltage

From the above, it is readily apparent that low values for R1 will reduce the distortion below the theoretical diode conduction voltage, but this approach loads the source amplifier. In addition, the dynamic resistance of the diodes becomes more invasive, allowing the clipped voltage to reach a higher than expected peak amplitude. For example, with an input of 2V RMS, 2.2k will cause the peak to limit at 1.32V, 1.2k gives 1.37V, and 680 ohms allows the peak to reach 1.41V. I shall leave this decision to anyone who may be interested in experimenting with the technique.

So, if you want to add a soft clipping circuit, you will benefit from lower levels of harsh high-order harmonics at clipping, but at the expense of effective power output and (much) higher than normal distortion at all levels from as low as about 20% of the maximum output voltage.

---

3 - Amp Power Reduction

If a soft clip circuit is incorporated into an amplifier, it must prevent the power amp from clipping at any sensible input level. Figure 5 shows how the level changes (this is due to the diodes' dynamic resistance) as the input voltage is changed. The red trace is with an input level of 1V RMS, and the green trace is at 5V RMS. Nearly all preamps will allow at least that much drive if the volume control is set to maximum, and this is what tends to happen at parties (and often with professional equipment as well).

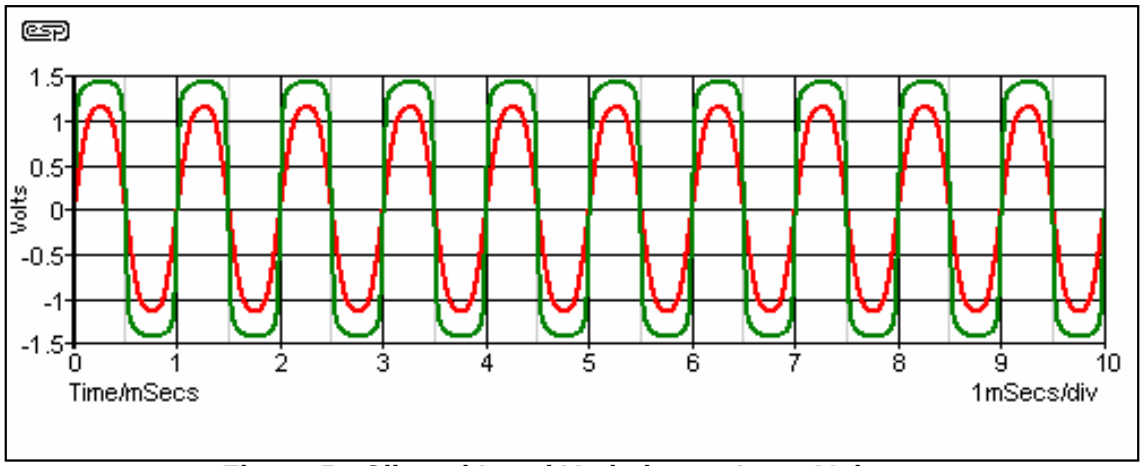

Figure 5 - Clipped Level Variation vs Input Voltage

This is essentially exactly the same information as shown in Figure 4, but uses the signal waveform. For the exercise, let's use a 100W (8 ohm) amplifier as our model, and we will apply a soft clipping circuit to it. Using the 4 diode clipper shown in Figure 3, we can do some basic analysis.

Allowing up to 5V input is probably silly, so we'll make that 2V, after which traditional hard clipping will

occur. A 100W/8 ohm amplifier will give about 28V RMS at the speaker terminals (40V peak). We have allowed for 2V input, so the gain needed (after the clipping circuit) is ...

Peak Input Voltage = 2 * 1.414 = 2.83
Peak Clipped Input Voltage = 1.32 (from Figure 4)
Gain = V_{OUT}/ V_{IN}= 28 / 1.32 = 21

The gain needed is achieved using a 20k resistor from output to inverting input, and a 1k resistor to ground. So far so good. Now, we need to decide on the maximum distortion figure we are willing to accept at a 'typical' peak output power. 1% is not unreasonable - certainly higher than we would expect from a transistor amp, but not unreasonable.

From Table 2 we see that with an input level of 700mV (RMS), distortion is 2.2% (measured) or 1.46% (simulated). The input level obviously needs to be a bit less than this, so 650mV is probably about right. The simulator says that this gives 0.94% which is close enough. The actual amplifier power at 1% distortion is determined by ...

V_{OUT}= V_{IN}* Gain = 650mV * 21 = 13.65V
Power = V^2/ R = 186 / 8 = 23W

Oh dear! A perfectly good 100W amp is now downgraded to 23W at 1% distortion, with the distortion rising quite rapidly above that. Sure, the distortion components will be low order odd harmonics, but intermodulation distortion is increased proportionally as well, and the otherwise distortion free (relatively speaking) amp output cannot be used to its full advantage. Use of a lower value feed resistance (R1) will improve matters, but as noted above may create other problems.

Will it sound like a valve amp though? Not really. While the distortion characteristics will be similar to a reasonable push-pull valve amp of roughly similar power, the higher than normal output impedance of a valve amp is another factor that gives the 'valve sound'. While this can be included as well, the clipping circuit cannot compensate for the gain variations in an amp with high output impedance.

---

4 - Conclusion

The effects of the soft clipping circuit can be modified over a wide range, by varying the feed resistance, type of diodes used and the peak levels expected. In general, the result is unlikely to be as hoped for anyway, because occasional transient clipping is usually inaudible. The harmonic and intermodulation distortion that has been added may be very audible with some material, and is unlikely to improve your enjoyment of the music.

Of course, you may find that you do like the effect (it is very common in guitar amps), so if you think that you'd like to experiment then you have enough information to make an informed decision as to how to go about it.

There is nothing that looks complicated at all in this technique, but as should now be evident, there are actually quite a few things that must be considered. As is so often the case, an apparently simple circuit can be far more complex than anticipated, and it is a matter of juggling the compromises to obtain the

results you want - within the limits of the technique.

While it would be relatively easy to incorporate the soft clip function into a DSP that may be providing other functionality (equalisation, crossovers, etc.) and avoid some of the limitations, the definition of a soft clip circuit requires that it should start to distort the signal earlier than expected. In the end, it is probably far easier to incorporate a clipping indicator so that clipping can be avoided altogether.

Introduction

Over the past few decades, there has been much musing, discussion and outright argument about the need for wide bandwidth in audio systems. Unlike most other discussions, I am not referring to extension to 30 or even 50 kHz, but well into the RF spectrum. There is apocryphal "evidence" that high speed amplifiers sound better, although after years of such debate and argument, no-one has been able to shed any light as to the possible reasons why this may be the case.

After an e-mail from Texas Instruments and a package of evaluation boards, documentation and a selection of high speed opamps, I started thinking about this issue seriously. The original aim was simply to have a look at an xDSL line driver, which was thought to have great potential as a headphone amp, and this is most certainly true - initial tests are described below, and a project describing its use is in production.

The real thing that got me to thinking was the seemingly impossible claim that different interconnects sounded

different. The tests I have run indicate that the differences between materials is so slight that it is all but immeasurable, and this is backed up by various others who have taken a similarly scientific approach, although in many cases to a far greater degree of refinement than my own testing. Despite all the tests, there still seem to be situations where different cables sound, well, *different*.

The following is somewhat speculative, since I don't have a radio frequency interference (RFI) problem where I live, and I am understandably reluctant to create some so I can test my theory properly. Lacking a fully shielded room (Faraday cage), and a large amount of very expensive test gear, it is very difficult to prove anything one way or another.

Nonetheless, I think that the discussion to follow may prove to have some merit - I am very interested to hear any feedback from anyone who is in a position to test the ideas that follow. The theory is quite solid, but the final proof is naturally in the listening and evaluation - provided it is done in a scientific and controlled manner. Any single non-blind (as opposed to a properly conducted double-blind) evaluation is a waste of everyone's time, as the results are purely subjective.

---

1. The Need for Speed

Although you will not see it written very often, the venerable uA741 opamp is quite fast enough for audio, despite the fact that it has a slew rate of only 0.5 V/us. Contrary to popular belief, audio does not have super fast transients, since the sounds we hear are predominantly created by mechanical or biological means. No mass (including air) can change its direction instantaneously unless an infinite force is used, and although I have come across a few pretty strong drummers (for example), there are none I would describe as "infinitely powerful". These simple mechanical laws (and the filtering used on CD), prevent the generation of very high order harmonics that are needed to produce extremely fast risetimes.

There is considerable evidence to show that many instruments (as well as speech) create harmonics in excess of 50 kHz, but they are low level, and do not (generally) contribute to fast rise times on transients. Having said that, it is universally agreed that the 741 is a sonic disaster - they sound bloody awful. To understand some of the reasons, we need to look at the frequency response, and its effect on the overall behaviour of the opamp.

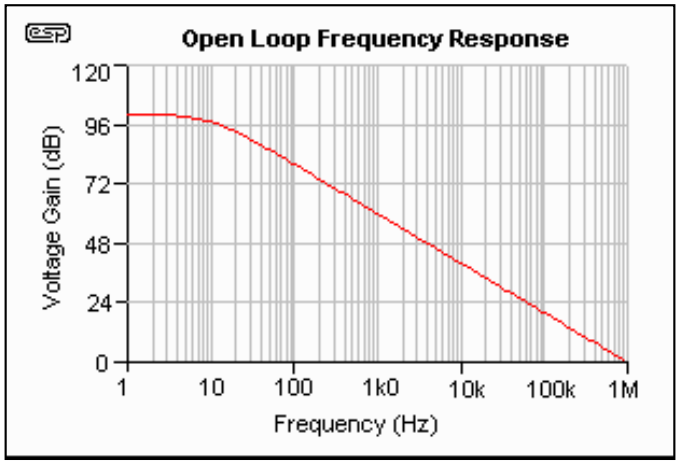

Figure 1.1 - uA741 Frequency Response

As you can see, there is a vast gain, but only at low frequencies. The internal compensation capacitor rolls off the response above 10 Hz, and this means that as the frequency increases, there is less and less feedback to correct the internal distortion. For the purposes of this discussion, there is a more insidious (and less well publicised) effect - the output impedance rises with increasing frequency. For reference, the closed loop

response is shown, where the gain has been set at 10 (20 dB). As you can see, the opamp is struggling to maintain output at 20 kHz, and at slightly above this frequency, *it has no feedback at all*!

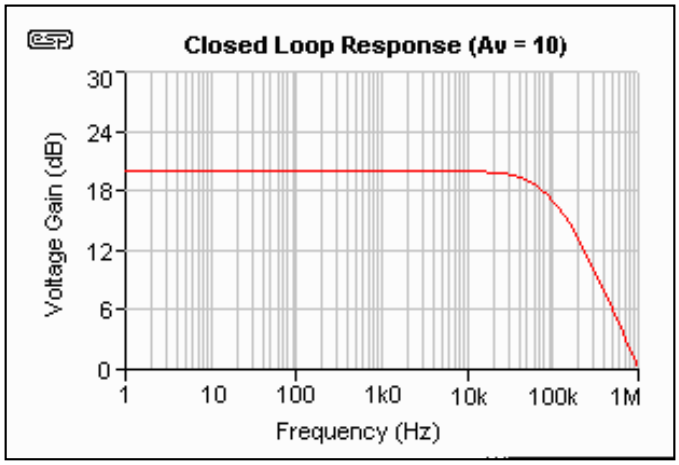

Figure 1.2 - uA741 Closed Loop Response

Even at 10 kHz, the gain has dropped sufficiently that there is little feedback available. It must be said that even gross distortion at 10 kHz is inaudible with a single tone, but intermodulation products are generated as a result of the multiple frequencies that are present with music. The effects of such distortion do not seem to have been covered in any great detail in most journals and articles, but tests do exist. They are never applied in reviews, nor are the results quoted in manufacturers' data.

The high frequency intermodulation products caused by the distortion at high frequencies may well be one of the reasons that wide band opamps are said to sound so much better than the likes of the uA741. Even so, the best of the best VFB opamps will still have the same problem - only the degree is different. There is no VFB opamp that has an open loop bandwidth that extends beyond about 1 kHz, so they will all suffer from a frequency dependent reduction in feedback factor, a consequent rise in distortion, and increase in output impedance.

This is where the use of very fast opamps becomes potentially important. A cable terminated by a zero ohm source will pick up very little external noise, and cable noise (microphony) is all but eliminated because it is the result of an extremely high impedance "generator" - the conductors and insulation material of the cable. Zero ohms is an impossible figure at best, and nearly all opamp circuits require a resistor in the output to prevent oscillation when a cable is connected. The "cable oscillation" topic is covered further a little later.

Even with a resistance of 100 ohms in series, the impedance is sufficiently low as to be quite effective in preventing noise pickup (including RF), and will still virtually eliminate microphony. Except ... as the frequency increases, so too does the opamp's output impedance. The 100 ohms at 1 kHz (for example), becomes greater even as low as 10kHz, reducing effectiveness further and further as frequency increases. By 10 MHz, the opamp's output is effectively an open circuit, having an impedance many times the characteristic impedance of the cable. At lower frequencies where opamp impedance is low, the 100 ohm resistor is a passable match to the cable, but only at one end. The cable *will* become resonant at some frequency, determined by the length of the cable, its effective inductance and capacitance, and its velocity factor. This happens with all cables, regardless of price, silver, wire size, or soaking in snake oil !

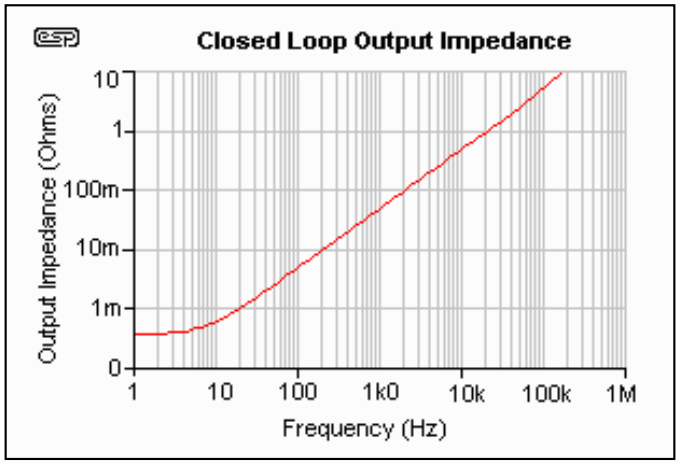

Figure 1.3 - uA741 Output Impedance Vs. Frequency

For effective shielding and transmission of RF, a cable is normally terminated at each end with its characteristic impedance. This impedance matching (source to cable to receiver) is essential to prevent reflections and standing waves at the operating frequency. Audio cables are not so terminated, and although this has no effect at audio frequencies, it potentially reduces the effectiveness of the cable at *rejecting* interfering RF signals. (It is actually undesirable to match the impedances in audio, as there is an inevitable 6 dB increase in noise, due to the reduction of signal level.)

The interfering RF affects not only the receiving circuitry, but the transmission end as well. RF signals that find their way into the output of an opamp that has a limited bandwidth (and high output impedance at the interfering frequency) can have a very profound effect on the sound quality. Non-linearities will always exist in any electronic equipment, but are normally reduced to very low levels (but never eliminated) by feedback. When the opamp (or any other low impedance output amplifying device) has a signal fed into its output that cannot be reduced to near zero by the low output impedance, the signal is fed back into the input, where rectification (AM detection) can take place. This phenomenon is often observed when equipment picks up AM radio stations, but with a high resolution system, there will be audio degradation well before the interfering signal is discernible as a radio station.

The problem may be exacerbated by the use of a feedback capacitor (as shown in Figure 1.4), which provides a low impedance path from the output back to the -ve (inverting) input. In theory, this also reduces the gain (and therefore the available feedback), but as shown, a 741 type opamp has no gain at all above 1 MHz, so any feedback path above this frequency will simply cause problems. This technique is common with fast VFB opamps, and "seems" not to cause any problems. This is a reasonable assumption in the case of an internal amplifier stage, but needs further investigation when output stages driving cables are concerned.

It is worth noting that this form of feedback will simply cause a current feedback opamp (such as the THS6012 described here) to oscillate, and must not be used under any circumstances.

Another technique I have not seen used in any commercial equipment except for power amplifiers (where it is almost mandatory), is a Zobel network at the output of preamps and other low level signal sources. This will ensure that the cable is terminated by a low impedance at nearly all frequencies, but this is difficult with opamps having limited high frequency response since the additional loading will only make distortion worse. An explanation of how (and when) this is useful will be covered later in this article.

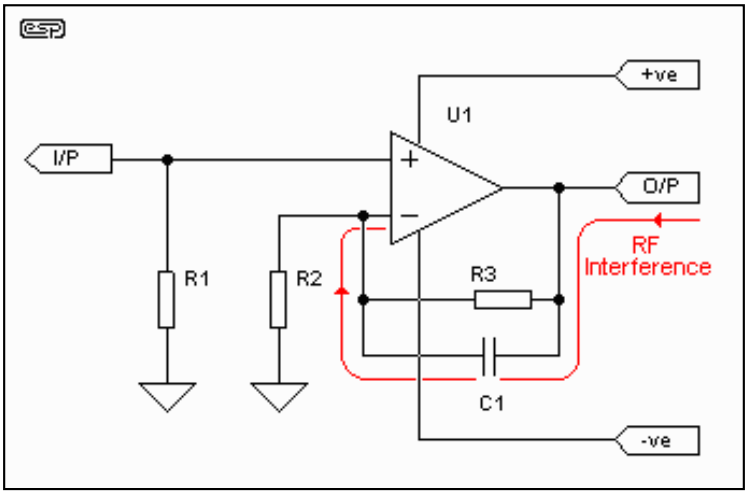

Figure 1.4 - Feedback Cap Provides RF Path to Input

The sources of interference are wide and varied. Some interfering signals are within the audio range, but the majority are radio frequencies, starting from the AM broadcast band at about 600 kHz, extending to the CB band (27 MHz), then through to amateur, commercial, TV bands and upwards. Other commercial sources of narrow band interference include RF welding equipment (used for welding plastics), microwave ovens, mobile phones and the like (although digital mobile phones are hardly narrow band, since the signal is pulsed).

In addition there are residential and commercial sources of broad band interference - brush type electric motors, arc welders, switching systems, arcing insulators on the power distribution grid - the list is almost endless.

Although it may seem that so far I have simply beaten the poor uA741 to death, it must be said that there are many other opamps that are very much faster, and also provide lower distortion, higher open loop gain and far lower noise. Even the very best of these still suffer similar problems at high frequencies (above 100 kHz), since they are designed for relatively conventional audio frequency applications. This does not necessarily mean hi-fi - there are a great many applications for the audio frequency range that have nothing to do with "audio" per se.

In case you were wondering, the noise pickup effects described above do not mean that you should rush out and get new cables. This has nothing to do with cables themselves, but has everything to do with the amplifier driving the cable, and/or receiving the signal at the other end. With the proper techniques in place, a coathanger will outperform the most expensive cable you can buy (assuming of course that shielded coathangers are available where you live :-)

A conversation with a friend recently uncovered the fact that he had a customer with an RF interference problem. Substituting the original opamp for one with a much wider bandwidth (in this case he used an OPA2134) solved the problem. A Zobel network was also added, and this managed to help the original opamp cope a little better, but could not eliminate the interference. I don't know what the original opamp was, but in any consumer equipment we can safely assume that it was cheap and nasty.

---

2. High Speed Opamps

Enter the (relatively) new devices from Texas Instruments. These were designed for xDSL (e.g. ADSL, or Asynchronous Digital Subscriber Line) applications, which use a large number of high frequency carriers to convey the data via multiple simultaneous channels (255 in the case of ADSL) . The carrier frequencies are

closely spaced, so very low distortion is essential to minimise cross-modulation of the carriers (basically intermodulation distortion). At the far end of an analogue telephone line the signal may be greatly attenuated, so low noise is also important.

The above specifications already sound very satisfactory for audio - low noise and distortion are requirements in nearly all hi-fi applications, but there's more. Unlike traditional voltage feedback (VFB) opamps, these new devices are current feedback (CFB), and have an extraordinarily wide bandwidth, so the degradation at the very highest audio frequencies is negligible, and there is no significant rise in distortion or output impedance until above at least 10 MHz. Indeed, the performance of the THS6012 in this regard is as good or better at 100 MHz than the uA741 at less than 100 kHz.

The fundamental difference between VFB and CFB opamps is quite simple ... well, it *is* when you simplify it to the level I am about to

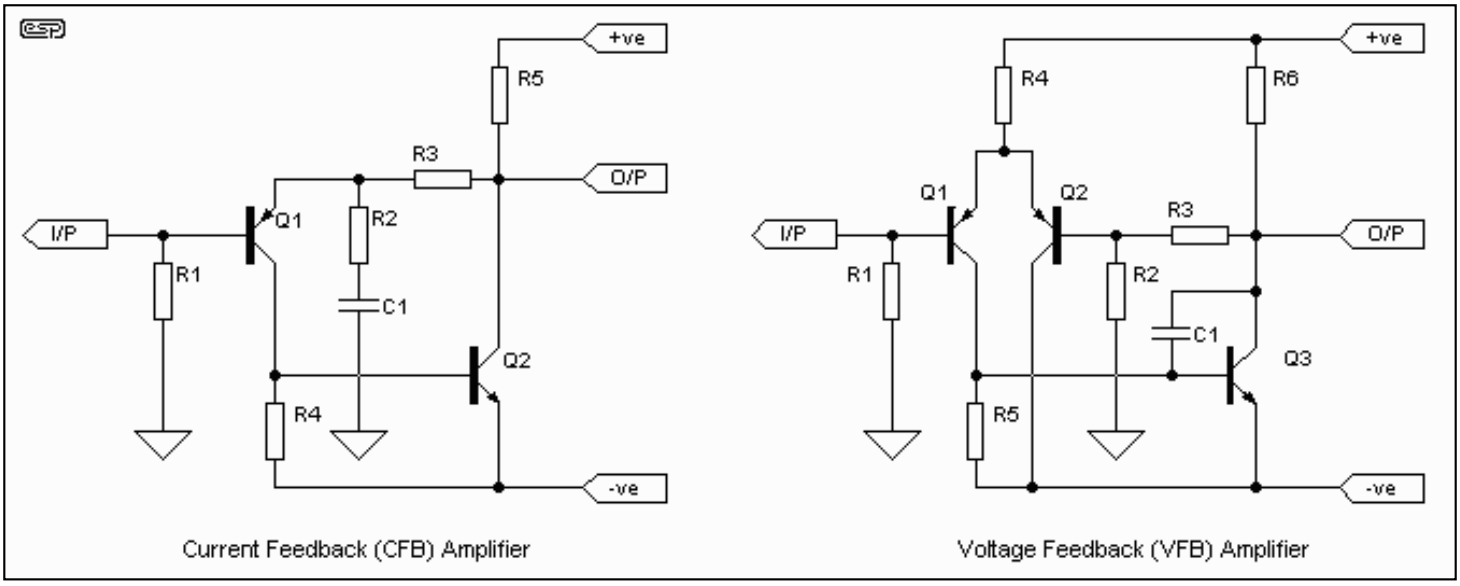

Figure 2.1 - Simple CFB and VFB Opamps

As well as those shown in Figure 2.1, other perfect examples of VFB versus CFB are some of the ESP published projects - the "El Cheapo" power amplifier is CFB (as is DoZ and the minimalist preamp), while the 60-100W and P101 MOSFET Hi-Fi amplifiers are VFB. The first thing one should notice that is different, is that the CFB amplifier has no Miller capacitor (also called the Dominant Pole). This is normally connected between the collector and base of the Class-A driver transistor. This is an absolute requirement for stability in a VFB amplifier, but with care, can be eliminated entirely (or at least reduced to a very much smaller value) in a CFB amp.

The result is a much wider open loop bandwidth for CFB amplifiers, but there is no longer any simple way to ensure DC levels through the amplifier are not shifted. In the case of the DoZ amp, minimalist preamp and El Cheapo, the DC shift problem is avoided by using capacitor coupling, but this is not always convenient or desirable. The issue is solved (at least to an acceptable degree) in the TI devices I have been testing, so DC offsets are not as big a problem as with relatively simple discrete designs.

Most commonly used opamps are VFB, and as such have an inverting and non-inverting input with approximately equal impedances. They may happily be used as either inverting or non-inverting amplifiers, and they are quite predictable in normal use. CFB opamps (to some degree) sacrifice DC accuracy for bandwidth, and this is done by eliminating the differential pair normally used as the input stage.

The gain in both the amps shown in Figure 2.1 is set by the ratio of (R2+R3) / R2, as one would expect, although it is not very accurate with the CFB amplifier (another of their little foibles). In the CFB amp above, C1 is needed because DC operation is not possible with this simple configuration. In a simulation done previously (see Amplifier Design), the VFB amp provides an open loop voltage gain of 1,640 (64dB). By comparison, the open-loop gain of the CFB amplifier is 2,190 (67dB) - considering that all other things were maintained equal, the open loop gain is somewhat better.

The real difference is the bandwidth, which was not shown in the original article. The CFB amp can provide an open loop -3dB frequency of over 1MHz, while the VFB amp (using a 33pF Miller cap) only manages 30kHz. These figures are much better than any normal opamp, but it must be pointed out that the noise and distortion figures for these simple circuits will be somewhat lacking compared to a premium opamp.

When the gain is reduced to 20dB (10 times), the -3dB frequency of the VFB amp is 5.6MHz, which is not too shabby at all. At the same gain, the CFB amp really shows its true colours, with a -3dB frequency of 67MHz - better than 10 times the bandwidth! In addition, the CFB amp has a much flatter phase curve, indicating that stability is potentially much better. The 33pF capacitor used in the VFB amp is likely to be marginal in real life, and depending on the transistors used, may need to be increased to prevent oscillation.

As one might expect, there are disadvantages to the CFB configuration as well. As well as DC offset, there is also a lower input impedance and higher bias current. This means that for optimum results, the source impedance should be very low - this is not an issue with video distribution amplifiers or ADSL equipment, since the source impedance will typically be 50 or 75 ohms. It can be an issue in audio, and in many cases a unity gain buffer will be needed in front of the CFB amplifier.

In addition, CFB opamps have different impedances for the +ve and -ve inputs. Conventional opamps use the same topology for each input - almost invariably a long-tailed pair (a.k.a. differential amplifier). As discussed in the Amplifier Design article, using this input stage means that a Miller capacitor is essential to maintain stability. The CFB opamp has a non-inverting (+ve) input that is moderately high impedance, and an inverting (-ve) input that has an extremely low impedance. As discussed above, the gain accuracy as set by the gain and feedback resistors (R2 and R3 respectively) is not as good as a VFB amp, and some tweaking of the gain resistor will be needed to obtain a precise gain.

The common unity gain buffer (where the output is tied directly to the inverting input) is not possible with a CFB amplifier, and a resistance must always be used. In addition, the resistance value is critical to stability and bandwidth - if it is too high, bandwidth suffers, and if too low the amplifier will peak at some high frequency, and may easily become unstable. At very low values (or zero ohms), instability is guaranteed, and the amplifier *will* oscillate.

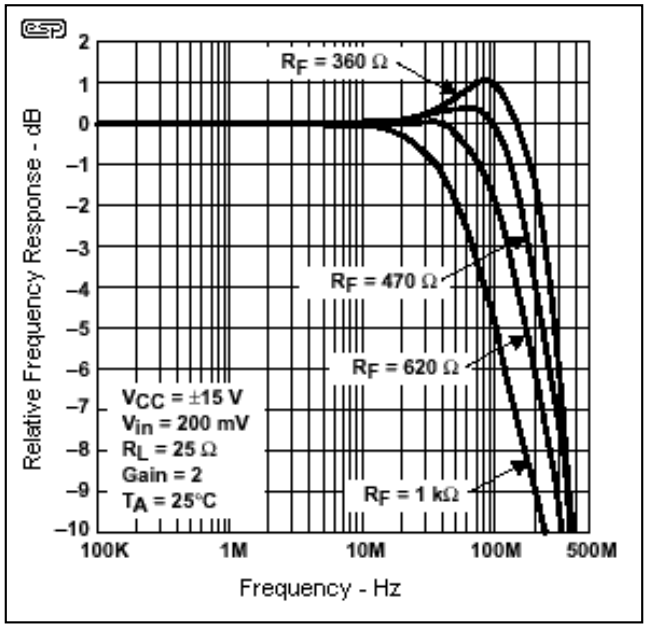

Figure 2.2 - Relative Frequency Response Vs. Frequency

Figure 2.2 shows the relative gain for various values of feedback resistor (adapted from the TI data sheet). The voltage gain is set at 2 (6dB), and as you can see, when using a 1k feedback resistance (the recommended compromise value), the amp is 3dB down at about 70MHz. Reducing the value will extend the -3dB frequency to around 250MHz, but at the expense of some peaking.

Even when set for a gain of 1000 (60dB), the THS6012's response is almost flat to 1MHz - this is more than an order of magnitude better than any compensated VFB opamp I know of - regardless of manufacturer or price. As an example of the difference, the NE5532 (dual internally compensated) will barely make it to 20kHz at the same gain. The NE5532 has a maximum open loop gain of 100dB, but only up to 1kHz - and these are still one of the fastest VFB opamps available. It is worth noting that VFB opamps must always be compensated (most commonly using the Miller or dominant pole capacitor) whenever feedback is applied. If not, they will oscillate.

For audio purposes, we don't need anything above 100kHz, but an extended response ensures that the interconnect will be terminated with a low impedance at nearly all potential interfering frequencies. This can be extended easily by using a simple RC filter at the output of the preamp. More on this later.

2.1 Cable Impedance

The impedance of cables receives little comment in the audio industry (other that for telephone circuits), and within the audio frequency band, this is perfectly reasonable, since it is unimportant. Where it is important is in RF work, but it is becoming more and more common that the two are combined - not because audio has become faster :-) but because the sheer amount of RF pollution is increasing every day.

The sources of RF interference (RFI) are discussed above, but the concept of cable impedance is such that it is worth covering here - albeit briefly. There are some cables that are quoted as being a specific impedance - 50 or 75 ohm coax, 300 ohm TV twinlead and 120 ohm unshielded twisted pair (UTP) for data connections are some examples.

The characteristic impedance of a cable is influenced by a number of factors, and it is easily calculated - although I shall spare you the gory details here. Where cables become sneaky, is when they are a specific

length compared to the wavelength of the signal. This is unimportant at audio, since the cable is always very short compared to wavelength, and the telephone system is the only audio application where impedance *is* important. This is due to the very long cable runs, up to 4km or more in some cases.

The wavelength is calculated by the following formula ...

Wavelength = C / f where C is velocity and f is frequency

For sound in air, C is 345 m/s, but in the electrical domain (in free air or a vacuum), C is 3 x 10^8 m/s. The velocity is reduced in any cable, and in a typical coaxial cable, the velocity is typically about 2.4 x 10^8 m/s. This means that for a 70MHz interfering signal, the wavelength is 3.42 metres.

RF is sneaky and cunning, and does not behave in what we might think is a sensible manner. A length of coax 857mm long is 1/4 wavelength at 70MHz. If one end is short circuit, the other end "looks" like an open circuit. An open circuit at one end appears to be a dead short from the other! If an audio cable is unterminated at each end, the final effect is completely unpredictable if RF fields are present, and it is just as likely to act as an antenna. The shield will not necessarily protect the inner conductor, but is quite capable of inducing a signal into it. Being unterminated (or marginally terminated at one end only), the interconnect is now capable of injecting RF into the amplifiers' inputs and outputs - with unpredictable effects on sound quality.

As far as I know, there are few tests to determine the susceptibility of most audio equipment's interconnects to the effects of RF over a wide range, but there is considerable evidence to show that many amplifiers are afflicted. Make a call on a digital mobile phone near most amps, and the characteristic noise is unmistakable. What more subtle effects do lower RF levels have? I don't know, but I doubt that they will enhance the listening experience.

So much for the technobabble. (For the time being, at least.)

---

3. THS6012 Dual Line Driver

There are two devices that I shall concentrate on, being those for which samples were supplied by TI. These are the THS6012 (500 mA dual differential line driver) and the THS1431 (High speed, low noise, fully differential I/O amplifier). Highly suitable audio uses are presented for each device, but it must be said that implementation is not trivial. Because of the wide bandwidth, these devices can (and do, I can assure you!) oscillate unless proper precautions are taken. Bypassing is critical, as is the PCB capacitance - especially at the inverting input. Even a few pF to earth from the inverting input will cause frequency peaking and possible oscillation, and when one of these little guys oscillates at 100 MHz or more, the current consumption (and subsequent device heating) can cause major problems.

A very brief specification of the THS6012 ...

- ADSL Differential Line Driver
- 400 mA Minimum Output Current Into 25 Ohm load
- High Speed
  - 140 MHz Bandwidth (–3 dB) With 25 Ohm load
  - 315 MHz Bandwidth (–3 dB) With 100 Ohm load
  - 1300 V/us Slew Rate, Gain = 5
- Low Distortion
  - –72 dB 3rd Order Harmonic Distortion at f = 1 MHz, 25 ohm load, and 20 Vpp output
- Wide Supply Range ±4.5 V to ±16 V

- Thermal Shutdown and Short Circuit Protection

The THS6012 is probably of greatest interest to the audio fraternity, simply because it is a dual amplifier, and is suitable for use in preamps or as a headphone amplifier.

A preamp with such a wide bandwidth is not possible with any conventional VFB opamp, but the input impedance of the THS6012 is somewhat lower than an OPA2134 or other premium opamp, and the maximum gain will be somewhat lower before oscillation becomes an issue. Remember, we are discussing an opamp with a bandwidth of up to 315 MHz - this is in the UHF (Ultra High Frequency) RF band, a mysterious place where circuit design is as much a black art as a science.

Note the slew rate, which is quite exceptional, and the distortion is quoted at 1MHz, and at 20V p-p into 25 ohms! Lower frequency or voltage, and higher impedance loads reduce it even further, and at audio frequencies is extremely low. So low in fact that I cannot measure it with my equipment (grumble).

3.1 THS6012 CFB Opamp Headphone Amplifier

Because of its high drive current, the THS6012 seemed imminently suited to a headphone amplifier, and indeed, this was the suggestion originally made by TI. Before I describe the technicalities, I will answer the question "So how does it sound?"

Quite frankly, I was disappointed. There was absolutely nothing that sounded of "amplifier" - this is probably as close to a straight wire with gain as you are likely to find. There is nothing I can say about it, other than it is as clean, tight and transparent as anyone could hope for. Bass response extends to DC, and even after the addition of a capacitor across the input to limit the HF response, it was only 0.1 dB down at 100 kHz. In short - the performance is exemplary in all respects.

In the best traditions of the subjectivists, it would be nice to be able to say "Oh, yes - the imaging is to die for, and the highs are sooo transparent". The foregoing may well be true, but me, I listen for noise and other artefacts, measure distortion (if possible), verify frequency response, and generally judge an amplifier on its accuracy. The THS6012 is exemplary in all respects, but (there has to be a down side) the input impedance is somewhat lower than one might expect, and because of the extremely wide bandwidth, instability can be a real problem if the proper precautions are not taken.

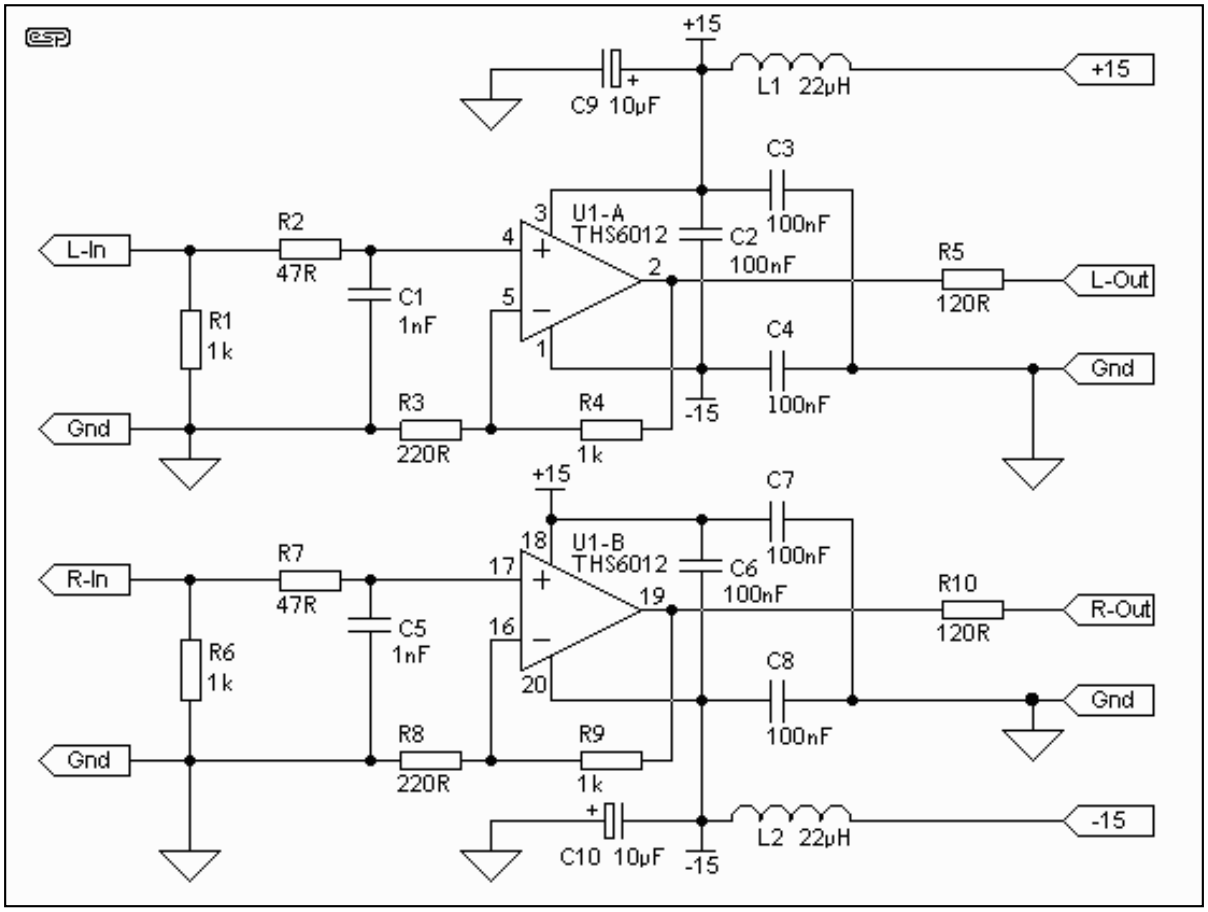

Figure 3.1 - Headphone Amplifier Test Circuit

As discussed above, this device uses current feedback (rather than voltage feedback as used in the more traditional audio opamps). In this case, the current feedback requirement means that the feedback resistors will be of a much lower value than "normal". I configured the amp with a gain of 12 (21.7 dB), and the output level was more than sufficient to cause hearing damage (if you like that sort of thing). Ideally though, the THS6012 should be operated at a lower gain, as this helps to reduce the chance of oscillation. Accordingly, most of the gain will be in a prior stage, and assuming that a high quality opamp is used, the overall performance is astonishing. A simple gain stage based on an NE5532 or OPA2134 dual opamp will be more than sufficient. If direct coupled from an opamp stage, R1 and R6 should be omitted to prevent excessive loading.

Even with the THS6012 configured for nearly 22dB, I could not measure the distortion, as it was virtually the same as the residual from my oscillator, and this applies to any frequency within the audio band. This is in contrast to the majority of small power amps that are used for headphones, whose distortion increases with frequency - especially above 10 kHz. Noise was completely inaudible. Another of my tests is for clipping performance, as there are many amplifiers that are wonderful below clipping, but fall apart when a transient clips. There is more information on this topic in the Amplifier Sound article, for those who may be interested.

Clipping performance was exemplary, showing only the very slightest rail sticking (or "overhang") at the highest frequencies. At normal audio frequencies, the THS6012 simply clipped, and resumed normal operation virtually the instant the signal was below the supply voltage again. This is (of course) what amplifiers are supposed to do, but there are a great many that don't ! Very slight clipping overhang was observed at above 80 kHz, but there is no musical instrument on the planet that will ever get any amp to clip at such a frequency, and even if it did, we certainly couldn't hear it.

The overhang when an amp clips is caused by the output devices saturating (turning on as hard as they

possibly can). When a transistor saturates, it takes a finite time for the device to recover (when the base "charge" is depleted). Some of you will remember ECL (Emitter Coupled Logic) - these logic ICs are extraordinarily fast because the transistors never turn fully on or off, thus preventing the slow-down as the base charge is dissipated. Slightly off the topic, but interesting :-)

3.2 THS6012 CFB Pre-Amplifier

The other primary uses for the THS6012 amplifier IC are as a preamp, or as a line driver feeding the signal through the interconnects from preamp to power amp. The huge bandwidth and current capacity of this device make it ideal for a buffer/ line driver amp at the output of any preamp circuit. The series resistance can be reduced much further than with VFB opamps, and a value of 12 ohms is quite satisfactory to prevent the cable from causing oscillation

This does not mean that the cheapest and nastiest cable should be used (although it will not affect the sound). A well made and sturdy cable is always the ideal, but these can be home-made for a minimal cost, and when properly driven, will outperform anything on the market.

As a preamp, the CFB opamp has one drawback, and that is its input impedance. It is too low to interface with normal signal sources without an input buffer. The optimum configuration for a preamp is to use a conventional VFB opamp as the input stage, with the THS6012 as the final gain and line driver. This combines the best features of both types of opamp, and it is possible to make a preamp that will be better in all respects than any currently available (including passive versions). I know that's quite a claim, but having experimented at some length with the device, it is well justified.

A two stage preamp means that the VFB opamp will not need to contribute very much gain, and indeed, with two stages each having a gain of 2, the overall gain is adequate at 12 dB, and the bandwidth of such a combination can easily be made to exceed 200 kHz. With a medium input impedance (47k typical) and an output impedance of (say) 12 ohms, there is the potential to build the finest preamp in the world, limited only by your imagination and assembly skills.

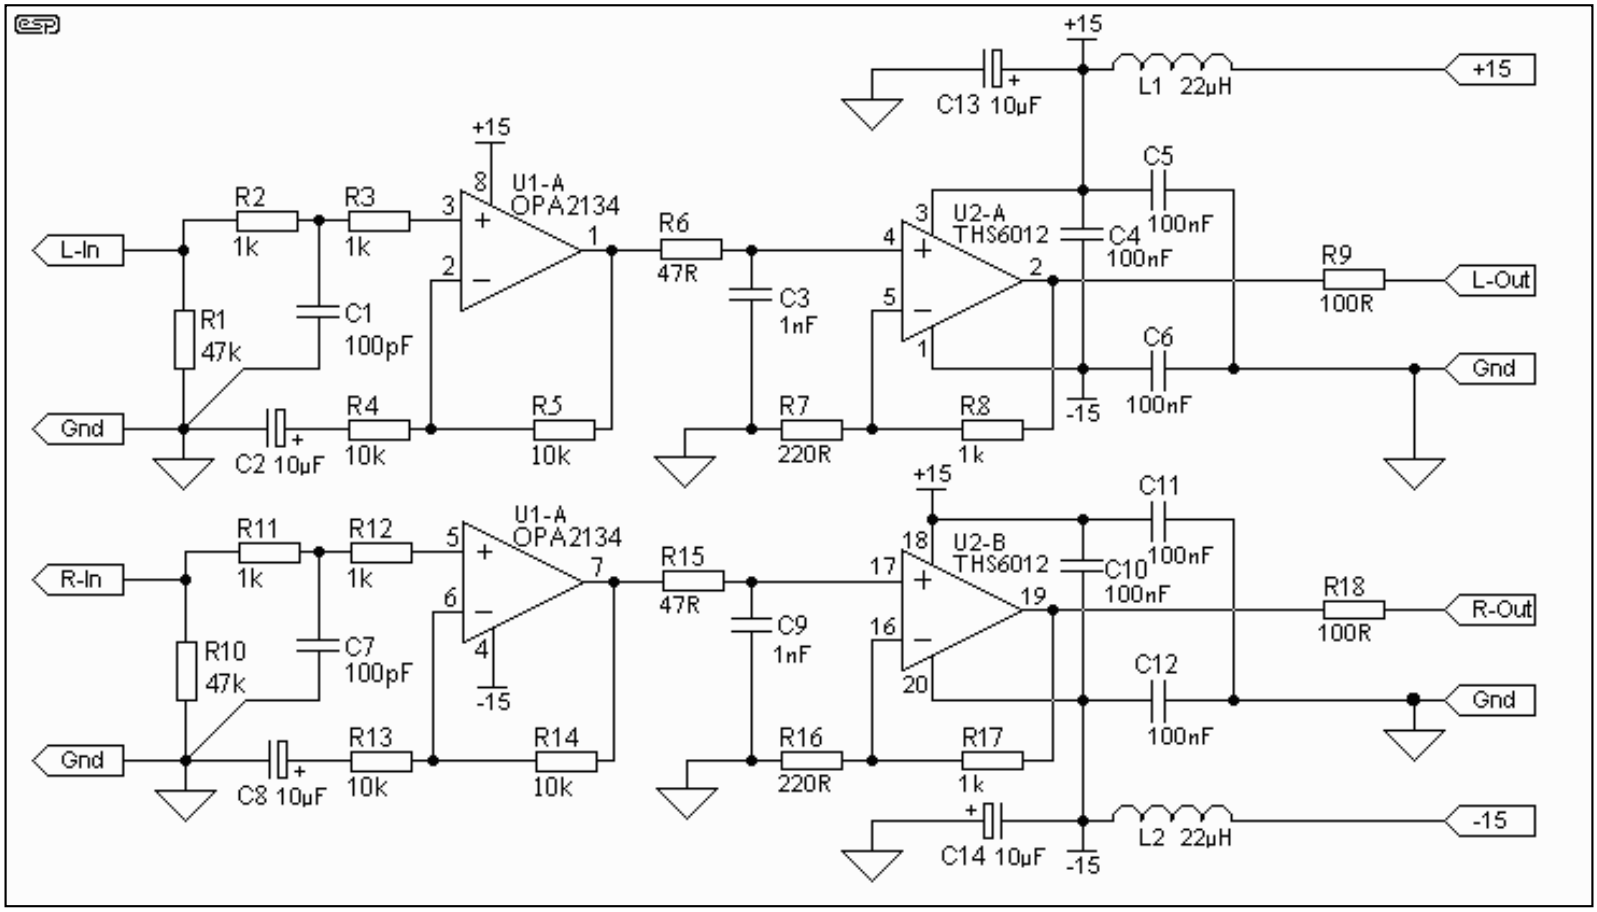

Figure 3.2 - Basic Concept of Preamp

Again, the circuit *looks* just like any other, and the output section is in fact almost identical to the headphone amp. This preamp has the ability to drive and terminate the output cable to well in excess of 500MHz. To my knowledge, there is no other hi-fi preamp available anywhere that has that ability. A Zobel network at the output is recommended - not for stability, but to ensure that the output impedance remains constant up to at least 500MHz. The inductance of a ceramic capacitor's leads (although very tiny indeed) will be sufficient to cause problems above this frequency, but this is still several orders of magnitude better than any other preamp available - regardless of price.

The OPA2134 input stage provides the necessary impedance conversion from the source to the input of the THS6012. This is a fast VFB opamp, and as shown has a gain of 2, or 6dB. The combined gain is about 20dB, which is more than enough, and may need to be reduced in many applications. Needless to say, a volume control is required, and with this arrangement you have little choice but to place it at the input. The same basic circuit can be used for the headphone amp as well - in effect they are identical applications, except for the higher current drain when driving headphones.

3.3 Zobel Network

The use of a Zobel network is well known in power amplifiers, and the most common is 10 ohms in series with 100nF, connected from the amplifier output to earth. This has a 3dB frequency of 159kHz, so above this frequency, where speaker leads are likely to present a high Q resonant circuit, the cable is effectively terminated by a low impedance that will effectively damp the cable resonance - at least from the amplifier's perspective.

That this has not been used in preamps before is somewhat surprising, but the most common (and generally

quite successful) method of preventing opamp oscillation is to use a 100 ohm resistor in series with the output. With lower resistances, this works with power amps too, but tends to reduce the available power and increases output impedance (thus lowering damping factor).

While the 100 ohm resistor (or other value, depending on the designer and the opamp) certainly works, it leaves the cable unterminated at RF, and increases the likelihood of interference pickup. The addition of a Zobel network to ensure that the cable remains terminated is risky with most opamps, since the effective impedance of the network will be very low, and because of the limited bandwidth, will need to become effective too close to the opamp's upper frequency limit and the upper end of the audio band.

This extra loading will stress the opamp - already straining to retain a flat response and with feedback falling at 6dB/octave. There is the very real likelihood that there will be an increase in distortion at high frequencies. This is not a problem in itself, but the intermodulation products will become an issue, and may be one of the reasons that opamps are often described in such derogatory terms by so many reviewers. Unfortunately (of course) most reviewers have no concept that there are different opamps with very different characteristics, so they gleefully lump them all into the same category.

A Zobel network intended to maintain an output impedance of 100 ohms at all frequencies will need to become effective at no less than about 150kHz for most conventional opamps, so the values would be 100 ohms in series with about 6.8nF, connected across the output as shown below.

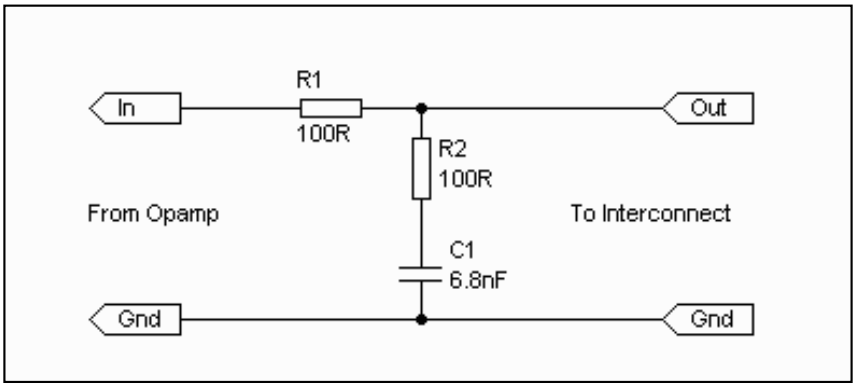

Figure 3.3 - Use of a Zobel Network for Preamps

With R1 = R2 = 100 ohms, and C1 = 6.8nF ...

This would be almost perfect for audio preamps, but the frequency is too low and the opamp loading too high! The -3dB frequency is about 160kHz, so the opamp must be able to retain its output impedance at a low value (less than 10 ohms) up to this frequency. Beyond that, the Zobel network will come into play, and will maintain the 100 ohm (or lower) termination up to that frequency where the capacitor's internal inductance is high enough to reduce the effectiveness of the circuit. Ceramic capacitors are absolutely essential for this, as they have the necessary bandwidth and low inductance that is needed.

The effect on the sound may not be minimal as we would hope, since although the capacitor is isolated from the signal path by the resistor, its reactance is significant at normal audio frequencies. At 20kHz, the cap has a reactance of 1.2k, so the opamp is quite heavily loaded at this frequency, increasing distortion.

The need for speed is again obvious - We need to use a faster opamp, and a much smaller capacitor. If the far end termination is also used, the loading (and distortion) will be much worse, and frequency response will suffer *within the audio band*.

With an ultra fast device such as the THS6012, the same circuit can be modified so the cable is matched better, and the Zobel network's influence will be so far outside the audio spectrum that it will have no audible effect whatsoever (other than reducing the cable's ability to act as a combined antenna and resonant circuit).

Substitute R1 = R2 = 68 ohms, and C1 = 1nF ...

Now, the -3dB frequency at the output is 1.6MHz, and the reactance of a 1nF capacitor is about 8k ohms at 20kHz. This is an insignificant load for any opamp, and the cable will be terminated by an impedance of not less than 68 ohms at all frequencies from DC up to several hundred megahertz. This will greatly reduce the tendency of the cable to act as an antenna, feeding RF interference into the output of the source amplifier, and into the input at the far end.

Another (identical) Zobel network across the input of the far end will maintain a reasonably good RF termination at both ends, but will have no deleterious effect for audio.

This should never be done unless you are certain that the preamp is capable of driving the impedance presented. A typical valve preamp with an output impedance of perhaps 10k, will be 3dB down at only 14kHz, and that is not allowing for the capacitance of the cable! The source impedance should ideally be less than 100 ohms.

The "far end" termination technique is intended only where wide bandwidth opamps having a very low output impedance and high drive capability are used as the line driver - it *will* cause problems with any source with an output impedance greater than about 200 ohms. With a 1k source impedance, an input circuit terminated as shown will be about 0.1dB down at 20kHz, with a 3dB frequency of about 150kHz. I do not believe that this would be good, and strongly recommend the use of a very fast, high drive capability, line driver IC.

Use of this technique is recommended, but only as part of a complete design, where the preamp and power amp (or electronic crossover) are designed to work together.

---

4. IC Mounting Details

The circuit details of both the headphone amp and preamp/ line driver are quite straightforward, but the device and its mounting are not. These ICs are only available as surface mount, which means that they are a little less friendly than "normal" ICs for the average constructor. The advantages are such that I believe the extra effort is warranted. There are considerable constraints on the PCB design, because of the extraordinarily wide bandwidth of the IC. The use of surface mount resistors is recommended for full bandwidth operation, but this further limits the design from an audio perspective. Conventional resistors can be used, but this must be done with care, or the amp will oscillate.

The THS6012 opamp IC uses TI's PowerPAD™ technology - there is a heatsink pad on the *underside* of the device, and a suitable thermal connection is important. Suffice to say at this time that using the method suggested by Texas Instruments is not recommended for home construction.

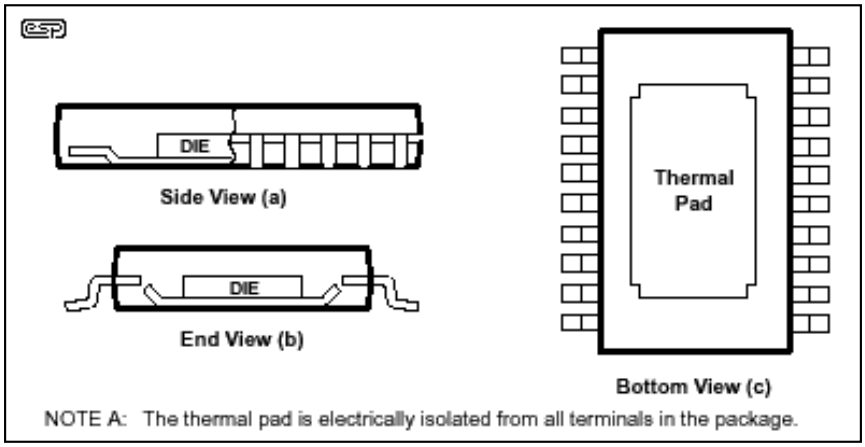

Figure 4.1 - PowerPAD Package Details

The thermal pad sits at the surface of the PCB, and with normal surface mounting and reflow soldering, it is easy enough to ensure that the pad is soldered to the board. A ground plane on the underside of the (double sided) PCB thus acts as a heatsink. This method of thermal management is ideal for automated assembly, but is very difficult for mere mortals to accomplish at home. I have devised a way of providing even better heatsinking that will be quite simple to do at home, and this will be described fully in the project article.

Proper power supply bypassing is essential, and the supply impedance must be as low as possible. This means ceramic bypass caps, as these are the only devices with the necessary size and bandwidth requirements. The size is important, because the bypass caps must be as close to the supply pins as possible - 2.5mm is the suggested maximum distance! The capacitors themselves must also have extremely low inductance, and ceramic devices are the only ones that will satisfy these requirements.

Otherwise, the circuits are unremarkable. They look just like any other opamp circuit, but with few slightly different component values. Well, that is until you listen to the results - there is nothing unremarkable about the sound, other than that it is as clean and un-coloured as if the amps were not there at all.

Conclusion

Does the foregoing mean that premium (conventional) opamps are a waste of time, and that the THS6012 should be the only amplifying device you will ever need? No. What I have attempted to convey here is that there is a place for very fast opamps, especially in areas where electromagnetic interference is a problem. These devices are also outstanding in all normal respects, and are (or should be) very worthy of consideration for your next preamp.

Simple preamps like the DoZ are not rendered obsolete either - the THS6012 just widens the selection, and provides some excellent benefits over the alternatives.

All this comes at a price however. The devices themselves are not cheap, and are much harder to mount on a PCB than the alternatives. Availability may also be an issue, and we can be certain that the normal retail electronics outlets will not stock such esoteric devices unless there is a considerable demand.

As a headphone amplifier, these opamps are superb, with not a single negative aspect. I really doubt that there is a better headphone amp on the planet - and yes, I really do mean that! Is it all worth the effort? That, I shall leave up to you.

I would like to thank Texas Instruments for taking the time to contact me, and for providing test devices and documentation for their range of high speed opamps and balanced line drivers and receivers.

Terminology

Slew Rate - the maximum rate of change of voltage for an active device. Slew rate is measured in Volts per microsecond, so an amplifier that can swing its output from +20V to -20V in one microsecond has a slew rate of 40 V/us

Characteristic Impedance - of a cable, that impedance determined by the diameter of the inner and outer conductors, and their relative spacing. Typical examples are 300 ohm TV ribbon cable, and 75 ohm coax

Velocity Factor - Electrical signals travel at the speed of light in a vacuum, but when trapped in a cable, their speed decreases. The decrease depends on the cable construction, and as an example, the velocity factor of 75 Ohm coax is generally about 0.8, meaning that the signal travels at only 0.8 of the speed of light (0.8 * $3*10^8$ = $2.4*10^8$ metres / second)

Narrow Band - RF signals that are confined to a relatively narrow frequency range (e.g. 10kHz either side of the carrier signal for AM radio).

Broad Band - Interference signals that spread over a wide frequency range, sometimes from the mains frequency all the way into the upper RF bands. Anything that creates arcs (such as most switches, welders, etc.) generates broad band interference.

1 - Introduction

A completely new technology for audio amplification has been evolving during the last 15-20 years that has a clear benefit over current widespread Class-A, and AB topologies. We are talking about the so-called “Class-D”. This benefit is mainly its high

power efficiency. Figure 1 shows typical efficiency curves vs. Output power for Class-B and Class-D designs.

The theoretical maximum efficiency of Class-D designs is 100%, and over 90% is attainable in practice. Note that this efficiency is high from very moderate power levels up to clipping, whereas the 78% maximum in Class-B is obtained at the onset of clipping. An efficiency of less than 50% is realised in practical use with music signals. The PWM amp's high power efficiency translates into less power consumption for a given output power but, more important, it reduces heatsink requirements drastically. Anyone who has built or seen a high-powered audio amplifier has noticed that big aluminium extrusions are needed to keep the electronics relatively cool. The loading on the power transformer is also reduced by a substantial amount, allowing the use of a smaller transformer for the same power output.

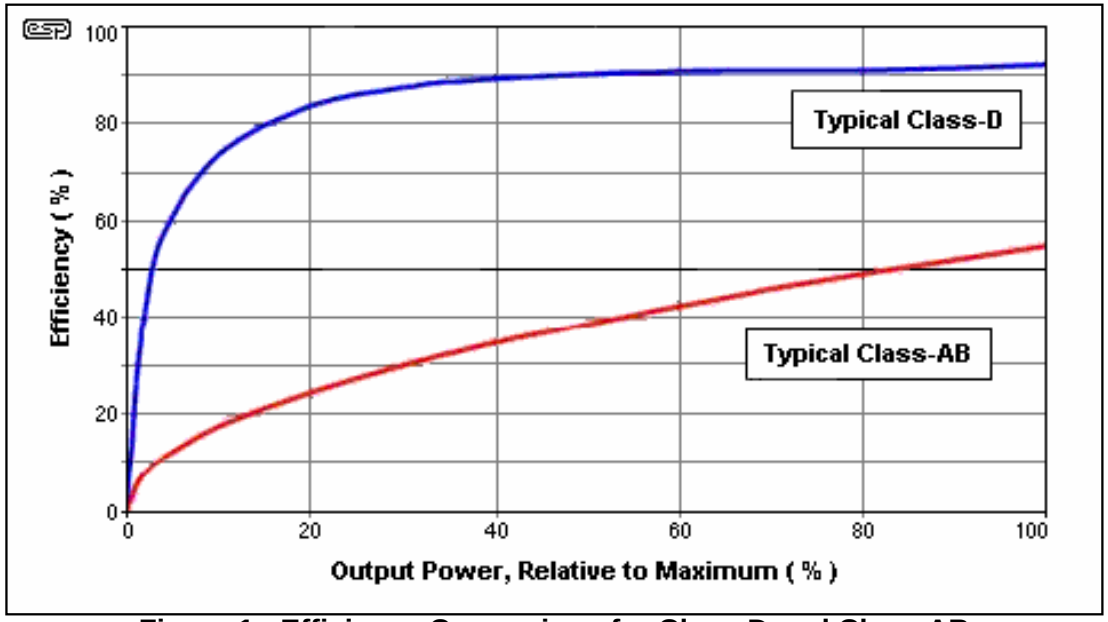

Figure 1 - Efficiency Comparison for Class-D and Class-AB

These heatsinks account for an important part of the weight, cost and size of the equipment. As we go deeper in the details of this topology, we will notice that a well behaving (low distortion, full range) Class-D amplifier must operate at quite high frequencies, in the 100KHz to 1MHz range, needing very high speed power and signal devices. This has historically relegated this class to uses where full bandwidth is not required and higher distortion levels are tolerable - that is, subwoofer and industrial uses.

However, this has changed and thanks to today's faster switches, knowledge and the use of advanced feedback techniques it is possible to design very good performance Class-D amplifiers covering the whole audio band. These feature high power levels, small size and low distortion, comparable to that of good Class-AB designs. (From now on, I will refer to Class-A and AB topologies as “classical”).

Complete 400W Full-Range Class-D Amplifier Module (Courtesy of ColdAmp)

From the DIY perspective, Class-D is rather unfortunate. Because of the extremely high switching speeds, a compact layout is essential, and SMD (surface mount devices) are a requirement to get the performance needed. The stray capacitance and inductance of conventional through-hole components is such that it is almost impossible to make a PWM amplifier using these parts. Indeed, the vast majority of all ICs used for this application are available *only* in surface mount, and a look at any PWM amplifier reveals that conventional components are barely used anywhere on the board. Since SMD parts are so hard to assemble by hand and the PCB design is so critical to final performance, DIY versions of PWM amps are very rare indeed (I don't know of any).

---

2 - How Class-D Works

In classical amplifiers, at least one of the output devices (let them be bipolar transistors, MOSFETs or valves) is conducting at any given time. No problem so far, but they are also carrying a given current where there is a voltage drop between collector-emitter / drain-source etc. Since P = V * I, they are dissipating power, and even if there is no output a small quantity of current must pass through the transistors to avoid crossover distortion, so some dissipation is present. As the output voltage increases, for given supply rails the voltage drop across the transistors will fall, but the current increases. At saturation (clipping), VCE or VDS will be low, but current is quite high (Vout / Rspk). Conversely, at low power levels, current is small but voltage drop is large. This leads to a power dissipation curve that is not linear with output power. There is a non-zero minimum dissipation (zero percent efficiency), and a point where maximum efficiency is reached ... about 78% in pure Class-B designs, 25% or less with

Class-A.

Class-D on the other hand, bases its operation in switching output devices between 2 states, namely “on” and “off”. Before discussing the topology specific details, we can say that in the “on” state, a given amount of current flows through the device, while theoretically no voltage is present from drain to source (yes, almost every Class-D will use MOSFETs), hence power dissipation is theoretically zero. In the off state, voltage will be the total supply rails as it behaves like an open-circuit, and no current will flow (that's very close to reality).

But how can our beloved audio signal be represented by an awful square wave with only two possible levels? Well, in fact it modulates some characteristics of this square wave so the information is there. Now we “only” have to understand the way the modulation is done and how to restore the amplified audio signal from it. The most common modulation technique used in Class-D is called PWM (Pulse Width Modulation) - a square wave is produced that has a fixed frequency, *but* the time it is in the “high” and “low” states is not always 50%, but it varies following the incoming signal. This way, when the input signal increases, the “high” state will be present for longer than the “low” state, and the opposite when the signal is “low”. If we do some maths, the mean value of the signal in a single cycle is simply ...

Vmean = Vhigh * D + Vlow * (1-D), where D = Ton / T, (duty cycle)

T being the period of the signal, that is, 1/Fsw (switching frequency).

For example, the mean value of a 50% duty cycle (both states are present for exactly the same amount of time) signal going from +50V to –50V is: 50 * 0.5 + (- 50) * 0.5 = 0V. In fact, the idle (no signal) output of a Class-D amplifier is a 50% duty cycle square signal switching from the positive to the negative rail.

If we modulate the input up to the maximum, we will have a near-100% duty-cycle. Lets put 99%: Vmean = 50 * 0.99 + (-50) * 0.01 = 49V. Conversely, if the signal is lowest, we need near 0% (lets use 1%), so Vmean = -49V.

PWM is usually generated by comparing the input signal with a triangle waveform as shown in Figure 2. The triangle wave defines both the input amplitude for full modulation and the switching frequency

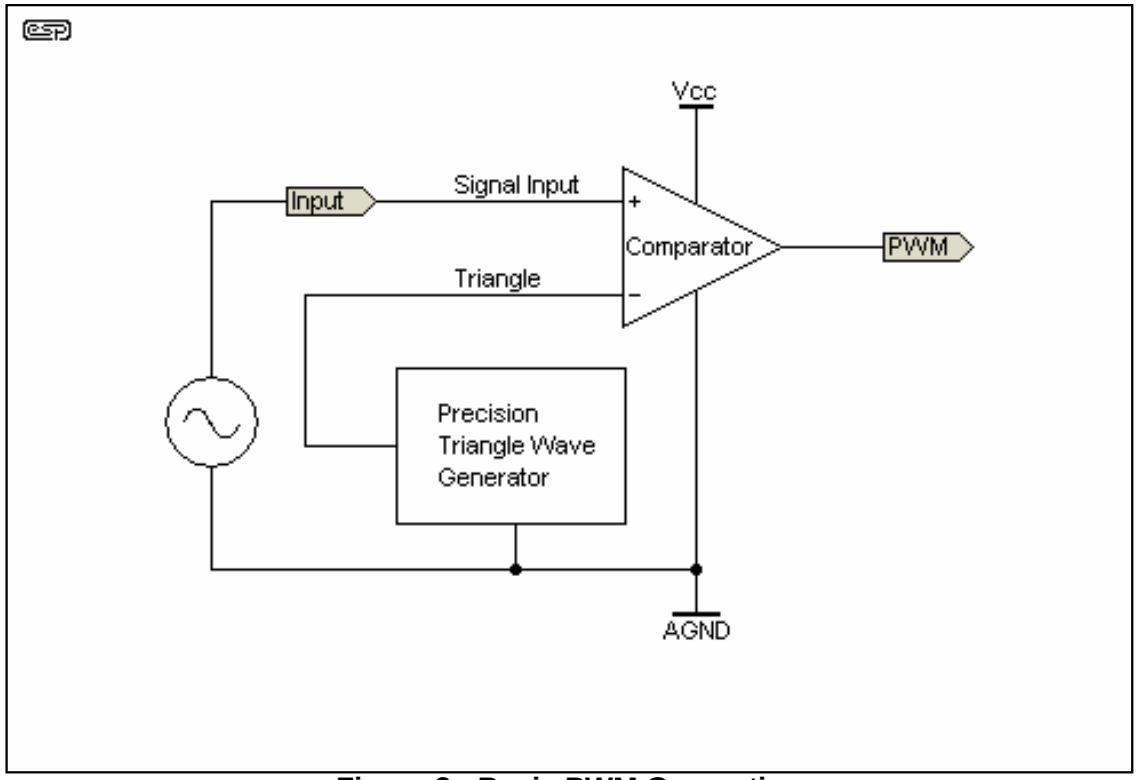

Figure 2 - Basic PWM Generation

Figure 3 shows a typical PWM signal modulated by a sine wave. Notice that it is designed so signals between –1 and 1V will produce 0% to 100% duty cycles, 50% corresponding to 0V input. The 'digital' output uses standard logic levels, where 0V is a logic '0' and 5V is a logic '1'. Because of this digitisation of the signal, PWM amps are sometimes erroneously referred to as digital amps. In fact, the entire process is far more analogue than digital.

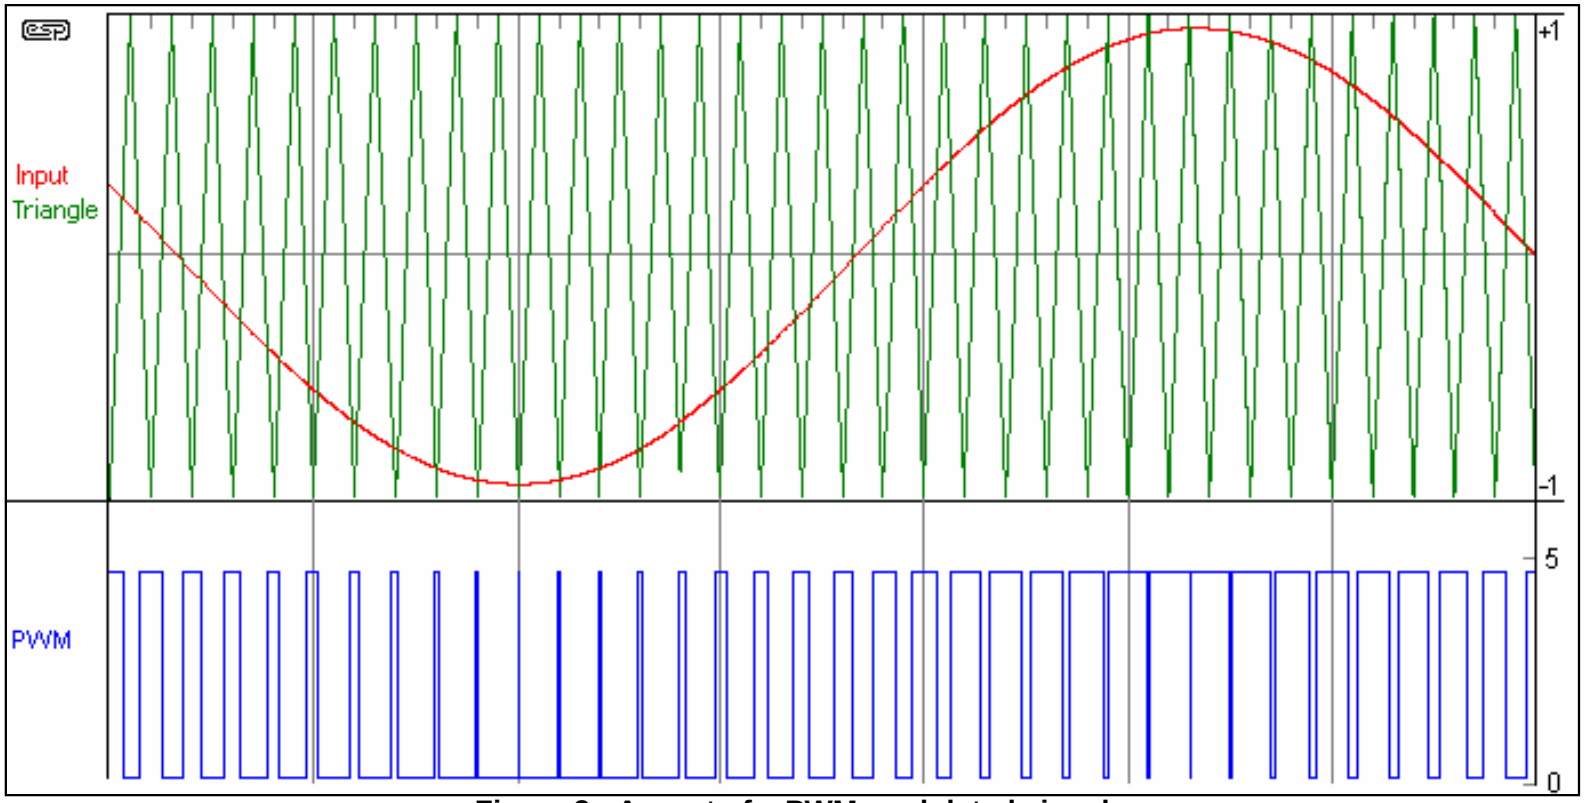

Figure 3 - Aspect of a PWM modulated signal

Notice that for a correct representation of the signal, the frequency of the PWM reference waveform must be much higher than that of the maximum input frequency. Following Nyquist theorem, we need at least twice that frequency, but low distortion designs use higher factors (typically 5 to 50). The PWM signal must then drive power conversion circuitry so that a high-power PWM signal is produced, switching from the +ve to –ve supply rails (assuming a half-bridge topology).

The spectrum of a PWM signal has a low frequency component that is a copy of the input signals spectrum, but also contains components at the switching frequency (and its harmonics) that should be removed in order to reconstruct the original modulating signal. A power low-pass filter is necessary to achieve this. Usually, a passive LC filter is used, because it is (almost) lossless and it has little or no dissipation. Although there must always be some losses, in practice these are minimal.

---

3 - Topologies

There are basically two Class-D topologies - half-bridge (2 output devices are used) and full-bridge (4 output devices). Each one has its own advantages. For example, half-bridge is obviously simpler and has more flexibility as a half-bridge amplifier can be bridged as with classical topologies. If it is not correctly designed and driven, can suffer from “bus pumping” phenomena (transfer

current to the power supply that can make it increase its voltage producing situations dangerous to the amplifier, supply and speaker).

Full bridge requires output devices rated for half the voltage as an half bridge amplifier of the same power, but it is more complicated. Figures 5a and 5b show both topologies conceptually. Obviously, many components such as decoupling capacitors, etc are not shown.

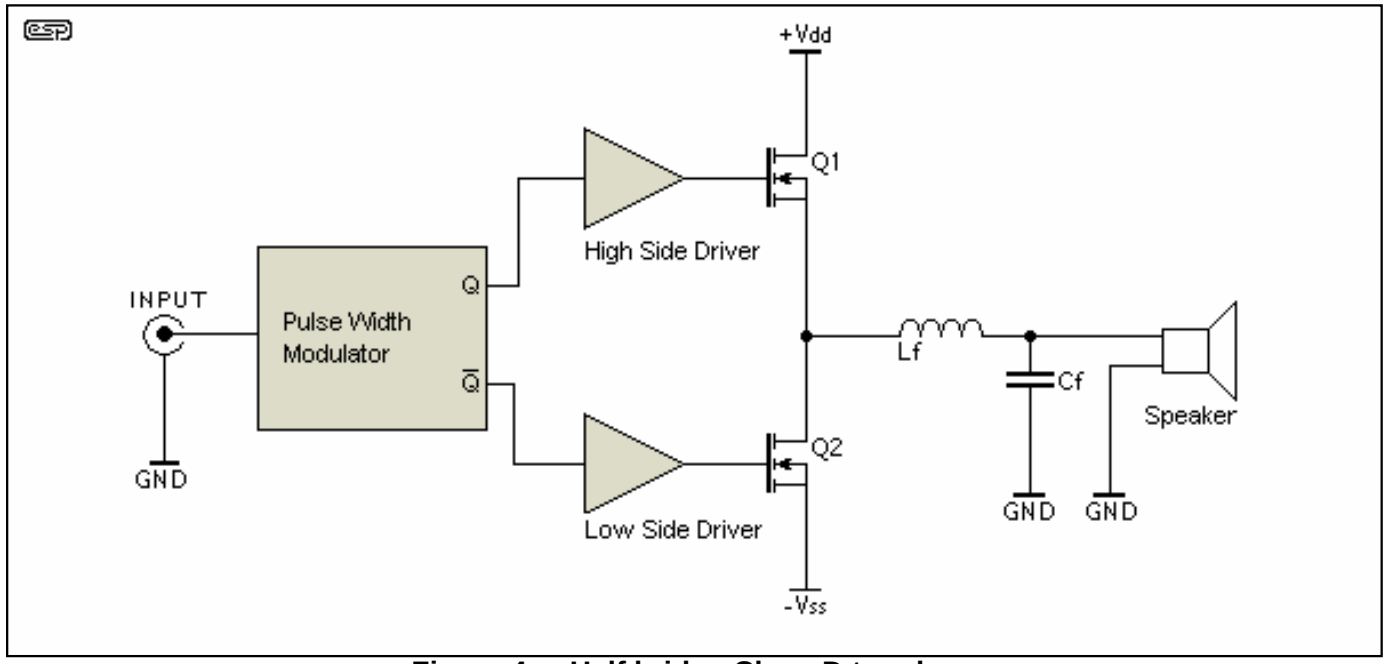

Figure 4a - Half bridge Class-D topology

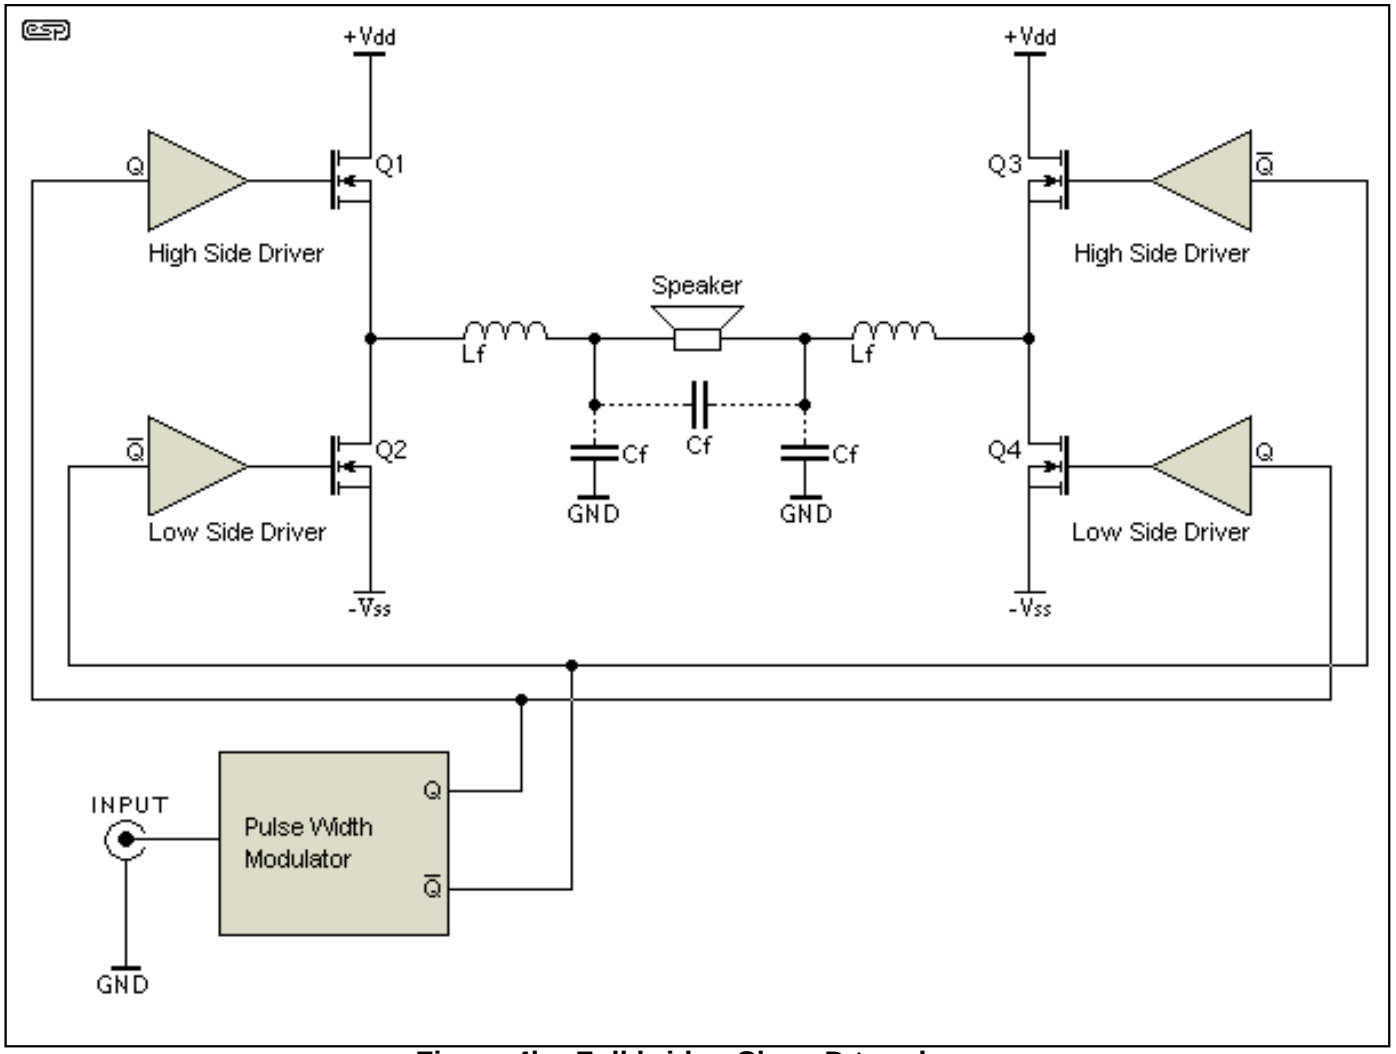

Figure 4b - Full bridge Class-D topology

Note that full bridge PWM amp needs only one supply rail - bipolar supplies are not necessary, but can still be used. When a single supply is used, each speaker lead will have ½ the Vdd voltage present. As it is connected differentially, the loudspeaker doesn't see any DC if everything is well balanced. However, this can (and does) cause problems if a speaker lead is allowed to short to chassis!

The filter may be implemented by means of a single capacitor across the loudspeaker, by a pair of caps to ground, or in some cases by both (as shown by the dotted lines connecting the caps).

For the rest of the document, we will concentrate on half-bridge topologies, although the vast majority of the ideas are also applicable to full-bridge designs.

Half bridge design

The operation of the half bridge circuit depicted in Figure 4a is as follows ...

When Q1 is on (corresponding to the positive part of the PWM cycle), the switching node (inductor input) is connected to Vdd, and current starts to increase through it. The body diode of Q2 is reverse biased. When Q2 is on (negative part of the PWM cycle), the body diode of Q1 is reverse biased and the current through Lf starts to decrease. The current waveform in Lf is triangular shaped.

Obviously, only one of the transistors must be on at any time. If for any reason both devices are enhanced simultaneously, an effective short-circuit between the rails will be produced, leading to a huge current and the destruction of the MOSFETs. To prevent this, some “dead-time” (a small period where both MOSFETs are off) has to be introduced.

Lf in conjunction with Cf and the speaker itself form the low pass filter that reconstructs the audio signal by averaging the switching node voltage.

Timing is critical in all this process: any error as delays or rise-time of the MOSFETs will ultimately affect efficiency and audio quality. So all the involved components must be high-speed. Dead-time also affects performance, and it must be minimised. At the same time, the dead-time must be sufficiently long to ensure that under no circumstance both MOSFETs are on at the same time. Typical values are 5 to 100ns.

The dead-time is a critical factor for distortion performance. For lowest distortion, the dead-time must be as small as possible, but this risks 'shoot-through' currents, where both MOSFETs are on simultaneously. This not only increases distortion and dissipation dramatically, but will quickly destroy the output devices. If the dead-time is too great, the response of the output stage no longer follows the true PWM signal generated in the modulator, so again distortion is increased. In this case, dissipation is not affected.

4 - Gate Driving

To ensure fast rise/fall times of the MOSFETs, the gate driver must provide quite a high current to charge and discharge the gate capacitance during the switching interval. Typically, 20 - 50ns rise/fall times are needed, requiring more than 1A of gate current.

Note that the schematics shown use both N-channel MOSFETs. Although some designs use N and P channel complementary devices, that is IMHO sub-optimal due to the difficulty of obtaining suitable P devices and matched pairs. So lets concentrate on N-channel only half-bridges. Note that, in order to drive a MOSFET on, a voltage above Vth must be present between its gate

and source. The lower MOSFET has its source connected to –Vss, so its drive circuit has to be referred to that node instead of GND.

However, the upper MOSFET is more difficult to drive, as its source is continuously floating between +Vdd and –Vss (minus drops due to on resistance). However, its driver must be also floating on the switching node and, what's more, for the on-state, its voltage must be several volts above +Vdd so a positive Vgs voltage is created when Q1 is on. This also implies a voltage shifting so the modulator circuit can communicate correctly with the driver.

This is one of the major difficulties of Class-D design: gate drive. To solve the issue, several approaches are taken ...

- Transformer gate drive: useful in half-bridge power supplies where duty-cycle doesn't vary widely. In audio amplifiers however, duty cycle ranges from 0% to 100%, so this method creates a problem because the signal is AC coupled. A DC restoration circuit (not shown) is needed.
- Discrete gate driving: some designs use transistors to perform both the level shifting and the MOSFET drive. Again, there is a problem: we need a voltage that is higher than +Vdd.
- Integrated drivers: there are a number of MOSFET drivers in the market, optimised for high speed, that can be used. Again, a voltage higher than Vdd is needed as well as level shifting.

Figure 5 (a, b & c) depict some possibilities for 'High Side' gate driving ...

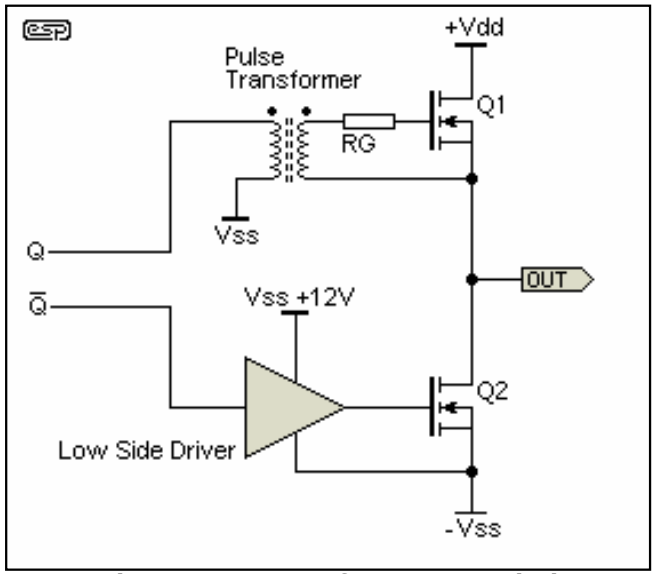

Figure 5a - Transformer Coupled

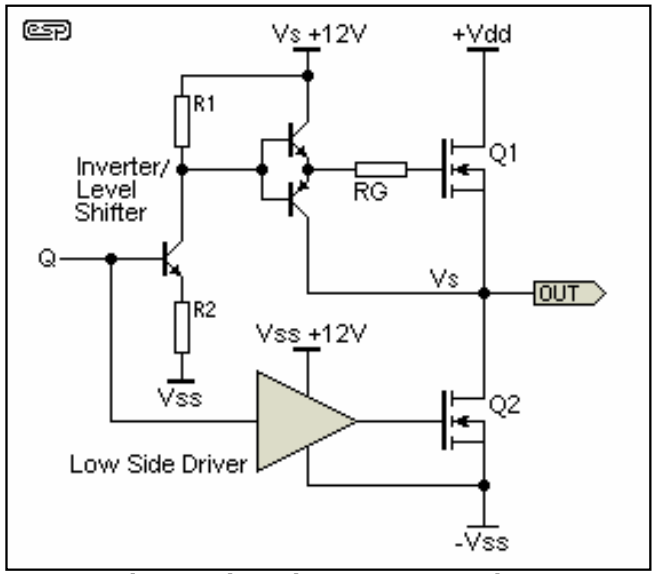

Figure 5b - Discrete BJT Driver

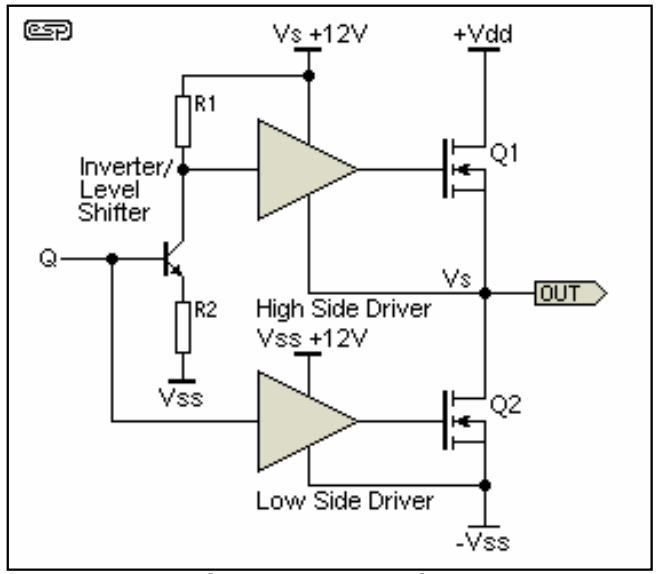

Figure 5c - IC Driver

Note that circuits in figures 5b and 5c have their PWM input referred to –Vss so may require previous level shifting of the

comparator output, that will normally be referred to GND. Fig 5a will require level shifting of the inverted PWM only, as the transformer input can be referenced to GND as shown. Many of the driver ICs available now have inbuilt level shifters, and these are optimised for speed. Remember that *any* delay introduced into the switching waveform can cause distortion or simultaneous MOSFET conduction.

We have still one problem to solve ... obtaining 12V above VS (the switching node). We can add another power supply, isolated from the main one, which (-) is connected to VS. This solution can be impractical, so other techniques are commonly used. The most widespread is a 'bootstrap' circuit. The bootstrap technique uses a charge pump built with a high speed diode and a capacitor. The output of the amplifier produces the switching pulses needed to charge the capacitor.

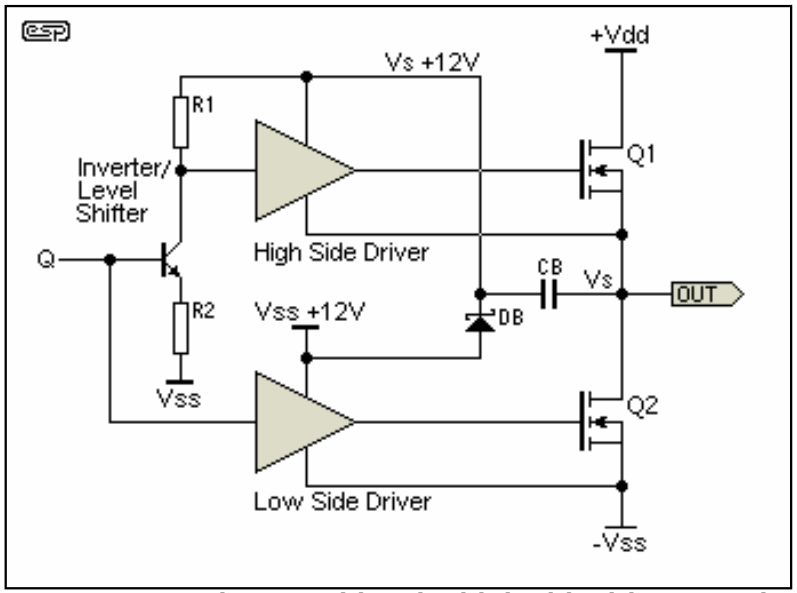

Fig. 6 Bootstrap capacitor provides the high side driver supply voltage

This way, the only auxiliary power supply needed is 12V referenced to –Vss that is used for powering both the low side driver and the charge pump for the high side driver. As the average current from this supply is low (although there are high current charging peaks during the switching events, they last only 20-50ns, twice during a cycle, so the average is quite low, in the 50-80mA range), this supply is easily obtained from the negative rail with a simple 12V regulator (paying attention to its maximum input voltage rating, of course).

---

5 - Level Shifting

As can be seen from the previous figures, in order to excite the MOSFET driver, the PWM signal has to be referred to –Vss. So, as the modulator usually works from +/-5 to +/-12V, typically, a level shifting function is needed. One can choose to shift the level

of the PWM signal and then generate the inverted version, or generate both outputs and invert both of them. It depends, for example, on the comparator type used (if complementary outputs are available, the decision is made).

A basic level shifting function can be performed with a single or two-transistor circuit similar to the one depicted in Figure 6 (before the high side driver). While this may work at low frequencies, it is important to simulate the behaviour of the comparator and level shifter, as they can introduce considerable delays and timing errors if not properly designed.

It is fair to say that the level shifter is one of the most critical parts of the circuit, and this is evidenced by the wide variety of competing ICs designed for the job. Each will have advantages and disadvantages, but in all cases the complexity is far greater than may be implied by the simplified diagrams.

---

6 - Output Filter Design

The output filter is one of the most important parts of the circuit, as the overall efficiency, reliability and audio performance depends on it. As previously stated, a LC filter is the common approach, as it is (theoretically) lossless and has a –40dB/decade slope, allowing for a reasonable rejection of the carrier if the parameters of the filter and the switching frequency itself are properly designed.

The first thing to do is to design the transfer function for the filter. Usually, a Butterworth or similar frequency response is chosen, with a cutoff frequency slightly above the audio band (30-60KHz). Have in mind that one of the design parameters is the termination load, that is, the speaker impedance. Usually, a typical 4 or 8 ohm resistor is assumed, but that would produce variations in the measured frequency response in presence of different speakers. That must be compensated for by means of proper feedback network design. Some manufacturers simply leave it that way so the response is strongly dependent on the load. Surely a non-desirable thing.

The design can be done mathematically or simply use one of the many software programs available that aid in the design of LC filters. After that, a simulation is always useful. Figure 7 shows a typical LC filter for Class-D amplifiers and its typical frequency response.

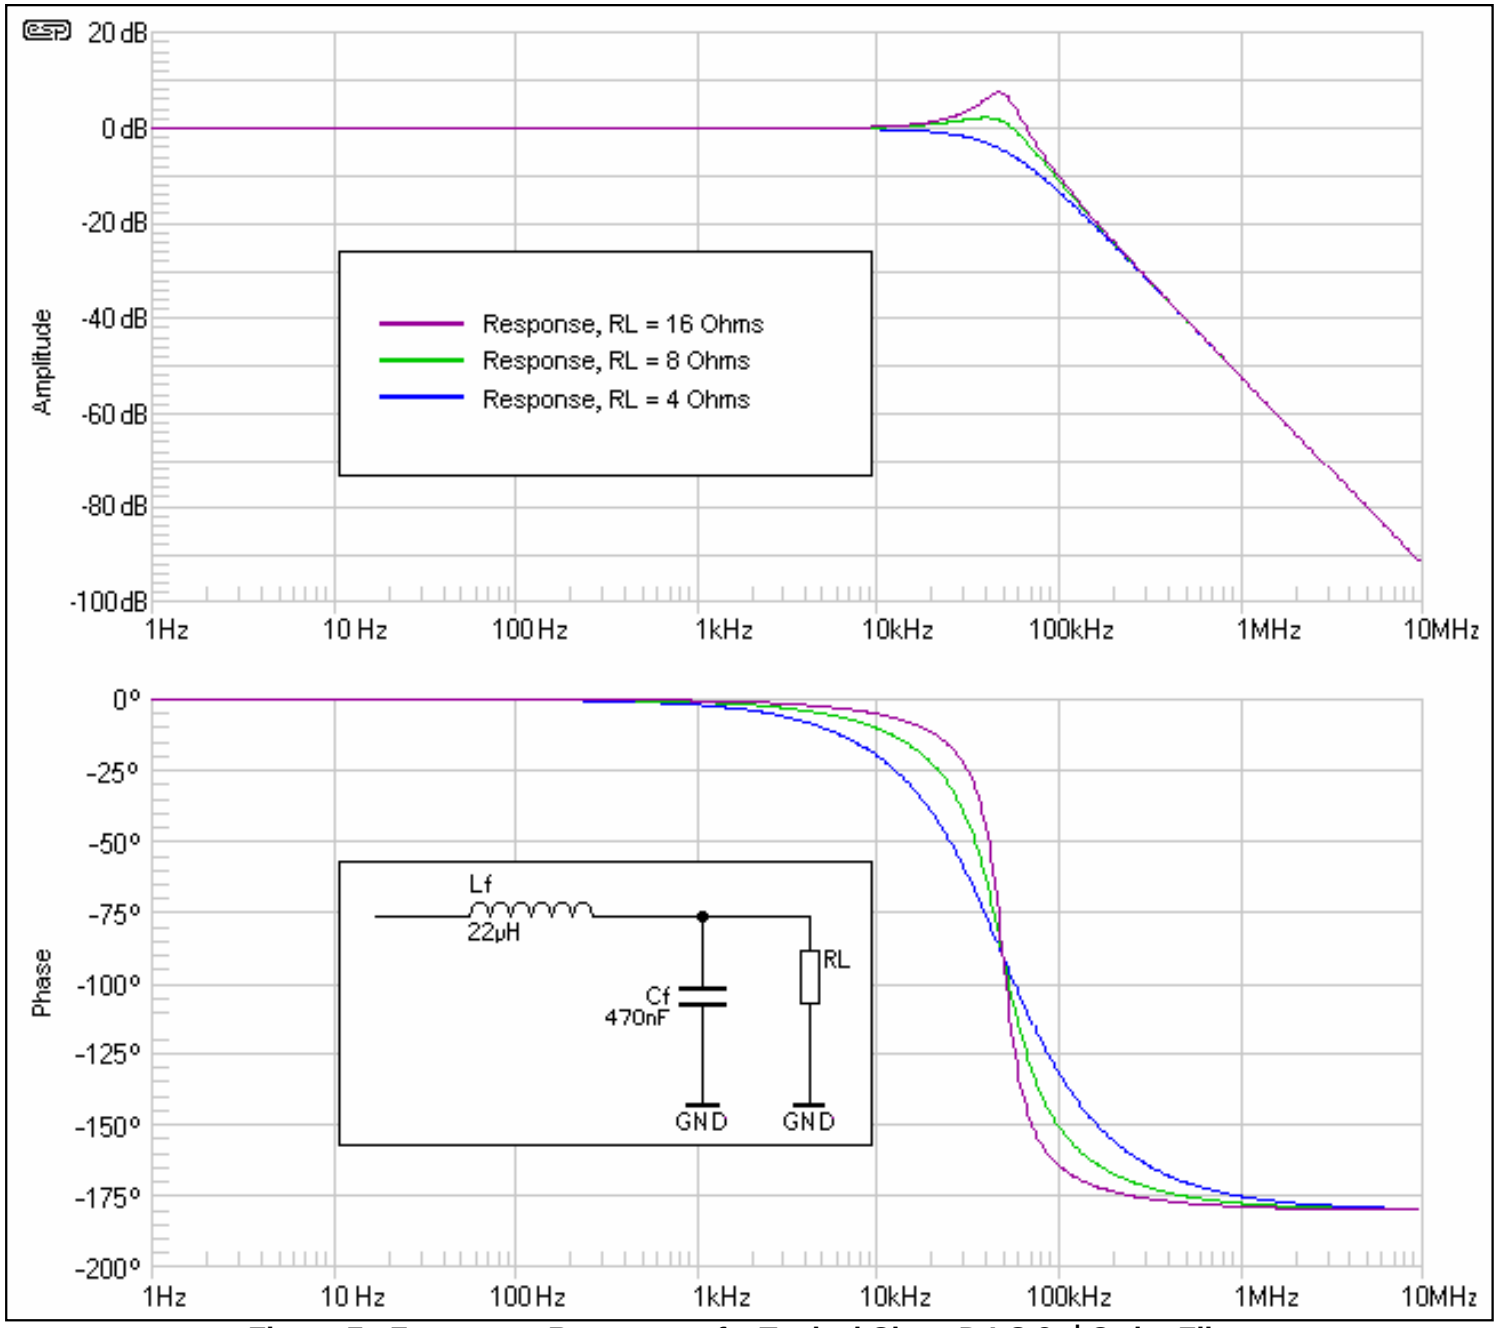

Figure 7 - Frequency Response of a Typical Class-D LC 2nd Order Filter

This simple filter has a –3dB cutoff frequency of 39KHz (with 4 ohm load), and suppresses the carrier as much as 31dB at 300KHz. For example, if our supply rails are +/-50V (enough for about 275W at 4 ohms), the residual ripple will have an amplitude of about 1Vrms.

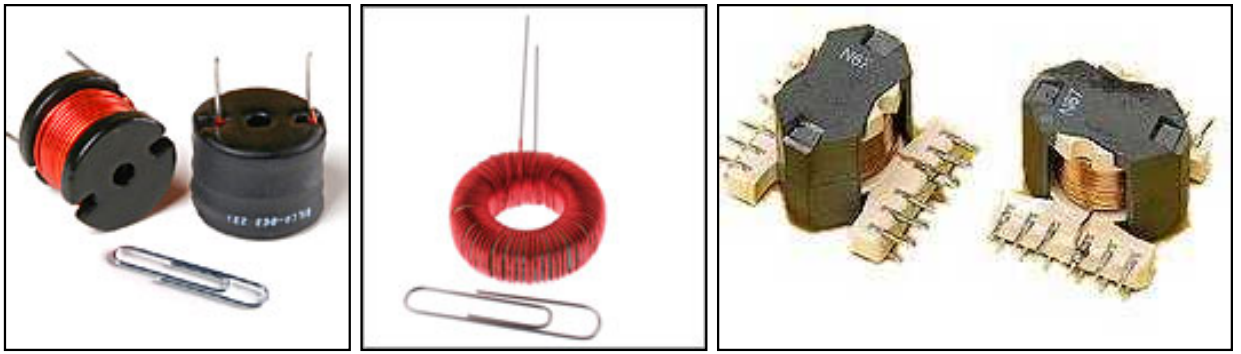
This ripple is, obviously inaudible, and 1V RMS will dissipate only around 200mW in a typical tweeter (not likely a problem, especially since the tweeters impedance will be a lot higher than 8 ohms at 300kHz). However, care must be taken as the speaker wires can become an antenna and affect other equipment. In fact, although a couple of volts RMS of ripple can seem low enough to run your speakers safely, EMI can be a concern, so the less carrier level you have, the better. For further rejection, higher order filters are used (with the potential disadvantage of increased phase shift in the audio band), although there are other clever ways to do it, as very selective bandstop or 'notch' filters tuned to the carrier frequency (if it is fixed, and that only happens in synchronous designs as the one described).

Well designed Class-D amplifiers have a higher order filter and/or special carrier suppression sections in order to avoid problems with EMI. As can be seen in Figure 8, the response is dependent on the load, and in fact the load is part of the filter. This is one of the problems to solve in Class-D designs. It doesn't help that a loudspeaker presents a completely different impedance to the amplifier than a test load, and many PWM amps have filters that are (and never can be) correct for all practical loudspeaker loads. Again, only a handful of good Class-D amplifiers use feedback techniques that include the output filter to compensate for impedance variations and have a nearly load independent frequency response, as well as to reduce distortion produced by non-linearities in the filter. Although passive components are thought to be distortion-free, this does not apply to ferrite or powdered iron cores that are used for the filters. These components most certainly do introduce distortion.

Now, The Filter Components ...
The output inductor has to withstand the whole load current, and also have storage capability, as in any non-isolated switching converter (Class-D half bridge design is in fact analogous to a buck converter, its reference voltage being the audio signal).

The ideal inductor (in terms of linearity) is an air-core one, but the size and number of turns required for typical Class-D operation usually makes it impractical, so a core is normally used in order to reduce turns count and also provide a confined magnetic field that reduces radiated EMI. Powder cores or equivalent materials are the common choice. It can also be done with ferrite cores, but they must have a “gap” where energy is stored. Wire size must also be carefully chosen so DC losses are low (requiring thick wire) but also skin effect is reduced (AC resistance must also be low).

Inductor core shape can be a drum core, gapped ferrite RM core, or toroidal powder core, among others. Drum cores have the problem that their magnetic field is not enclosed, hence producing more radiated EMI. RM cores solve this problem but have most of the coil enclosed, so cooling problems may arise as no airflow is possible. IMHO, toroids are preferred because they feature both closed magnetic field that helps control radiated EMI, a physically open structure that allows proper cooling, and easy and economical winding, as they don't need bobbins.



Coil Shapes ... Drum, Toroid & RM Style Coils and Cores (Wilco & Coilcraft)

Many core manufacturers such as Micrometals or Magnetics offer their own software, very useful to design the output inductor as they help choosing the right core, wire size and geometrical parameters. The capacitor usually falls in the 200nF to 1uF range, has to be of good quality too, in order to ensure good high frequency behaviour and low losses and of course has to be rated for the whole output voltage. Usually, polypropylene capacitors are chosen. Needless to say, you cannot use electrolytics!

---

7 - Feedback

As I have stated previously, timing errors can lead to increased distortion and noise. This cannot be skipped and the more precise it is kept, the better the design will perform. Anyway, open loop Class-D amplifiers are not likely to satisfy demanding specifications, so (negative) feedback is almost mandatory. There are several approaches. The most simple and common is to take a fraction of the switching signal, precondition it by means of a passive RC low pass filter and feed it back to the error amplifier.

To put it simply, the error amplifier is an opamp placed in the signal path (before the PWM comparator) that sums the input signal with the feedback signal to generate a error signal that the amps automatically minimises (this is the concept of every negative-feedback system, anyway).

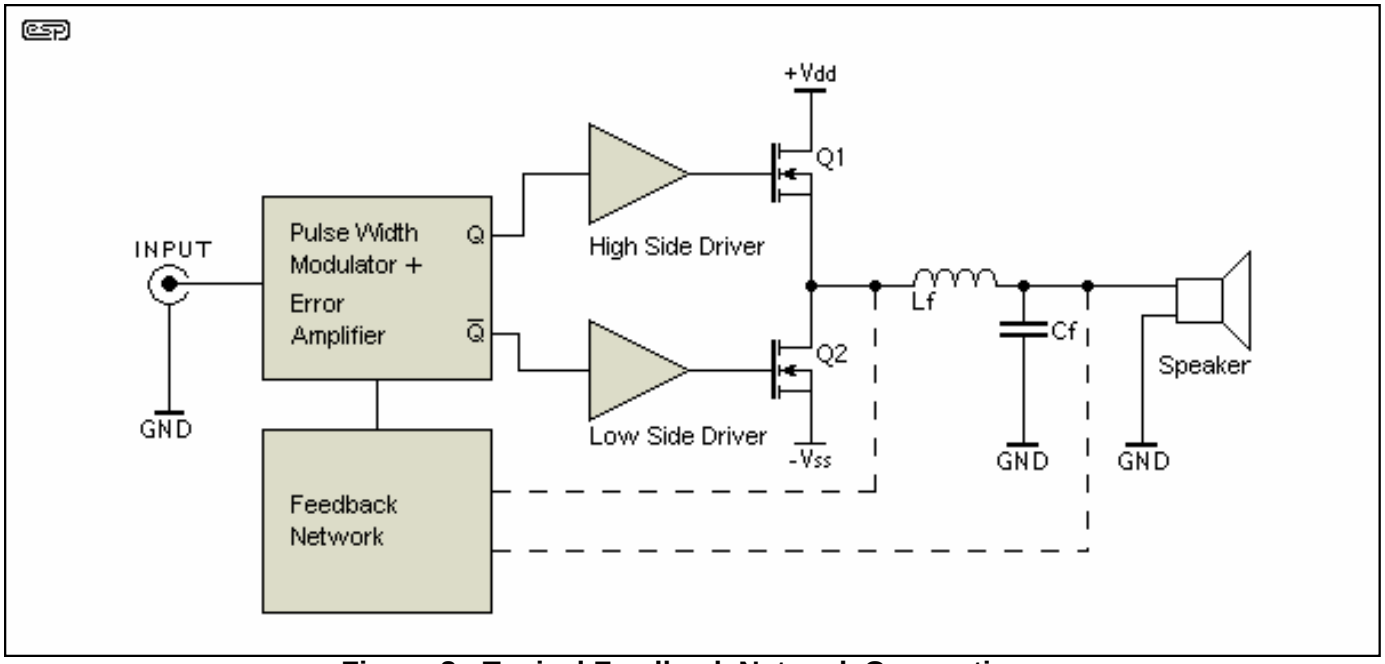


Figure 8 - Typical Feedback Network Connections

Although good results are obtained this way, there is still a problem: load dependency, due to the speaker being an integral part of the filter, hence affecting its frequency response as shown above.

Some more advanced amplifiers take the feedback signal from the very output, trying to compensate this. This way, a constant frequency response is obtained, with the further gain that the inductor resistance contributes much less to the output impedance, so it is kept lower, hence damping factor is higher (higher speaker control). However, taking feedback after the filter is not an easy task. The LC introduces a pole and hence a phase shift that, if not properly compensated, will make the amp become unstable and, ultimately, oscillate. Feedback may be taken from both the switching node and the filter output. Although this can give very good results, it is still difficult to maintain stability because of the phase shift through the output filter.

---

8 - Other topologies

Pure PWM (based on triangle generators, also called 'natural sampling PWM') is not the only way to go in order to construct a Class-D amplifiers. Some other topologies have arisen, many of them based on auto-oscillation, where the hysteresis in the comparator and delays between the comparator and power stage can be taken into account to design a system that oscillates by itself in a somewhat controllable manner.

Although simpler, these designs have some disadvantages, IMHO. For example, the switching frequency is not fixed, but

depends on the signal amplitude. This makes output notch filters ineffective, yielding higher ripple levels. Besides, when several channels are put together, the difference in switching frequency between them can produce audible beat tones that can become very annoying. This can also happen of course with synchronous design as the one described here, but there is a simple solution - use the same clock for all the channels.

Self oscillating designs in particular have some other difficulties like start-up: special circuitry may be needed that forces the amplifier to start oscillating. Conversely, if for any reason the oscillation stops, you could end up with an 'always-on' MOSFET, and thus a large amount of DC at the output, followed almost immediately by a dead loudspeaker. Of course, these issues can be solved with proper design, but the added complexity can void the initial simplicity, thus no gain is obtained.

Low distortion in a PWM amplifier requires a very linear triangle waveform, along with a very fast and accurate comparator. At the high operating frequencies needed for optimum overall performance, the opamps used need to have a wide bandwidth, extremely high slew rate, and excellent linearity. This is expensive to achieve, requiring premium devices. Some of these constraints are relieved somewhat by self oscillating designs (therefore making them slightly cheaper), but this is not an effective trade-off for the most part.

Clocked designs (fixed frequency) are not easier to make than self-oscillating or modulated switching frequency designs, but are certainly far more predictable and tend to have fewer problems overall. The ability to synchronise multiple amplifiers ensures that mutual interference is minimised. An 'advantage' claimed by the proponents of non-clocked and 'random switching' designs is that the RF energy on the speaker leads is spread over a wide frequency range, potentially making such amplifiers more likely (or perhaps less unlikely) to pass EMI testing. From an overall perspective, this is more likely to be a hinderance than a benefit, as it is no longer possible to optimise the filter network for maximum switching frequency rejection.

There are also PWM amps that claim to be truly 'digital', using One-Bit™ technology, or generating the PWM signal directly from the PCM data stream. Although the manufacturers of such amplifiers will naturally proclaim their superiority over all others, such self-praise should generally be ignored. Implementing feedback in a 'pure' digital design is at best difficult, and may be impossible without using a DSP (digital signal processor) or resorting to an outboard analogue feedback system. Including additional ADCs and DACs (analogue to digital converters and vice versa) is unlikely to allow the amplifier to be any 'better' than the direct analogue methods described in this article.

A relative newcomer to the scene is the Sigma-Delta modulator, however at the time of writing this still has problems (challenges in corporate speak). The main issue is that the transition rate is too high, and it must be reduced to accommodate real-world components - particularly the power switching MOSFETs.

The 'pure' digital solutions described above have another shortfall, and that's the fact that the number of different pulse widths is finite, and determined by the clock speed. A digital system can only switch on a clock transition. Based on currently available information, only around 8 x oversampling is possible if a digital noise shaping filter is added to the system. An analogue

modulation system has an effectively infinite number of different pulse widths, but this is not possible with any true digital implementation.

These latter comments cover a very complex area, one is outside the scope of this article. However, even the scant information above will give most readers far more information that is commonly available - especially from manufacturers of digital Class-D amplifiers.

---

9 - Some Final Notes

In conclusion, Class-D amplifiers have evolved a lot since they were first invented, achieving levels of performance similar to conventional amplifiers, and even better in some aspects, like an inherent low output impedance that allows effortless bass. All this, with the great advantage of high efficiency. Of course, only if they are properly designed.

However, although very attractive, Class-D designs are not very DIY friendly. In order to achieve a properly working design in terms of efficiency, performance and EMI, very careful PCB layout is mandatory, some component selections are critical and of course proper instrumentation is absolutely required.

This article has been written in order to throw some light about the internals, advantages and difficulties of this not very well-known (and even less well understood) technology. Everyone thinks that “Class-D” stands for “Digital”. I hope that after reading this article, no-one thinks that any more

Valve Amplifiers
- do they <u>really</u> sound different?

Despite a decade and a half of transistor development, many hi-fi enthusiasts have remained faithful to valve amplifiers. Now it seems amplifier manufacturers worldwide are having a second look at this once all-but-discarded technology.

This article is a partial reprint from the November 1977 edition of Australian Hi-Fi Review, with only the discussion section and review of the hybrid valve amp I designed. Please see the copyright notice at the end of this document.

Valve Amplifiers

WHEN Harold Leak introduced his company's (H.J. Leak & Co) first transistorised amplifier, the famous Leak Stereo 30, he remarked that in his opinion, eliminating the output transformer was the greatest advantage of the new model.

The Stereo 30 was a very significant development. It was the first commercial transistorised amplifier from a leading British manufacturer, previously renowned for state-of-the-art valved designs. Its introduction reflected the very sudden shift world wide from vacuum state electronics to solid-state, at a time when the thermionic valve was still capable of further development and exploitation.

It's easy to understand why amplifiers and hi-fi electronics in general became transistorised so rapidly. Transistors saved costs, and in terms of standard test procedures, measured far better. Total Harmonic Distortion (THD), for example, that still-revered but relatively unrevealing yardstick of performance for hi-fi amplifiers, was invariably lower with transistorised units. Power outputs were far

higher than from valved models of equivalent prices. Hi-fi amplifiers had now, it seemed, reached a peak of development, with minimal distortion and unlimited power availability (or so it seemed) to drive the new breed of inefficient speakers.

In the fifteen years or so since the great transistor revolution, the valve-versus transistor argument has constantly been debated. Many audiophiles regret having sold their old Quad 2's, their Fishers, their Scotts, their Leak TLl 2's, Stereo Twenty's and Sixty's and so on, having found the new transistorised designs less satisfying sonically despite vastly superior general specifications (right on! - Ed).

Until fairly recently, many of the problems associated with transistorised amplifiers remained unidentified, and there is little doubt that further problems have still to be identified and overcome. Yet there is no evidence that a transistorised amplifier (even one based on miniature integrated circuits) cannot sound at least as good as the very best valved models. Harold Leak's remark in connection with output transformers is one of the best arguments in favour of transistors, for it seems to be the output transformer more than any other component in a valved power amplifier which dictates performance quality. And good output transformers are very expensive indeed.

If we are to establish why a valved amplifier sounds better than a transistorised amplifier (and we're still far from convinced that this is so) we must look at the technique in both instances. It would appear that conventional methods of test and measurement give little real indication of how a particular component is going to sound, and this is probably because of the enormous difficulty of providing a controlled and quantified test signal simulating the sort of signal derived from musical sounds.

In a practical situation, an amplifier is faced with signals of astounding complexity, vastly different from the far simpler signals derived from test equipment.

In addition, an amplifier is also faced with a practical loudspeaker for a load, and an investigation of the behaviour of a speaker as seen by the amplifier reveals a situation which often makes the dedicated audiophile want to give up the whole idea of high quality sound reproduction and retire to a desert island! Many amplifiers particularly transistorised ones-can be excused for complaining audibly about the sort of load they are called upon to feed.

And at the amplifier front end, there is another interface problem, that of the source (invariably the pickup cartridge and its need for equalisation and good S/N ratio poses the greatest difficulties) and its effect on the preamp input performance.

There is a lot of evidence to suggest that a good transistorised preamp is superior to a good valved one, not simply in terms of measured performance but in terms of the audible result.

There is no doubt that most valved amplifiers contribute to a categorically different audible result from that of most transistorised amplifiers, in fact an experienced ear can almost invariably judge whether a valved or transistorised model is in use. This points to an influence by design and manufacturing technique on the result - which might seem obvious but which should not happen in theory.

Most high quality valved amplifiers of recent manufacture and design (within, say, the past couple of decades) use the so-called ultra-linear push-pull output stage, which inherently cancels out high-order-

harmonic distortion and has a number of other important desirable characteristics.

As its description indicates, this type of output stage employs a pair of valves in which one 'Pushes' and the other 'pulls' - a mechanical analogy being a two handled saw. Both valves operate throughout a complete cycle, swinging from positive to negative as demanded by the input signal. The use of two valves rather than one increases output amplitude to give more power than would be achieved via a single-ended output (quite feasible with valves). In fact many ultra-linear push-pull output stages will produce a useable signal with one of the valves removed, at the expense of power loss and increased distortion! (We don't recommend you try this, incidentally, if you own a valve amplifier).

Transistor Amplifiers

Most transistor output stages are rather different. Again, a pair of transistors is used, but in so-called complementary or (quasi-complementary) mode. In effect one transistor of the pair handles the nominally positive side of the signal while the other remains dormant. These roles ire reversed with the nominally negative side of the signal - the previously operating transistor handing over work to the formerly dormant transistor.

Some transistor amplifiers operate in a similar fashion to the type of valve units just described, although there are currently severe practical limitations mainly the voltage handling ability of power transistors-resulting in poor efficiency and excessive heat output.

Class A push-pull output stages are inherently distortion-cancelling and each amplifying device, be it valve or transistor, operates in a complementary electrical sense at all times. Deviations of performance from the ideal of either device are compensated by the other. But with so-called Class B stages, one transistor of a pair is constantly switching in and out of operation, handing over to the other transistor during its period of no operation. An obvious difficulty here is to achieve a smooth changeover or 'crossover' (not to be confused with loudspeaker dividing networks), and the main reason for the 'transistor sound' of most early (and unfortunately some present-day) transistorised amplifiers is/was poor crossover performance (where the switch from one transistor to another failed to give perfect signal continuity) leading to a spiky distortion most evident at low Output levels and high frequencies. Many transistor amplifiers actually had better performance at high output levels, quite the reverse of most good quality valved amps.

And then, of course, there is the output transformer. This is used in valved amplifiers to match the valves (which demand ahigh impedance load) to the loudspeaker, which is a low impedance device.

Transformers are extremely costly and in theory are responsible for a number of serious performance deficiencies including reduction of damping factor, phase shift toward the high frequency end of the spectrum, and, in a practical situation using a complex loudspeaker load and extended upper frequency response instability with consequent oscillation. No wonder Harold Leak was keen to eliminate this component!

On the other hand, the transformer serves as a 'buffer' between loudspeaker and amp proper. This can be advantageous with practical loudspeakers in avoiding the 'ricochet' effect of transistorised amplifiers

faced with back-EMF from loudspeakers resulting from unwanted diaphragm motion. This output from the loudspeaker can, in some circumstances, penetrate back to interfere with a signal passing out toward the speaker; a consequence of the inherently low impedance of transistorised amplifying circuits. Valves are inherently high impedance devices, and the effects of back-EMF from the speaker are therefore far less likely to achieve significant penetration at sufficient level to degrade performance. This must not be confused with damping factor per se which is generally rather better in transistorised amplifiers than in valved models.

A further factor in favour of transistorised amplifiers is long-term consistency of performance. Although total failure of transistorised amps seems to be more frequent than with valved units, repairs normally cost less and are quicker. Even so, overall reliability of transistorised amps seems to be better, especially in terms of performance consistency over prolonged periods.

Valves deteriorate at a fairly steady rate, and regular replacement is essential for top performance to be maintained. And, with very high quality amplifiers, this isn't always a matter just of replacing a valve - almost invariably, matched sets are required and it is also wise to optimise grid bias voltage level when valves have been replaced. Regular transistor replacement, on the other hand, is not necessary.

Generally speaking a transistor either works or it doesn't - and only requires replacing if it has an inherent fault or has been abused.

Of course, there are other fundamental differences between valved and transistorised amplifiers, and a study of these shows that a transistorised amplifier should be able to out perform any valved amp. This is certainly true of low-level amplifier stages, transistors generally having better signal-to-noise ratio, better frequency response in terms of overall bandwidth, better linearity across that bandwidth, and greater efficiency.

At the present time, hybrid valved/ transistorised amplifiers would seem to offer the greatest potential for best audible performance-transistors being used for all amplifying stages up to and including the driver stage, and a valved output stage.

In our experience, a top valved amp gives a sweeter, smoother result than a top transistorised amp, but this is a generalisation and we have heard at least one transistorised amplifier, currently being developed by Axxxxxx, a local manufacturer, which seems to have none of the audible deficiencies of either type. Nevertheless this (prototype) unit is still unhappy with some complex resistive/ reactive loads presented by multi-way loudspeakers, but the designer and development engineer are confident this problem can be overcome.

So much for technicalities. We've only scratched the technical surface here; there are far more behaviour characteristics of each type of amplifier which account for audible differences despite indications of identical expected performance from standard measurement techniques.

A--'S TRANSISTOR VALVE AMPLIFIER

Unfortunately delays in production prevented our reviewing A--'s fascinating new amplifier in this issue. This amplifier, as reported last month, is based on a valve output stage but uses transistor front-end and driver stages.

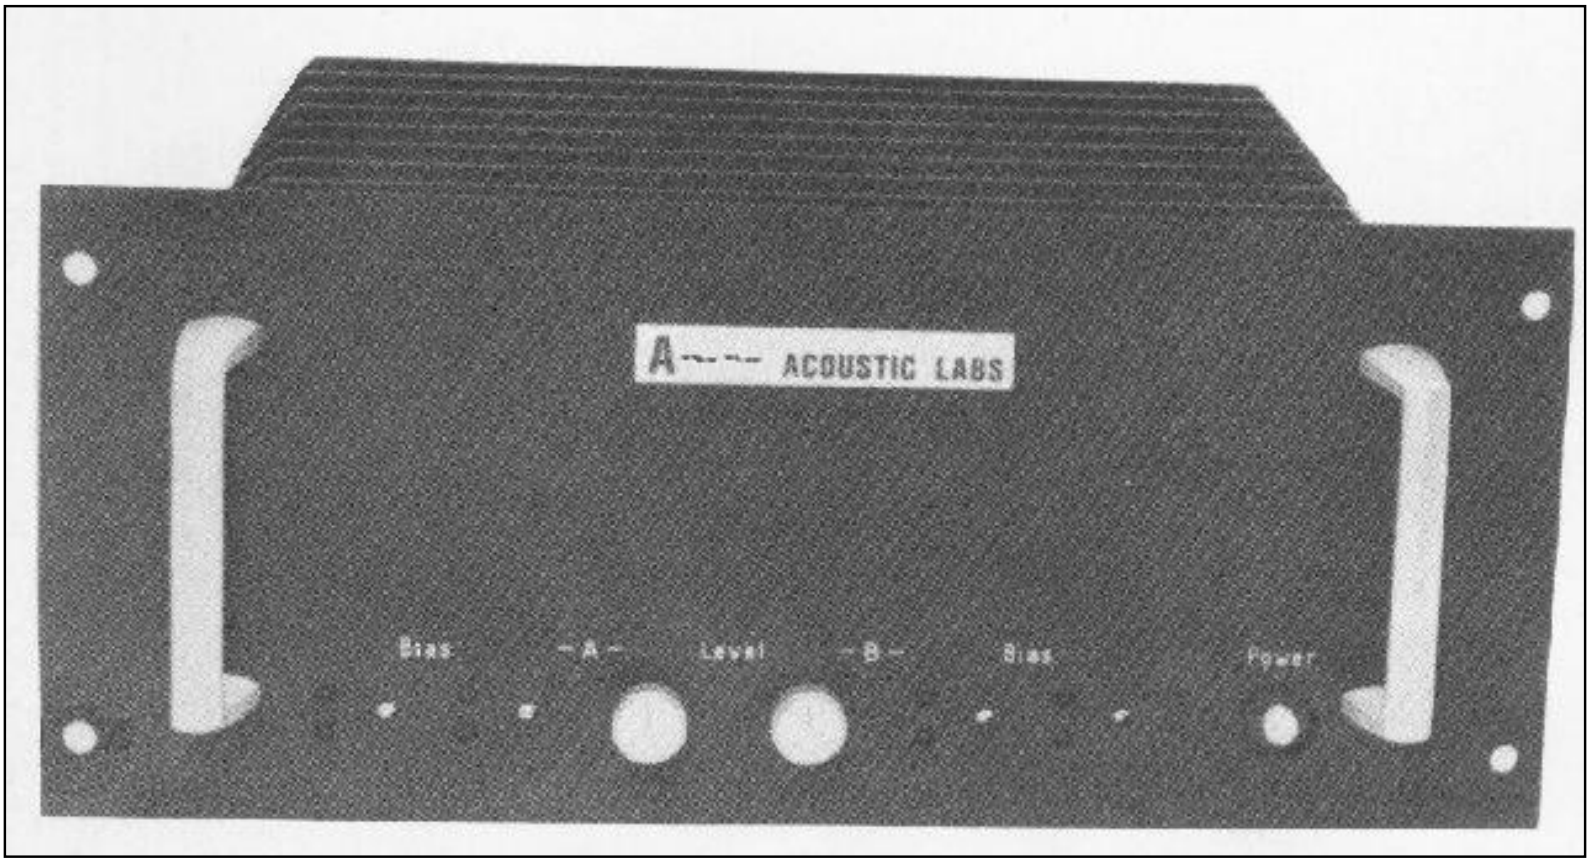

Figure 1- The Transistor / Valve Power Amp

An interesting feature of the preamp is a high-gain pickup input designed for use with low-output moving coil cartridges, plus of course the usual RIAA-compensated facility for cartridges of higher output. Following latest trends for top performance equipment, the preamp has no tone controls, and is fitted only with volume, balance, input select and tape monitor facilities.

The power amp has an ingenious system for optimising grid bias of each output valve, which contributes to minimum distortions and increased valve life. A pair of light-emitting diodes (LEDs) and a screwdriver-operated potentiometer associated with each valve is fitted to the front panel and adjusting the potentiometer for equal light intensity from both LEDs (of the pair) provides correct grid bias voltage. Level controls are fitted for each channel.

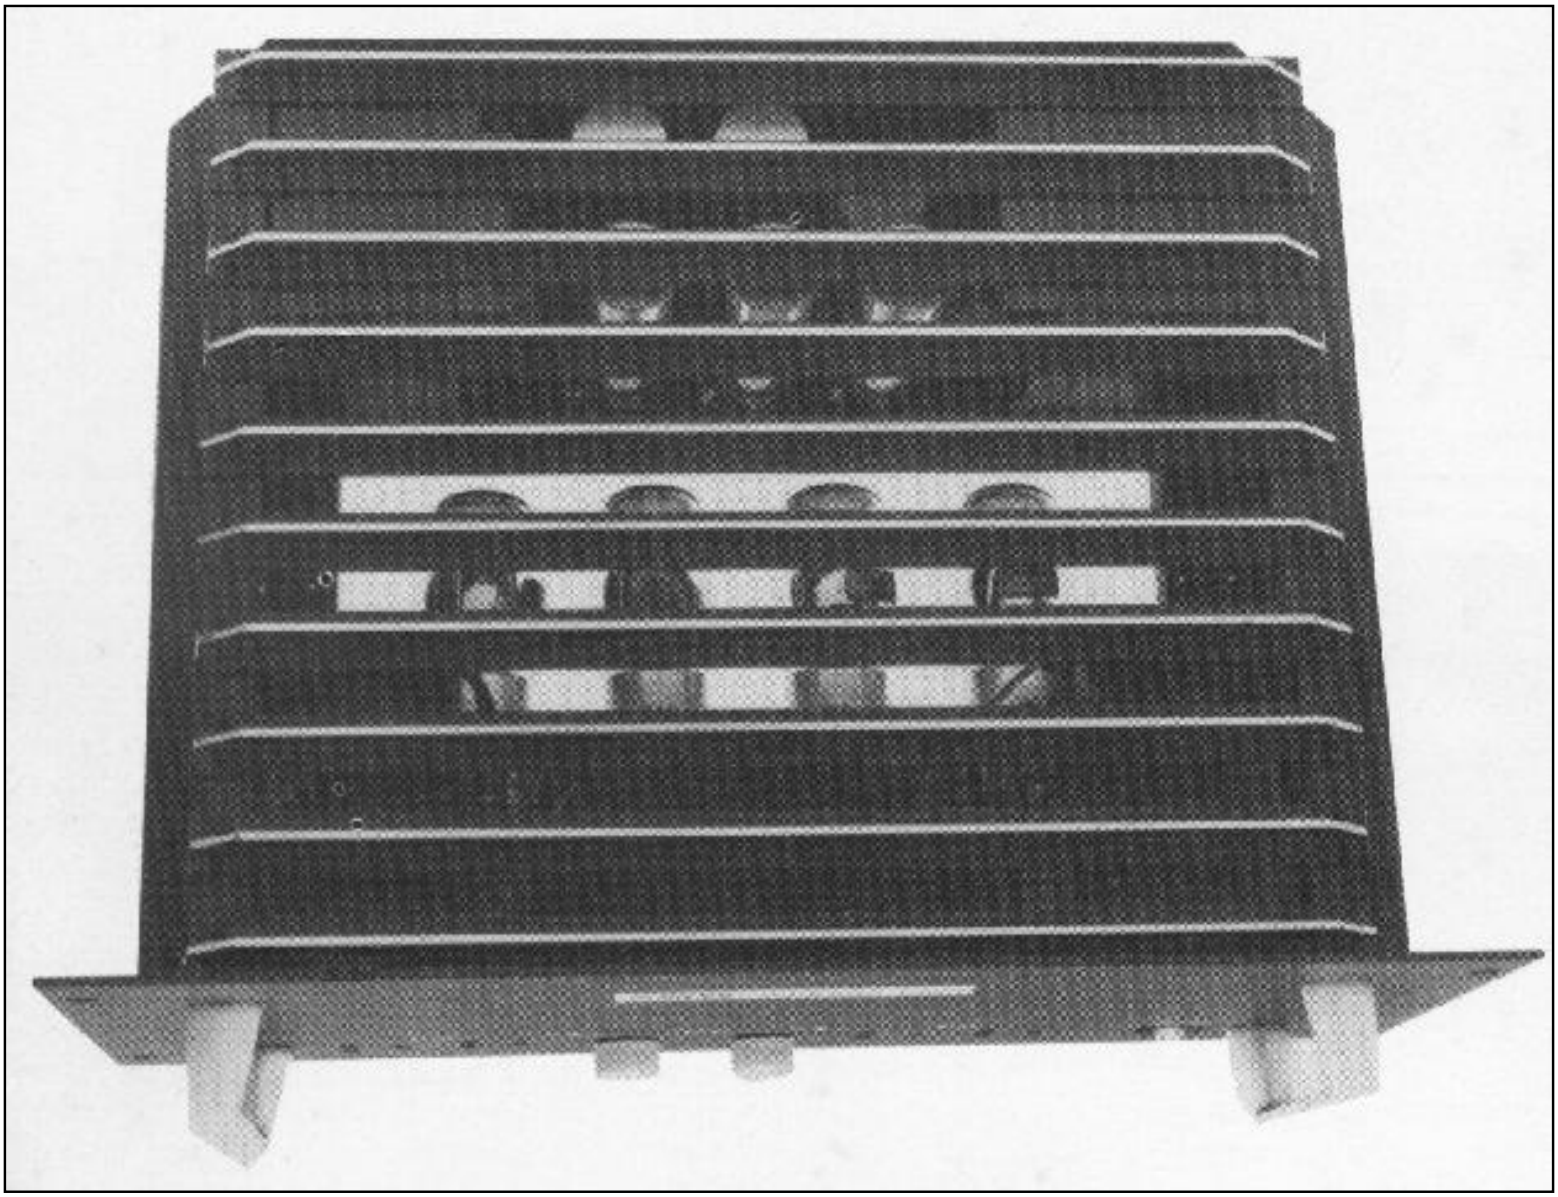

Figure 2- Top View of the Valve Power Amp

The power amp looks quite a monster and the sight of those enormous KT88 output valves, visible through the gaps in the T-section aluminium cover members is quite nostalgia-invoking.

The preamp, provided with a remote power supply which helps improve signal-to-noise ratio, has, by comparison, an unobtrusive appearance although we understand production models will be slightly different.

Power amplifier performance was excellent, low frequency sounds being particularly well defined and with good extension to extremes. There was no characteristic valve sound, the overall result being essentially neutral and with good definition of fine detail, impressive transient performance and excellent stereo imaging.

The preamp, whilst again having no specific performance deficiencies in terms of tonal balance, tended to sound a shade 'grainy' at times, especially when called upon to deliver high outputs. However this

was not unpleasant but rather gave a powerful, 'gutsy' sound which one observer described as giving the amplifier 'balls!' (blush, blush!).

Production is currently in full swing and samples of the amplifier should be available from AMW retailers during December. Rated output of the amp should be in the vicinity of 100 watts per channel, thanks to the use of very carefully wound and efficient output transformers - the prototype was claimed to yield some 60 watts per channel but sounded far more powerful than most amplifiers of this rating.

We're very much looking forward to seeing and hearing production samples of this very fine new Australian product, which upholds the firmly established AMW reputation for fine performance.

Price is expected to be around $2,300 for the preamp/power amp combination.

ESP / Rod Elliott's Notes: The electronics of the power amplifier and preamplifier referred to in this article were designed by me – I cannot take credit for the design of the power amp casing nor the specification for the output transformers, as they were the domain of my business partner of the time. The amp was designed on contract to A-- Acoustic Labs.

Also note that if some of the comments seem a little dated, this article was written in 1977, so they are indeed dated. The basic ideas are still the topic of debate, so although everything changes, it still stays the same (except the price, of course - if you could build one of these for $2,300 today you must have stolen the parts!).

Please note that I have reproduced the text verbatim - I do not necessarily agree with the comments regarding the difference between valve and transistor amplifiers, nor with all the technical matters raised.

Elliott Sound Products **A-B Switch Box For Amplifier Comparisons**

Phil Allison
(Edited By Rod Elliott)

I have finally been able to add "Project X", thanks to Phil Allison. Somehow, "X" just seemed appropriate :-) Have fun.

Introduction

This is probably going to be a very controversial device. Its purpose is to prove people wrong and that is very confronting. If you don't wish to have your cherished beliefs about amplifiers and audio generally challenged then do not build or use this unit.

Many of you will know about the ABX system for doing audio comparisons. No doubt it is a very fine piece of design but out of reach for the average person. Some years ago I felt that a much simpler device would at least allow me to do comparisons on power amplifiers while the music played in a similar way to ABX. This device was the outcome. After using it for a few *seconds* my attitude to audio listening tests changed forever. If you are game for a challenge then try it yourself. It will cost you under $50 to build. It may be the best or worst fifty bucks you ever spent depending on your attitude.

The idea is that the listener, you, sits in the hot seat and concentrates on familiar music on your favourite speakers in your own lounge room with the ability swap power amps over without moving more than one finger. If there is even a small change in timbre or definition it should be instantly audible. The stereo image and any other factor can be checked precisely since you can sit totally still during the switchover. Well at least that was what was expected to happen.

Switch Box Design

The design is totally simple and I lashed mine up in a couple of hours and put it to use immediately. A couple of good quality relays, some hefty terminals and banana plugs and a long wire finishing in a hand held push button are the ingredients. The circuit is as shown and is self-explanatory. What is does however, is staggering.

Providing the two amps to be compared are of high quality (why would you be interested in anything else?) and of course fault free, the gains are carefully matched and have similar bandwidth the device permits instant and *seamless* switching of the amplifier outputs to the speakers at the push of the button in the listeners hand.

Because the relays switch in a couple of milliseconds there is **no** audible interruption. This surprised me at first and I tried my sine wave generator set to 100 Hz and pushed the switch. About half the time I could hear a faint “tick“ sound but this was not audible on musical program

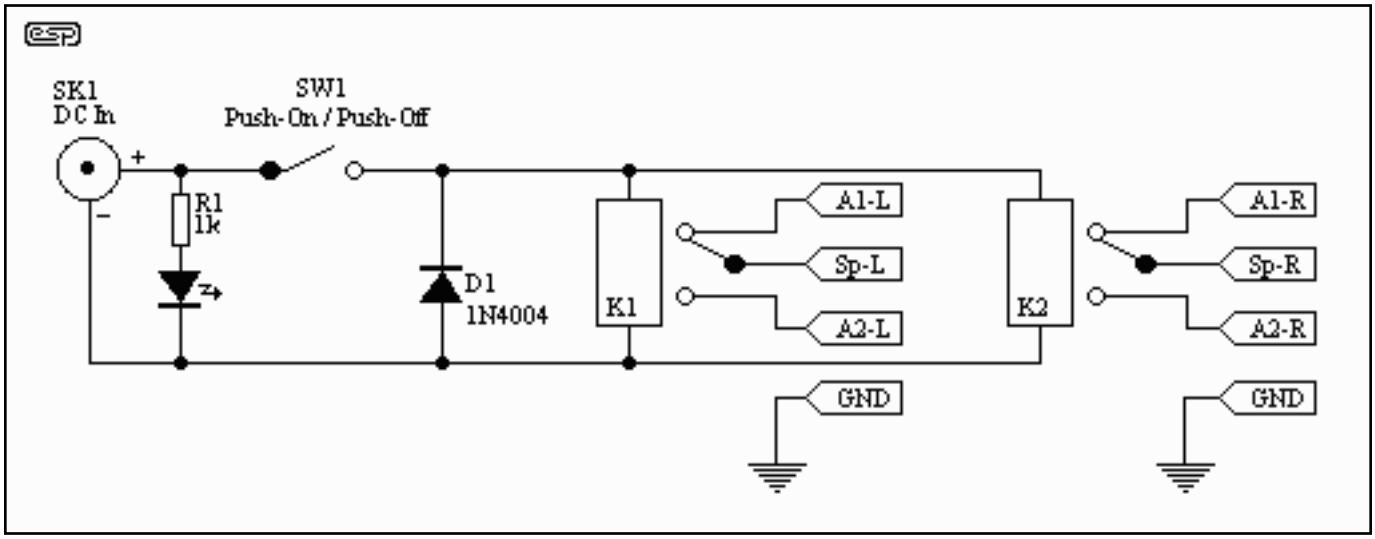

Figure 1 - The A-B Switch Box Schematic

A description of the circuit is hardly needed (but I'll give a brief one anyway). The DC voltage must be matched to the relays, and 12V is suggested as the most practical. The relays should be high quality, high current types, and DPDT relays can be used with the contacts paralleled for lowest resistance. Gold flashed contacts are desirable, but standard silver contacts should be quite adequate unless there is severe atmospheric pollution in your area.

The speaker grounds for the two amps were connected together at the box and the speaker grounds were coupled as well. Use short thick leads for connection to the amps. It is possible this might cause an earth loop hum with some combinations.

The switch (marked "Push-On / Push-Off") is the remote switch, and needs a lead that is long enough to reach the listening position. There is no real limit to the length, even with light duty figure-8 "speaker" lead, but in excess of 10 metres or so may cause some voltage loss. The LED is optional, and may be omitted. If fitted, be very careful that the LED cannot be seen from the hot seat, as it will dim slightly when the relays are energised, thus giving a visual clue - this you don't need!

Setting up the test

1. Build the box as shown in Figure 1 and place the two amplifiers close together. If one is on top of the other, then place some cardboard in between to prevent metallic contact and possible hum loops. (Make sure that you don't obstruct any air vents.)
2. Make "Y" leads to connect the left and right input signals to both amplifiers.
3. Use an audio generator or test CD to set gains to read equally +/- 1% on a digital multimeter at about 400 Hz. Leave the speakers unconnected while you do this.
4. Place the pushbutton on the “hot seat” or where you would normally listen to stereo from.
5. Check operation of the box by switching with no music and listen for the click of the relays as they changeover. There may be a faint click from the speakers too, due to small DC offsets. Trim these out if possible - the idea is to get a seamless change with no audible cues.
6. Put your favourite track on the CD player or turntable it you prefer vinyl.
7. Listen, and gently push the switch whenever you want to change amps.
8. Go and check why the box is not working.
9. If step 8 is not needed check your wiring for correct phase and levels again.
10. When you have everything right try it on your friends and family. They will likely think you have gone mad and or are playing tricks on them. The most likely comment is simply “the switch is not working”.
11. Sit quietly and contemplate what you have just found, and all its implications.
12. Don't blame me, I did warn you!!!

Notes:
When comparing amps of different power ratings, stay within the capacity of the smaller unit. Valve and transistor amps may be compared as long as the valve model has a damping factor greater than 25. Amps with subsonic filters may be distinguishable from those without on some material.

Matching the gain may be difficult if the amps do not have level controls. Solder a 10 kohm multiturn trim pot to the back of each RCA plug on the amp with more level to set the gain.

You ***must*** use a push-on, push-off hand held switch. Never use one that needs to be held

down to make the relays change over.

After the initial surprise (shock) wears off, try the old stop and restart A-B test method again. See what happens!

Editor's Notes

This is a contributed article, and the author (Phil Allison) has made this information available for the sake of audio, and not for profit or personal gain. The views expressed are not necessarily those of the editor, and no inference is made one way or another.

I do suggest that if you want to test this technique that Phil's instructions must be followed to the letter - even the smallest variation in level can invalidate any A-B test. Comparisons between valve and transistorised amplifiers are likely to show differences, only partly due to the higher output impedance of a valve amp, and extra care is needed to balance the levels with this combination.

It is also important that there are no visual cues that might alert you that one amp or the other is in operation. To be safe, place a screen of some sort between you and the amplifiers and switch box. As Phil has stated, if amplifiers are of different power ratings, make sure that neither amp clips (distorts) at any point during the tests. This will be immediately audible, and is not a valid test for an amplifier's sound quality (since it has none when clipping!)

If you don't want to be confronted by this switch box, build one anyway. It will allow you to make comparisons between amplifiers that are otherwise impossible to do with accuracy or repeatability. You might find that there are audible differences, or you might not. Either way, it gives you the ability to know (rather than assume or imagine) that one amplifier is different from another.

ABX Double Blind Audio Tester

Steven Hill / Rod Elliott

Introduction

This project describes the construction of test equipment for double-blind or ABX testing of source components - preamplifiers, tuners, DACs etc. or even, if that is your particular vice, interconnects. It builds on the work done by Phil Allison described in Project X. I recommend that you read that project description before you commence this one. If you do not like what you read there, then you might as well stop reading at this point.

Double-blind and ABX tests do not allow the listener to know which component they are listening to, and furthermore don't allow the test controller to know either. This guards against visual cues to the audience (including body language).

There is information on the principles behind ABX testing elsewhere on the WWW, therefore, I intend to give only the briefest description here.

An ABX test allows the listener to select either A or B as many times as they like, and ultimately decide which of these is X, where X is randomly selected by the equipment to be either A or B, and the responses are logged for correlation when the test is complete. For example, a 1000Hz tone is assigned as A, and a 1500Hz tone as B. Random selection determines which of these is X. Listen to A then X, listen to B then X, and decide if A or B sounds like X (this would be a rather easy test for anyone to get right, of course- but if B were to be 1001Hz it may be more of a challenge).

True ABX testing is normally not easy and uses a microcontroller or a PC to interface to the switching module. This was not an option as the project is meant to be simple and inexpensive. The simple remote control (part 2) requires an operator to control switching between A and B and to whom the active channel is known. However, if you proceed to build the double-blind remote (part 3), then the unit is a true ABX comparator - you select the next test in the sequence with the 12-position rotary switch and then have the opportunity to decode if X is input A or input B. This is "double-blind" because the sequence is not known until the test has been completed.

With the basic unit, two pieces of equipment (for example, two preamplifiers) are under comparison (A and B). They are fed from the same source. The audience hears first A and then B. Thereafter, the test controller selects either A or B as X and repeats the test for up to (about) twenty iterations, changing from A to B at his or her whim, and the audience is required to write down which they think it is for each iteration. Thereafter, the results are analysed to find out whether the audience was able accurately to identify which piece of equipment was in use at each iteration of the test.

There is no requirement that A and B are selected the same number of times during any single test. In fact, a test controller once ran a whole test with A. None the members of the audience selected “A” for each iteration. I leave you to consider what that result says about people’s confidence in their ability to identify different components.

The project is in three parts of which you must build at least two. I recommend that you build only parts 1 and 2 to start with. You might find that your experience of this piece of test equipment is so infuriating that you will regret the time spent on building part 3 if you proceed with it immediately.

It is vitally important that the output of the devices under test is equal. A difference of 1dB is normally sufficient to bias the test, normally in favour of the louder channel. Therefore, you will need a test-tone CD for calibration purposes if using CD as your source or an LP with test tones if using vinyl. If comparing tuners, you will probably find that tuning in the white noise between stations is the only way you can calibrate the two pieces of equipment. You will also need a multimeter.

Unless you are using a (very expensive) true RMS digital multimeter, you should not use a test tone above 500Hz. With an analogue meter you can use a higher pitch but I do not recommend that you go higher than 1kHz.

Part 1: The controller box

The circuit diagram should be fairly easy to understand. There is nothing difficult about it, and no electronics are involved in the audio path.

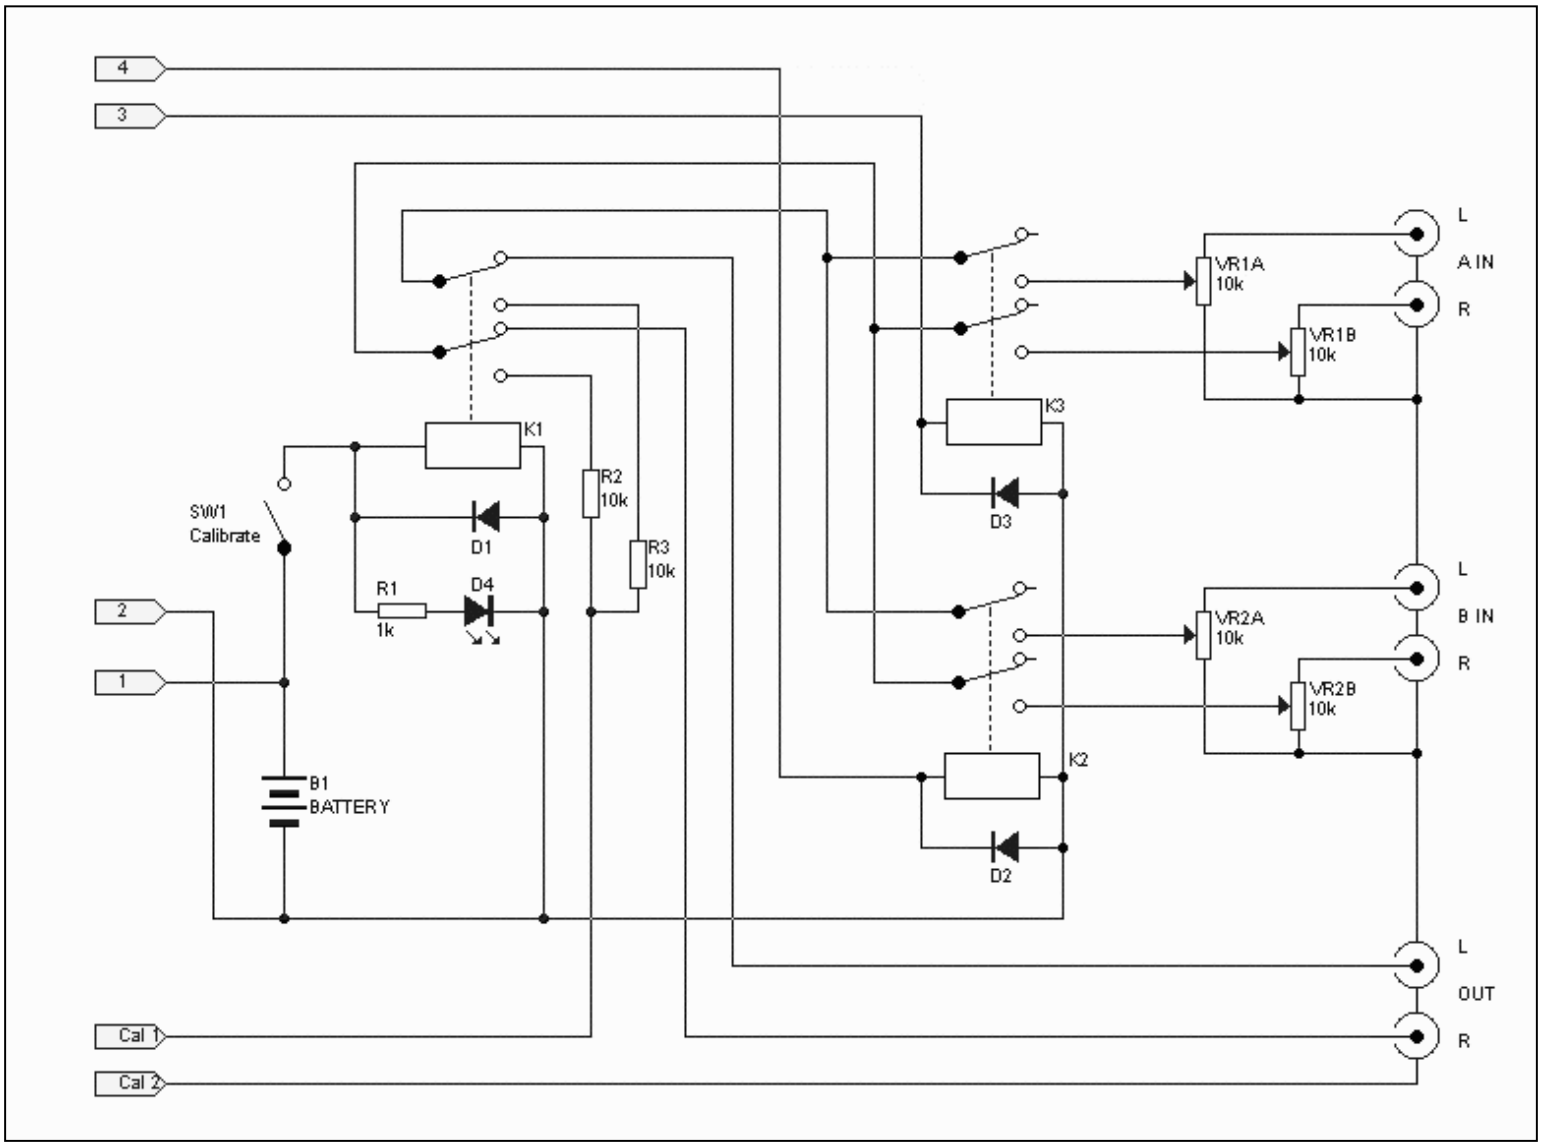

Figure 1 - The Switching Unit

Connections 1 through 4 go to either of the remotes and should be wired to a four-pin connector. The relays K1-3 can be low current types. The battery must match the voltage of the relays. I used 6V DPDT relays. K3 and K2 are used to select input A or B respectively. K1 mutes the output for calibration purposes. You could replace K1 with a switch if you wish but you then have to run more wires inside the box. The voltmeter connects externally to the two pins marked “Calibrate”. Pots are used on both inputs solely for consistency – if a pot is used on only one of the inputs, then some people may use this as “proof” that the device modifies one channel and not the other, and this can be used as an excuse as to why the results failed to correlate “correctly”.

The circuit should be built on a piece of Veroboard or similar and mounted in a shielded metal case. SW1 and D4 are mounted on the outside of the case, as are the connectors for attaching the voltmeter, the 4-pin connector for connection to the remote and the RCA plugs for the A and B inputs and the X output.

If you are proposing to use only the remote described in part 2 you do not need to take any precautions to ensure that K2 and K3 are inaudible at the listening position. However, testing using the part 3 controller requires that the relays be inaudible at the listening position. To do this you will have to mechanically decouple the circuit board from the case and also use some acoustic dampening material in the case. See note 2 below.

WARNING: I do not recommend that you omit the muting part of the circuit. When you come to use this device, you will first choose the music you wish to hear for the test and establish a realistic listening level Then you mute the output and use the 0dB level test tone to adjust the levels of both channels to the same voltage. You will probably find that the steady-state voltage is greater than 2V RMS. Unless you have monster loudspeakers, a tone at this level, fed through a power amplifier with a 30dB gain (which is common), will probably destroy your speakers and will do nothing for your hearing.

I have found that different pieces of music require different volume settings to establish a realistic listening level. An AB test where you are wincing at the volume or straining to hear the music is of no use. The calibration mute circuit has been included to speed up the recalibration between tests using different pieces of music.

That said, however, if you wish to go through the process of either (a) turning off your power amplifier(s) or (b) disconnecting your loudspeakers each time you need to recalibrate, you can omit this part of the circuit. However, you have been warned. (And you have forgotten to reconnect the speakers and/or turn on the amp(s) before proceeding with the test.)

VR1 (and optionally VR2) is included for trimming of the voltages during calibration. Obviously, the volume should be set using the preamps' volume controls (if those are what you are comparing). However, if you are testing preamps, both of which have stepped volume controls, you might find it difficult to match the voltages at your realistic listening level. That is what VR1 is for. If you don't expect to be doing this, VR1 can be omitted. For A-B testing of other equipment, such as tuners, VR1 will be required.

Part 2: The Manual Remote and its Operating Procedure

This is a simple selector which can be built in a small plastic box and is connected to the controller using four-core cable. Heavy duty cable is not required. The cable should be long enough that the operator can sit further away from the source equipment than a person in the normal listening position. SW1 is a 3-position rotary selector switch used to select A or B or null (center position). The channel selected is indicated by the relevant LED. SW2 is a DPDT toggle switch which flips the channel from A or B or vice versa. This can be used for simple A-B testing. I have found that there is an audible break when a toggle switch is used for SW2. You might find no break is audible if you use a rotary selector.

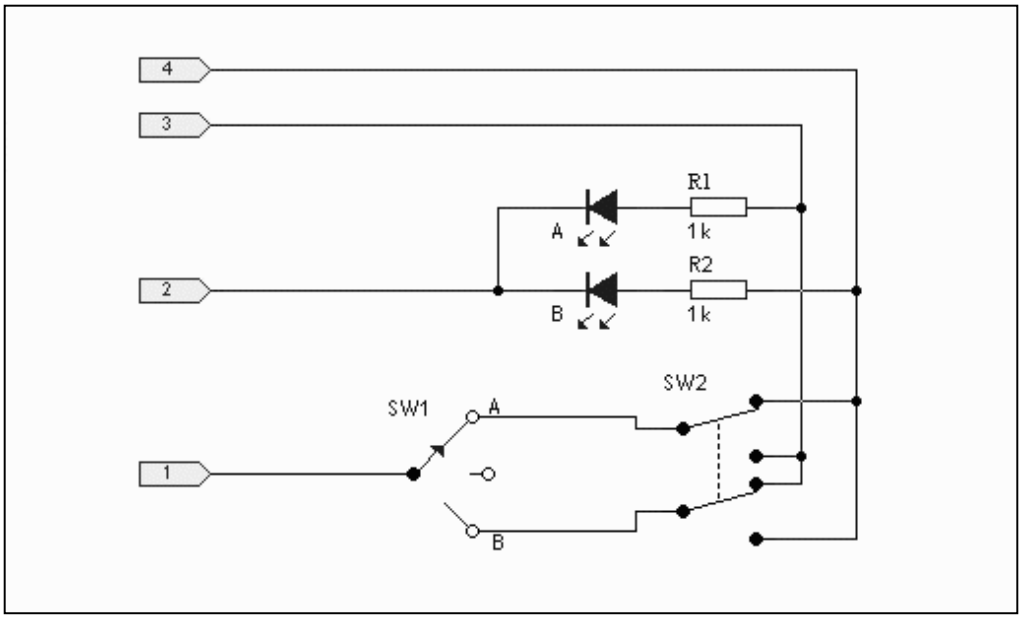

Figure 2 - The Basic Remote Schematic

To do an AB test with this remote you will need a (patient) assistant. The procedure (using as an example two preamps as the devices under evaluation) is as follows:

a) Use Y-splitters to connect the source equipment to each of the preamps. Connect the output of one preamp to input A and the other to input B on the controller box. Connect output X to your crossover or power amplifier.

b) Select one of the channels and play some music adjusting the volume on that channel to the desired realistic listening level.

c) On the controller box, mute the output using the switch provided. Connect a voltmeter to the calibration terminals. Insert the test tone CD, play a 0dB calibration tone and note the voltage. Use SW1 on the remote to change to the other channel and adjust the volume so that the same voltage is displayed. If stepped volume controls are in use, you might need to trim using VR1 on the controller. (Set VR1 to the maximum before calibrating and use it to attenuate the voltage.) Once the voltage is adjusted, remove the test-tone CD and replace the music CD and turn off the muting switch. Do not touch the volume controls again for the duration of the test.

d) Assume your normal listening position. You will need a pencil and paper to record your choices.

e) The person conducting the test (the operator) should sit out of view of the listener with the remote to hand. The listener must not be able to see the LEDs on the remote. Decide which one of you controls the source and how many iterations of the test will take place.

f) The operator selects first channel A and the listener familiarizes him/herself with the particular characteristics of the preamp connected to that channel. Channel B is then selected and familiarization of that that channel takes place.

g) The operator now selects either channel, the music is played and the listener to writes down whether A or B is his choice for X. The listener does not divulge to the operator his choice. The test is then continued for the number of iterations agreed upon, with the operator selecting either A or B. I recommend that, to avoid any unintentional bias, the sequence of changes be determined in advance of the test by some random operation (tossing a coin, throwing a die, for example). The operator should carry out this random operation prior to conducting the test.

h) The last iteration of the test having been concluded you may either check the results or return to step (b) with another piece of music.

The listener's choices are then compared with the operator's notes of the actual channel in use during each iteration. It should be immediately apparent whether any there is any correlation between the listener's choices and the actual selections.

If you do not have a patient assistant, or patience has run out, you might wish to proceed to ...

Part 3: The double-blind remote and its operating procedure

This remote uses cascaded SPDT slide switches to set up an A-B sequence which can be used blind for testing purposes and then read back to check the results. It should be apparent from the schematic how this works. The separate poles of SW1 and SW2 must each connect to lines 3 (A) and 4 (B). SW3 selects between SW1 and SW2. For each position on the rotary selector SW4, three SPDT slide switches are required. I have built this with a twelve-position selector using 36 slide switches.

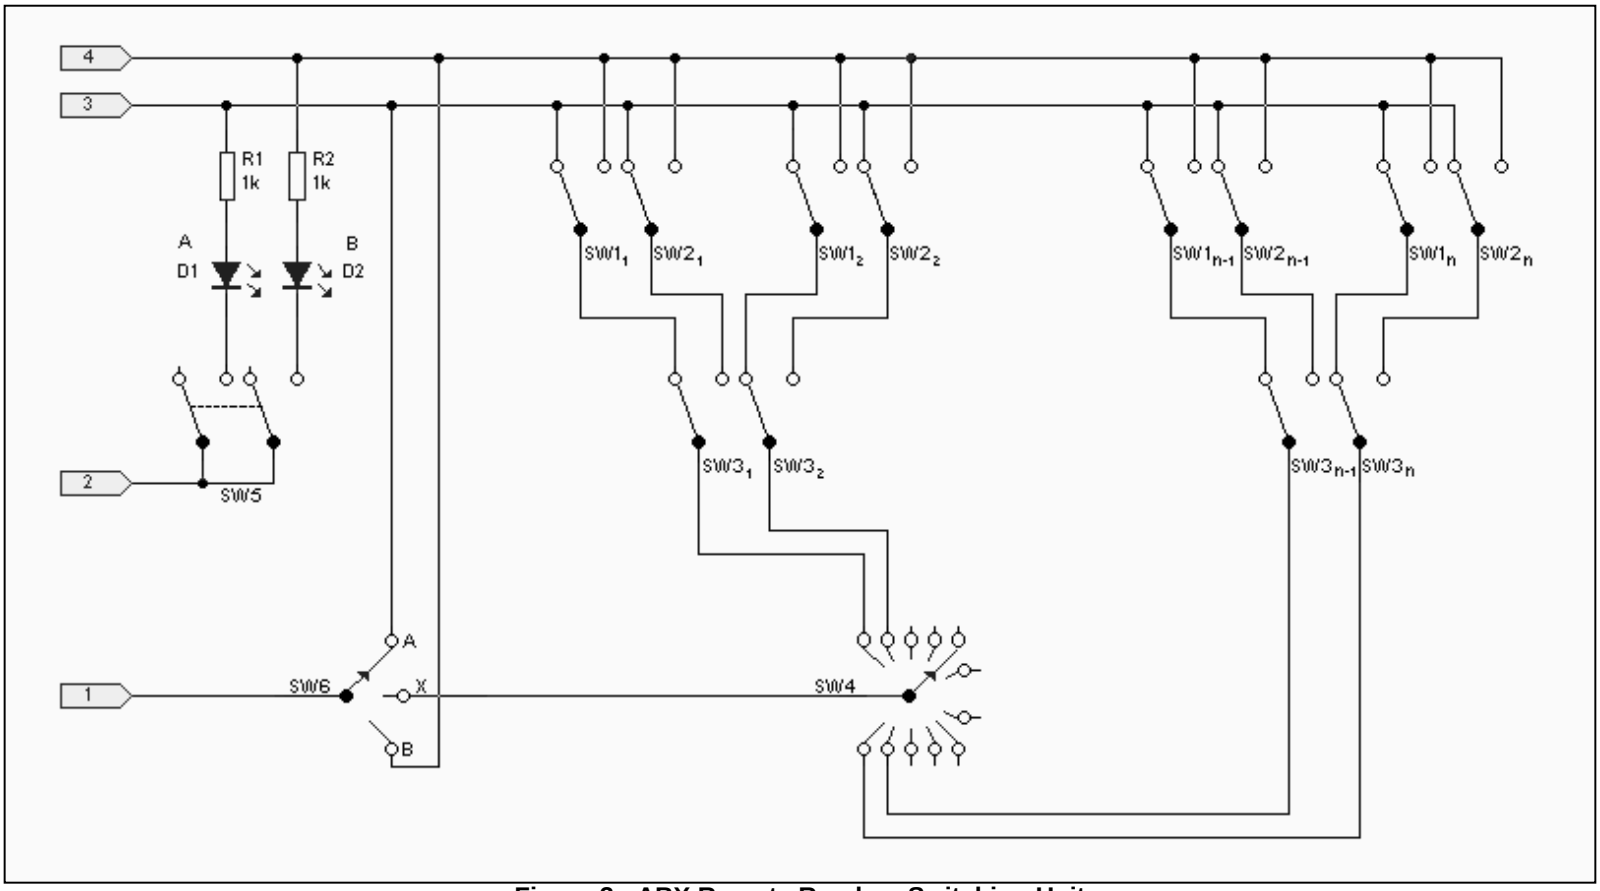

Figure 3 - ABX Remote Random Switching Unit

In the above, "n" is the number of poles on the rotary switch. If a 12 position switch is used for SW4, then "n" is 12, and "n-1" is 11.

The schematic, for clarity, shows the switches SW1, SW2 and SW3 connected together in a regular sequence. However, when building this remote, the switches are hooked up in an irregular fashion so that it is not possible from the outside of the box to identify what function any particular switch has, nor how they are wired in relation to one another. The separate poles of each switch (SW1 and SW2), however, must each connect to the A and B buses. If you do not do this you will introduce a bias in favour of one of the channels. The photo shows my own unit. Properly constructed, it should look like a mess of wires, as does mine. The orange and blue wires are the bus lines, the green wires the connections between the centre poles of the SW1s and SW2s and the brown wires go to the rotary selector.

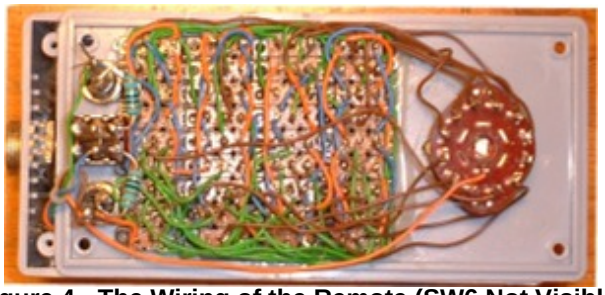

Figure 4 - The Wiring of the Remote (SW6 Not Visible)

If you decide to proceed with this part of the project, I must warn that this remote is tedious to construct and you must proceed with great care because trouble-shooting an incorrect hook-up or a dry joint can be difficult. You should first wire between the centre poles of the SW1s and SW2s to the SW3s, then run the bus wires to the outside poles of the SW1s and SW2s and finally connect from the centre pole of the SW3s to the rotary selector. Solid-core or magnet wire is recommended. The remote can be constructed in a plastic case.

So how do we use this abomination?

i) It is connected to the control box with the same four-core connector that you made up for part 2.

j) Before proceeding with the test, set up the test sequence by moving half of the total number of slide switches on the box. SW5 must be open at this time; no LEDs illuminated.

k) SW6 switches selects A or B for calibration as per (b) and (c). SW5 is closed (LEDs in circuit) during this step.

l) Open SW5 so that no LEDs are illuminated.

m) Assume your normal listening position and use SW6 to select A and B as in step (f)

n) Move SW6 to the X position. Is it A or B? Write down your choice. Proceed through all the other positions on SW4 marking down your choice each time.

o) When all positions have been sampled, close SW5, rotate the selector SW4 and observe which channel was in use for each iteration of the test. Correlate your results.

p) If you wish to repeat the test, proceed again from step (j).

Notes

1. It is probably legitimate to build part 3 with only an 8-position switch (24 slide switches) and run the test twice for 16 iterations (or a 10-position switch with 30 slide switches for 20 iterations). In this case, you would read back the results as in (o) note them down without correlating them, stop the music, perform step (j) and then proceed again from (m).

2. I mentioned in part 1 that, if you were considering building part 3 of the project you should ensure that the relays are not audible from the listening position. This is because, with an "off-the shelf" rotary switch, even thought they are nominally break-before-make, you will probably find that there is no interruption of the sound when changing positions even if there is a change of channel. If this is the case and if there is no change of channel, the relevant relay will not drop out. However, a change of channel will cause the relays to switch and you will hear it at the listening position, which is something of a give-away! If this troubles you, specify true "break-before-make" switches for SW1 and SW2 and then the relays will always click. (Actually, this is probably less troublesome than trying to insulate the controller box but has the downside that there might be an audible break in the music.)

3. You should be able to acquire all of the parts, including the cases, for less than $100. Parts 1 and 2 are simple to build. Part 3 will take a fair amount of time. However, the results of using this equipment may well astound or confound you and those to whom you demonstrate it. Did you ever wonder why your local high-end audio store does not have something so inexpensive like this so that you can compare your modest preamp, or whatever, with the mega-bucks piece of kit you have been drooling over ever since some reviewer's panegyric: "The best preamp I have ever heard for (only) the cost of a small family car."?

4. I mentioned at the beginning that you could use this to compare interconnects. How? Simply connect it in reverse: source into X, the cables under comparison to A and B then via a Y-splitter to the preamp. The presence of the Y-splitter and the controller box does not invalidate the test because the same "degradation" of the signal occurs to both cables. The author accepts no responsibility for domestic discord or other unpleasantness arising out of the use of this test equipment for such purposes.

5. ABX testing of CD players, turntables and cartridges etc. is problematic because of the difficulty of synchronizing them. However, the flip switch on the manual controller can be used to make a direct comparison between the two pieces of equipment.

I hope that this little project will amuse you. I should be happy to hear from anyone who builds it and takes it along to their "high-end" audio supplier for the purposes of comparison. Mail me on abxcomparator@hotmail.com.

Steven Hill, August 2002

Editor's Notes

Steven has done something I had thought would only really be possible using a microcontroller or a PC to achieve. The

random switching is of such complexity that it would be virtually impossible for anyone to know and remember the combinations created by each switch. Especially if assembled according to the instructions - the switches are not only capable of giving an excellent randomisation of their own accord, but if they are wired in a random fashion as you build the unit, the likelihood of being able to remember the combinations is extremely low.

Will it be worth the effort? Only you can answer that, and it depends on how serious you are about being able to tell the difference between pieces of equipment. Just like Phil's original Project "X", your first reaction may be that the unit is not working - the LED indicator that Steven included in the design to allow you to correlate the results will certainly prove that A and B are being selected, and if you are *really* unsure, you can always switch off one of the units under test.

All in all, this is an ambitious project, but one that every hi-fi reviewer should make (or have made) - I expect that if this were done, a great many of the glowing reviews we currently see would diminish. They may even vanish altogether.

Needless to say, the tester can be also used to verify that the expensive capacitors you bought really don't make any difference, or that all well constructed interconnects sound the same. This is all very confronting, but it is necessary if we are to get hi-fi back on track, and eliminate the snake oil.

1.0 - Introduction

Although few would regard the AM/MW broadcast band as being capable of high fidelity reception, the reality is that most good quality AM broadcasters put to air quite a high quality audio signal, covering quite a wide audio bandwidth (to around 8kHz or so). The problem is that the majority of AM receivers in use today make use of the superheterodyne circuit principle (conversion to an intermediate frequency (IF) prior to detection), something that unfortunately results in very severe sideband cutting, with the result being audio bandwidth and quality comparable to an ordinary telephone channel.

Those who have heard AM under ideal conditions will know how good it can sound, with a clarity, bandwidth and subjectively superb quality that has to be heard to be believed. I have been tinkering with wideband AM receivers since my late teens, and in fact these were my first dabblings into the wonderful world of high fidelity. I have many fond

memories of laying in bed listening to the late night jazz music programs as reproduced through my home made 'crystal set' tuner feeding my old pioneer audio amp and old AR28 loudspeakers. I remember thinking, "that sounds so good". In those days we had no real FM service in our area, and AM on the medium wave broadcast band was all that was available. That was a very good incentive to see what could be done with wideband AM reception. Although I had only a very basic knowledge of radio and electronics at the time, I think I did a reasonable job with that very basic set-up. That initial passion has continued to this day! The great advantage of a simple 'crystal set' type of AM tuner, or similar is that all processing takes place at the (RF) signal frequency, and despite the limitations of this approach, the full modulation impressed on the carrier can be recovered - something not easily done with a superheterodyne receiver without much additional circuit complexity and refinement.

---

2 - Description

I mentioned the crystal set in the introduction. Apart from the charm of a receiver that requires no power source, a well designed crystal set tuner feeding an audio preamp/ power amp combination can give excellent results under ideal conditions. There is a lot more to diode envelope detection than one might think, especially if one is aiming for high quality detection. The process of diode detection is often explained in overly simplistic terms in text books, in my opinion. In reality, there are lots of factors that affect the ultimate potential quality of a simple RF diode detection system, such as the RF injection level and the loading on the diode (the so-called AC/DC ratio), which has major implications on the overall detector distortion profile, especially at high modulation percentages (very common practice these days in the broadcast industry in the endless quest for a 'loud' signal).

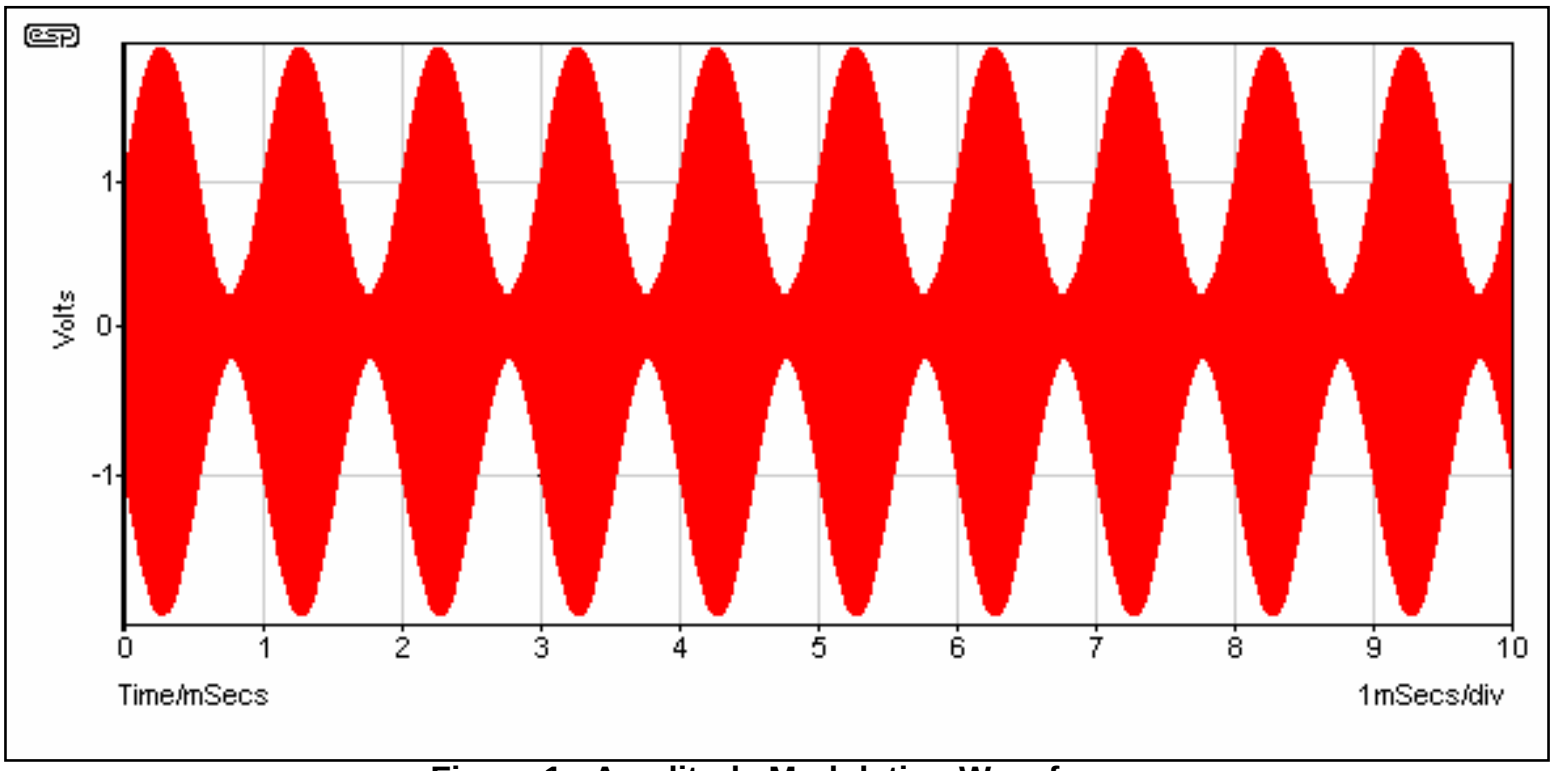

Figure 1 - Amplitude Modulation Waveform

The amplitude modulation waveform is shown in Figure 1. Maximum modulation level occurs when the RF signal falls to zero (maximum negative modulation), or is doubled (maximum positive modulation). Practical limitations mean that the minimum is usually around 5-10% of the static (unmodulated) RF power to prevent 'splatter' - a form of RF distortion that causes massive interference across the radio frequency spectrum. The maximum can be up to 150% of static power, and phase switching is often used to ensure that the highest level signals always increase transmitter power. This is possible because audio waveforms can be highly asymmetrical. The audio signal is *always* compressed and limited to ensure that over-modulation cannot occur.

Germanium diodes are considered mandatory in this service due to their low turn on voltage and consequent good sensitivity to weak RF signals. Although true germanium diodes are still being made, many electronics parts stores are now stocking germanium diode 'equivalents', diodes that are actually silicon schottky (hot carrier) diodes, fabricated to electrically resemble germanium diodes as sensitive RF detectors. They are actually pretty good. As with all silicon schottky diodes, they exhibit very little reverse leakage, very good weak signal sensitivity and low noise. They do possess a higher junction capacitance than most point contact germanium diodes, but this is not a problem in crystal set service. In a moderate to strong signal strength area, a simple diode detector of this type will work well. Combined with optimal diode loading and a selective tuned circuit front end, this kind of approach will indeed work well and provide a high quality audio program source for AM reception.

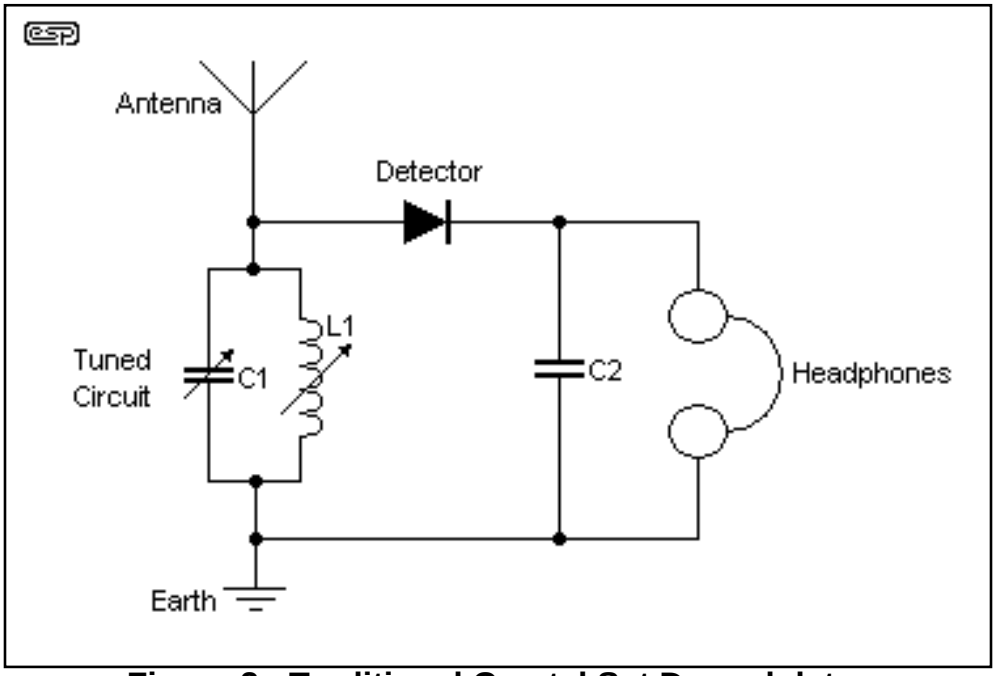

Figure 2 - Traditional Crystal Set Demodulator

Figure 2 shows the general arrangement of a 'traditional' crystal set. As shown, both the tuning coil and capacitor are variable, although many different arrangements have been used. Some sets used variable capacitance and a tapped coil, others a fixed capacitance and a variable coil. Still others used an RF transformer (so L1 has an additional winding) to create a better impedance match between the antenna (aerial) and headphones. Piezo-electric earpieces were commonly used because of high sensitivity and impedance. The audio signal can be taken to an amplifier rather than headphones.

The need for a selective front end and optimal diode loading are rather important. The relatively low impedance of the diode detector circuit will invariably heavily load its feeding tuned circuit, something which can cause problems such as station overlap and generally poor station selectivity in tuning. My preferred approach is to use double tuning, where using two separately tuned and coupled networks results in much improved 'nose and skirt' selectivity. This does complicate the design admittedly, but the overall selectivity improvement is definitely worthwhile. With single coil tuned circuit arrangements, a commonly used approach is to use coil taps in order to reduce the loading problems by connecting the diode and antenna to a point on the coil of lower impedance. This approach can work well, but it is not quite as good as two separately tuned networks in practice.

The diode loading aspect is actually a rather complex subject, but basically, the ratio of the AC and DC load on the diode output should be approximately equal for the best handling of high modulation depth with minimal detector distortion. This normally means a relatively low value diode load resistor, followed by minimal capacitive shunting as would invariably be needed for RF filtering purposes. A very high impedance for the following

audio preamp helps too. A following audio stage impedance of at least 250k is considered optimum. Actually, it is interesting to note that in these modern days of solid state technology, we are actually at some definite disadvantage as lower circuit impedances are generally the order of the day. Valve audio preamps of the past routinely possessed input impedances of the nominal required value.

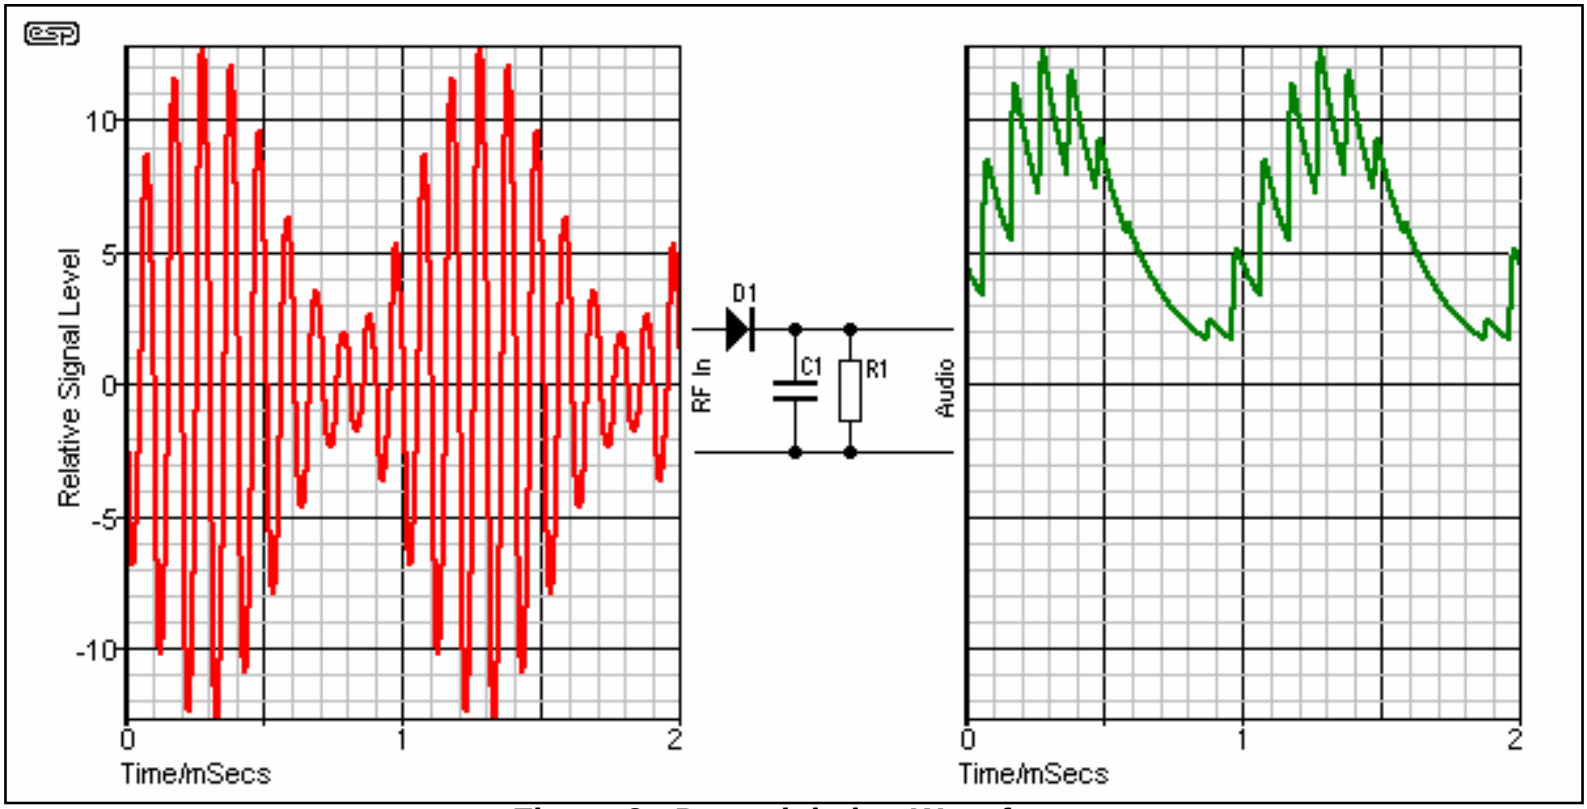

Figure 3 - Demodulation Waveform

The demodulation waveform is shown above. This assumes an ideal (or 'perfect') rectifier - i.e. a diode with no forward voltage drop, no resistance, and no junction capacitance). Because all of these parameters are included free with real components, an alternative diode demodulator is shown below. The RF waveform is shown on the left, but the carrier frequency is reduced to the minimum for clarity.

After passing through the diode, C1 integrates the signal. The cap charges and discharges slightly with each positive-going RF signal, and the remaining signal is the audio. It is always important that the capacitor value is worked out to be correct for the following load resistance (R1). If it is too large, that will create distortion - even if the diode is perfect. This is visible in Figure 3 at the negative-going audio peaks. If too small, excessive RF is applied to the following stage(s).

Note the DC offset in the demodulated audio signal. This is used in superhetrodyne (and some early TRF - tuned radio frequency) receivers to activate AGC (automatic gain control) of the RF stage(s) to ensure maximum RF level without excessive distortion.

Listening tests and evaluations show that proper diode buffering makes a very audible difference in a high quality AM tuner application. It is worth noting that diode detectors like to work with a moderate to strong level of RF input, and audible distortion does increase somewhat at lower signal levels. I have developed a novel method of using adjustable voltage bias with a 1N5711 UHF mixer hot carrier diode that does provide improved performance at lower RF signal strengths. This biased diode detector has an incredible ability to produce clean detection under even the weakest signal strength conditions by careful adjustment of the bias potentiometer! As an aside, it must be mentioned that the subject of diode detector distortion is a complex one, and much more involved than one might think. It is gratifying though, that good results can be obtained with simple circuitry.

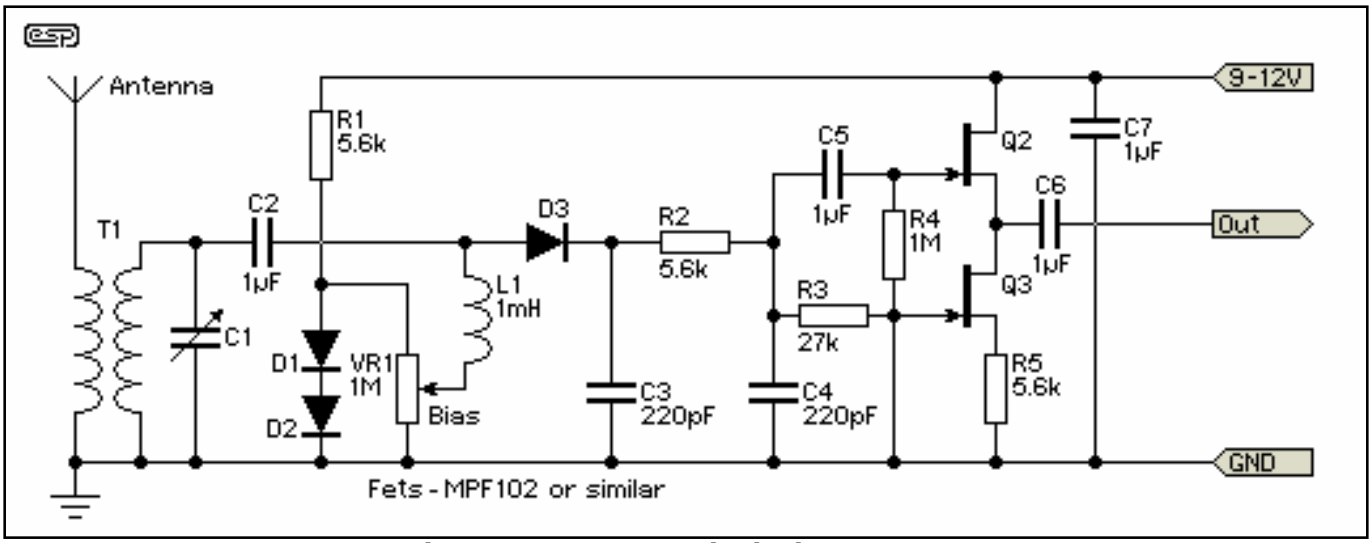

Figure 4 - Improved Diode Detector

Based on some simulations that ESP did with the circuits, a biased detector can reduce distortion from around 6% to 1% with a strong signal, with potentially greater improvements at lower levels. As noted though, this is a complex issue, and not one that lends itself well to simulation - unless the simulator is optimised for RF analysis. Most are not.

However one doesn't have to use a diode type of AM detector. There are other ways to achieve high quality AM detection. I have investigated a number of bipolar transistor and field effect transistor circuits that offer excellent general performance and other advantages as well. The 'infinite impedance' detector, using a field effect transistor is a personal favourite. It is based on a very old triode valve circuit from the early days of 'wireless'. FETs (Field Effect Transistors) are remarkable devices, especially in RF applications, and their close electrical similarity to valves is a very useful characteristic indeed. A FET version of the infinite impedance detector is easily made, and offers very high quality AM detector performance. A particular advantage results from the very high gate impedance of the FET into which the tuned circuit is fed. This effectively eliminates

the selectivity problems caused by diode detectors. I have used single tuned arrangements combined with infinite impedance detectors with excellent results in terms of good selectivity. Such is the advantage of a very high input impedance.

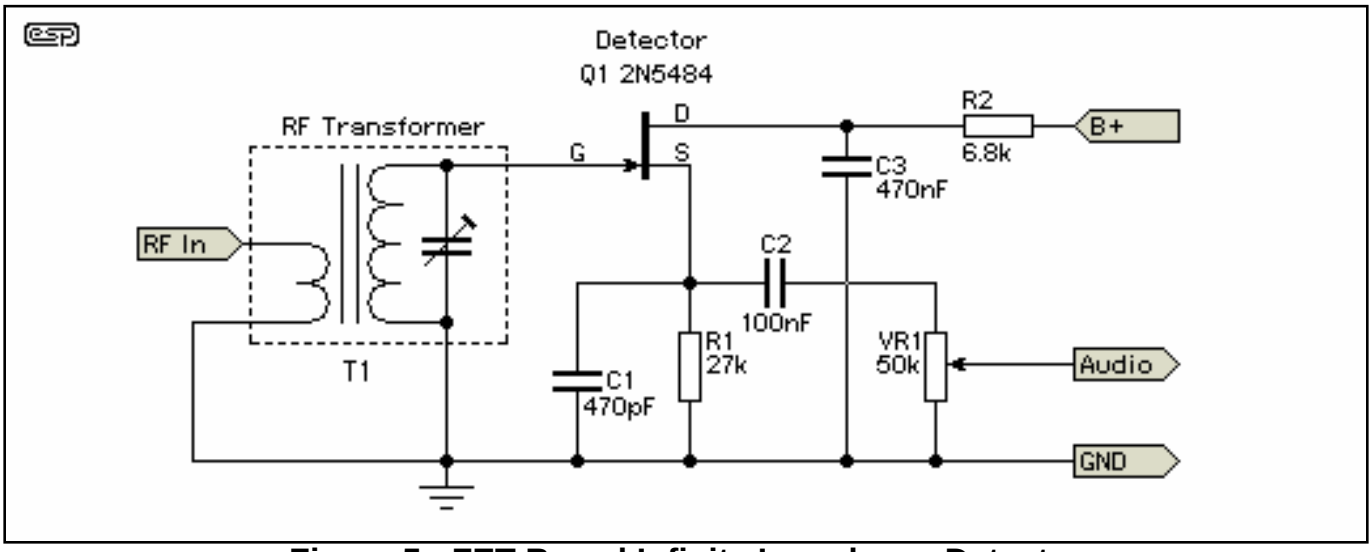

Figure 5 - FET Based Infinite Impedance Detector

A basic 'infinite impedance' detector is shown in Figure 5. While this will work very well, there are some refinements that improve performance. In my set-up, I make use of a high input impedance FET source follower modified with another FET constant current source for improved linearity and lower distortion. The second stage acts as a buffer between the detector and audio preamp input.

The version of the infinite impedance detector I have developed was adapted from the generic circuit that has appeared for many years in the ARRL Handbook, a long available and well regarded text, well known to Ham Radio operators all over the world. The circuit I've developed is more suited to tuner applications, and differs from the basic generic circuit in that the value of the source resistor is much higher, which overcomes a slight tendency to intermittent oscillation, has improved RF filtering, and includes a modified FET source follower output stage for improved audio drive into a following audio preamp stage.

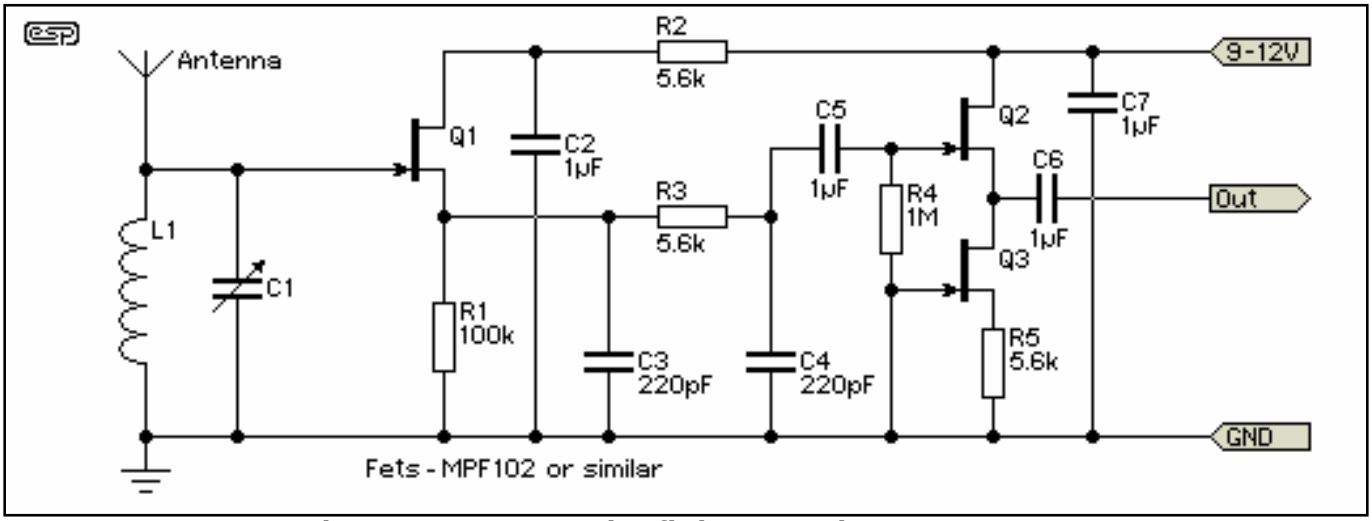

Figure 6 - Improved Infinite Impedance Detector

All round, the field effect transistor based infinite impedance detector is pretty amazing, offering high audio output, low distortion, excellent sensitivity and is quite free of the weak signal diode detector distortion tendency. It offers impressive performance for such a simple circuit. Just connect a tuned circuit and audio system, and one has quite a high quality AM program source.

All of these AM detector circuits offer potentially excellent recovered audio quaity, limited only by the quality of the original audio modulation. The infinite impedance detector offers the overall advantage of simple 'no fuss or adjustment needed' apart from tuning, but the biased diode detector has the advantage, by virtue of precise bias adjustment, of coping with any signal strength situation (strong or weak). This does require that the bias be individually optimised for each station received which can be a trifle annoying! However the audio quality under ideal bias adjustment has to be heard to be believed! Also as discussed earlier, due to selectivity considerations, a more complex "double tuned" input is considered desirable, however another option is to add a FET stage in front of the diode detector in order to relax potential selectivity concerns (as discussed previously). So many possibilities!

---

3 - Construction Techniques

Welcome to the wonderful world of building things at work at radio frequencies (RF)! Those who've only dabbled with audio gear will be slightly shocked by the way things are done at RF. It's basically a different world. At times, I've even wondered if Ohms Law applies at RF! At broadcast band medium wave RF, things aren't too critical, but it still pays to do things the right way. At RF, the effects of stray and 'incidental' inductance and capacitance become an important factor. Even a short piece of wire represents a substantial amount of inductive reactance at RF.

XL = 2 * π * F * L... and ...
XC = 1 / 2 * π * F * C

Where XL = inductive reactance, XC = capacitive reactance, F = Frequency, L = Inductance and C = capacitance

Things like excessively long leads are a no-no at radio frequencies - you will get around 5-6nH of inductance for each 10mm (1cm) of straight wire, depending on lead spacing and many other factors. My favourite method of construction is using a piece of copper clad circuit board material and wiring all components 'point to point' with all earth (ground) connections going directly to the copper surface of the circuit board material which provides a low impedance ground plane. Veroboard or similar is also quite ok at lower radio frequencies if used appropriately.

Pre-wound coils and ferrite rods can be purchased from the usual parts shops, along with suitable variable capacitors with a maximum capacitance of about 260 pf. The two outer leads of the variable capacitor need to be commoned together to obtain maximum capacitance. I prefer to wind my own coils in the interest of optimising coil Q (or coil quality). This is a very complex subject in itself, and many differing winding approaches are used, including the use of so-called litz wire. I use ordinary enamelled copper winding wire of about 0.315 mm thickness, along with spaced turns, where a slight gap (about a wire thickness) is placed between each turn. This helps with coil Q. A drop of super glue adhesive at the start and end of a winding is perfect for stopping a coil from unwinding itself. For the MW band, about 50 turns on a ferrite rod will be needed, however the exact number of turns may vary somewhat depending on local conditions and the desired tuning range.

For simple crystal set type of AM tuners, unless one lives close to a local transmitter, some kind of external antenna and earth connection will likely be required (just like in the old days). Remember that a simple crystal set tuner is a purely passive detector arrangement without any additional active front end RF gain, and the diode detector needs all the help it can get, hence the need for an external antenna. Depending on the method of connection to the tuned circuit, the antenna can affect the tuning range of the tuned circuit. With simple receivers like these, external factors can have a big impact. Remember too that the audio output level is entirely dependent on the incoming RF input level. A lot of empirical adjustment may be needed, but that's half the fun. An earth connection is also needed, but sometimes existing earthing through the audio gear is sufficient. I have an earth rod driven into the ground outside my window in the garden outside with a short connecting lead.

4 - Conclusion

Individual construction arrangement techniques are left up to the constructor, but remember the general guidelines when working with RF circuitry and also try to leave a little space around the coil(s) from any metal (enclosure etc) in the interests of not degrading the coil Q. Very importantly, when working with any type of external antenna, safety is absolutely paramount! I spent nearly four months in hospital after a serious accident when I fell from a roof, and I live with permanent spinal cord injury as a result. Don't repeat my mistake!

Despite the limitations of this kind of approach to wideband AM reception, I personally have found this a very satisfying way to listen to local AM stations with the sort of audio quality that no ordinary receiver can match. In fact, one may realise that your local AM radio station may have some transmission problem such as distortion or other defect. Such is the potential resolution of this kind of AM tuner. It is rather sad that many transmission defects will go completely unnoticed when listening on an average receiver with a poor audio bandwidth and lots of inherent circuit noise and distortion but are immediately noticed when listening on a high resolution system such as these AM detectors provide! In any case, once you listen to true wideband AM audio you will never think of AM in the same old way ever again!

1.0 - Introduction

A great deal has been made of the 'sound' of capacitors. Dielectric losses (dissipation factor, dielectric absorption) feature heavily, with some fairly outrageous claims made as to the importance of these losses in amplifiers and other audio equipment. There are sites on the Net showing that different caps have different properties, and this is often used a 'proof' by

many people that the differences are audible. There are sites that seem to have impeccable credentials, but have managed to create nothing but FUD (fear, uncertainty & doubt) with wild claims of irreparable damage to the signal by using the 'wrong' kind of cap ... even as a supply bypass (yes, it's true - this claim *has* been made). In some cases you will read things like "listening tests have indicated ... (blah, blah, blah)". But where is the data? Who conducted the test? How was it conducted? Was the test ever *really* conducted at all? Most claims of this nature indicate that there is a hidden agenda, so beware.

What is often missed completely, is that capacitors used for signal coupling must have a very low impedance for all frequencies that one expects to pass through the system, and in general, the impedance (capacitive reactance) should normally be less than half the circuit impedance - for the *lowest frequency of interest*. For example, a coupling cap that is used at the input an audio amplifier may have a value of 1uF, with a following resistive load of 22k (this is fairly common in ESP designs).

The capacitor has a reactance of 7.9k at 20Hz, and 22k at 7.2Hz (this is the -3dB frequency). At this frequency, if 1V is applied to the input, 707mV will be 'lost' across the cap, and the amplifier will get an input signal of 707mV. The reason for the voltages not being 50% of the input voltage is due to phase. This is quite normal, and causes no problems. A double blind test of any two capacitors of the same value and reasonable construction will not reveal any audible difference - even if the music has significant very low frequency content, and the loudspeakers can reproduce it. At 40Hz, the capacitor has a reactance of just under 4k, and at 1kHz this has fallen to 159 ohms. These figures apply reasonably accurately at all voltages, impedances and frequencies.

Dielectric losses (dielectric absorption and dissipation factor are lumped together for my analysis) are blamed for 'smeared' high frequencies, thus implying that as the frequency increases, the problem gets worse. However, as the frequency increases, the amount of signal across the cap falls, so at the highest frequencies the capacitor is effectively almost a short circuit. The influence of *any* coupling capacitor diminishes as frequency increases, and is most significant at the lowest frequency of interest.

These effects are examined by a combination of simulation and actual testing - and to alleviate any concerns, no components were harmed in the production of this article (sorry). Simulation features heavily here, simply because most of the effects are extremely difficult (some are almost impossible) to measure. The resolution of the simulator is far greater than any known test instrument, but one has to be careful to ensure the models used act in the same way as real components.

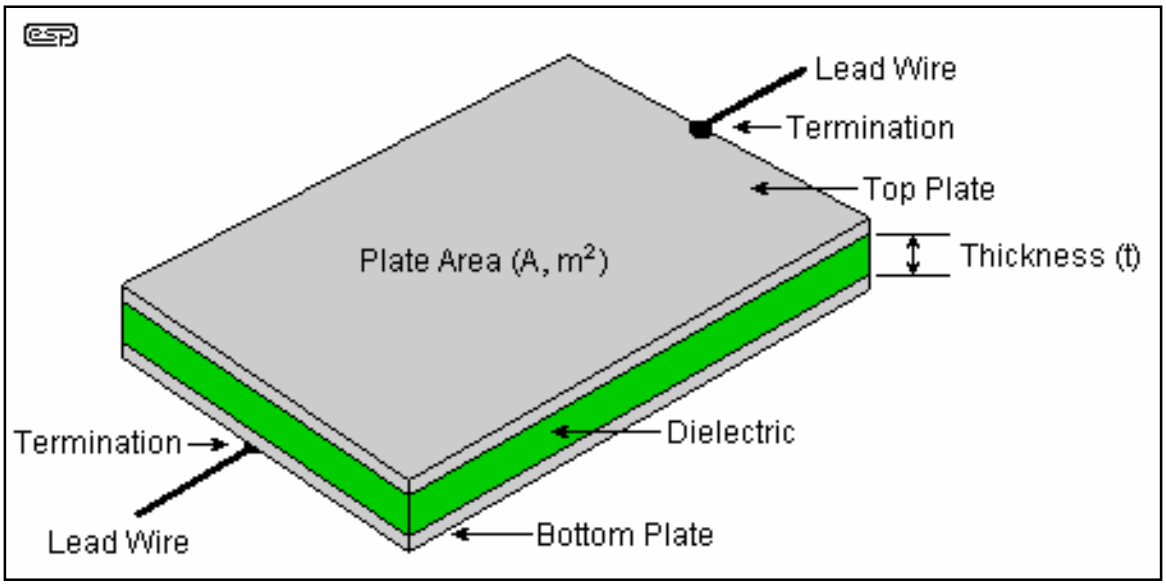

Figure 1A - Basic Capacitor Construction

Figure 1A shows the general form of construction for a capacitor. The plates shown may be metal foil, or more commonly for most caps, a metallised film. This is very thin and typically long and narrow, then it is rolled up and encapsulated. In some cases, the cap is made flat, with interleaved plates and dielectric. This allows the maximum capacitance for a given volume.

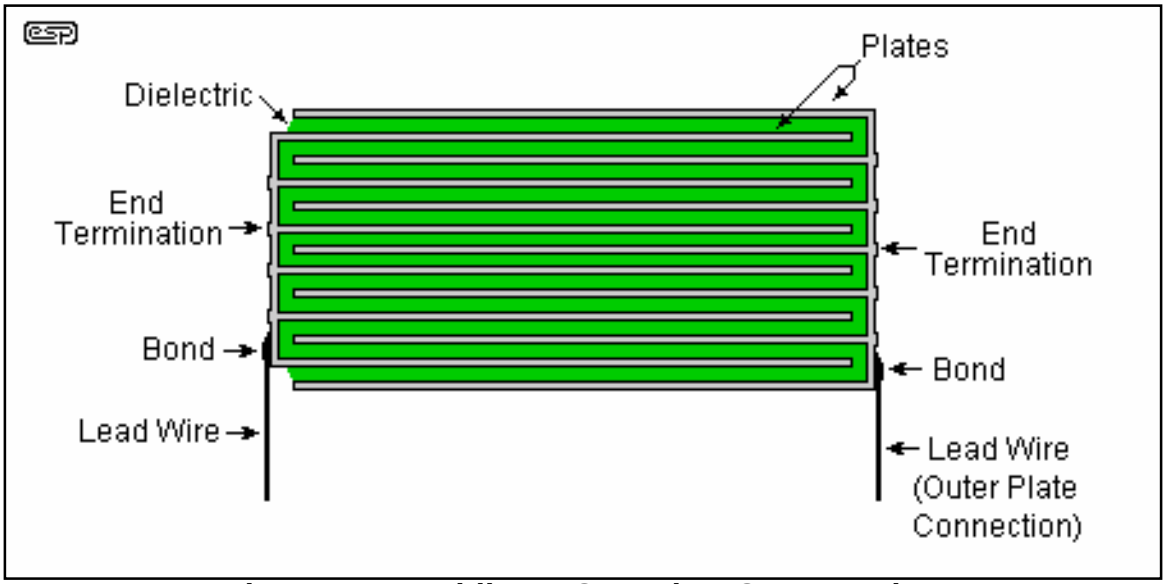

Figure 1B - Multilayer Capacitor Construction

Figure 1B shows the general construction of a multilayer cap, and is also representative of the cross-section of a traditional wound capacitor. With some capacitors, one end is marked with a band or is otherwise indicated as the outer foil. This can be useful for sensitive circuits, where the outer foil (or plate) end may be connected to earth (ground/ chassis) to shield the capacitor against interference. This is usually only ever needed in very high impedance circuits, or where there is considerable external noise.

Note the way that the ends of the foil are joined. This prevents the signal from having to traverse the length of the plates. Because one edge is joined in a 'mass termination', only the width of the plates (i.e. between the terminations, plus lead length) is significant for inductance.

The capacitance of a pair of plates is determined by the formula ...

> $C = 8.85 \times 10^{-12} kA / t$ where C = capacitance (Farads), k = dielectric constant, A = area (m^2) and t = dielectric thickness (m)

So, for example, a pair of plates of 0.01m^2 area, separated by 1um, and having an insulation with a dielectric constant of 3 (e.g. polyester), will have a capacitance of about 260nF. These plates might typically be a metallised layer of 10mm width, and having a length of 1m [1]. While this is probably not very useful, it may come in handy one day (or perhaps not). The dielectric thickness is mainly determined by the voltage rating.

Typical values for k (dielectric constant) are as follows ...

Material	**k**
Vacuum (reference)	1.00000
Air (Sea Level)	1.00059
Aluminium Oxide	7 - 12
Ceramic	5 - 6,000
Mica	3 - 6
Mylar	3.1
Polycarbonate	2.9 - 3.0
Polyethelyne	2.25
Polyester	2.8 - 4.5
Polypropylene	1.5
Polystyrene	2.4 - 2.6
Teflon	2.0
Snake Oil	Unknown

Table 1 - Dielectric Constants

This is just a small sample - see references for more. Only a few of the vast number of dielectrics available are useful, and only some of these are listed above. Of the many sites that give this information, there is considerable variation for many materials - this is to be

expected because of the range of different material formulations, even within the same chemical compound group. Snake oil has been included, but there is no actual data associated with it. Yes, this is in jest, but as you may discover, there is a great deal of snake oil used in the audiophile capacitor industry.

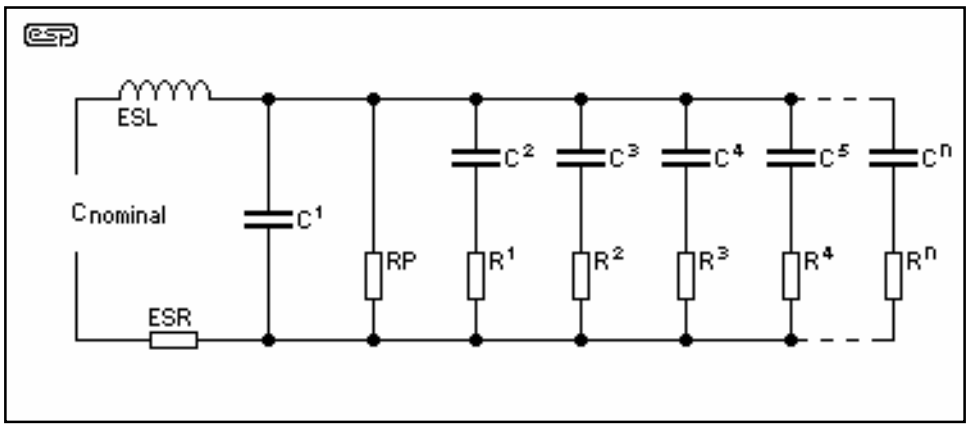

Figure 2 - Capacitor Equivalent Circuit

The generalised equivalent circuit of a capacitor is shown in Figure 2. The nominal capacitance is the value of C^1, with ESR and ESL (equivalent series resistance and inductance) in series. The parasitic capacitances (C^2 - C^n) and their series resistances represent the dielectric loss (resistance) and dielectric absorption (capacitance). These are infinite, with ever diminishing capacitance and series resistance. Figure 5 shows values used for simulation purposes.

It is important to understand the equivalent circuit of any component, because this allows you to simulate or measure the effects with the 'flaws' greatly accentuated. In many cases, it is not necessary to do either, since the effects will be quite obvious once seen for what they are.

2.0 - Dielectric Loss

The first thing to understand about dielectric loss, residual charge, series resistance and inductance, and all the other ills that afflict capacitors, is that they are quite normal, and appear in all real-world components. What is at issue is whether these cause a problem for normal audio signals at normal levels. There is no point testing capacitors by placing a 70V AC signal across them if this will never happen in the circuit being investigated. There is even less point doing this with capacitors that are rated at 50V ... DC!

While coupling capacitors are a primary target of the upgrade brigade, these are the most benign because of the very low voltages across them. Capacitors used in filter circuits are deliberately selected so that they cause the signal to roll off at the selected frequency, and this will be examined later in the article.

First, let's look at the voltage across a 1uF coupling cap connected to a 22k input impedance amplifier. At 40Hz, this is only 180mV for a 1V input, and by the time we get to 10kHz the voltage across the cap is down to less than 700uV. This is shown in Figure 2, and Figure 3 shows the circuit used for the measurement.

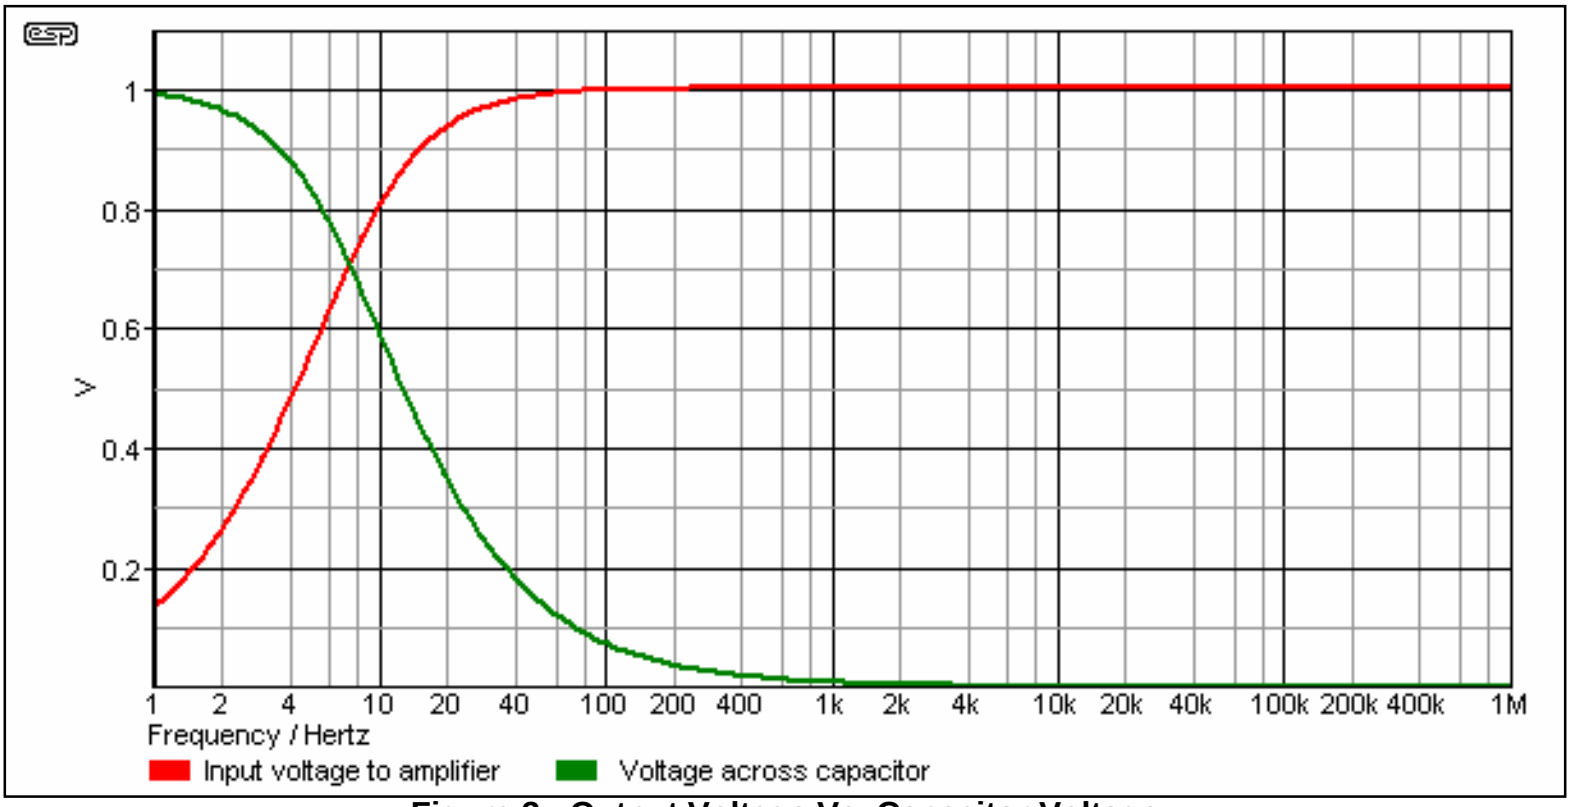

Figure 3 - Output Voltage Vs. Capacitor Voltage

The test circuit is shown below. It is simply a matter of measuring the voltage across the capacitor and the resistor. With a 1V RMS applied signal, each will measure 0.707V when the capacitive reactance is equal to the resistance. This is the low frequency -3dB frequency.

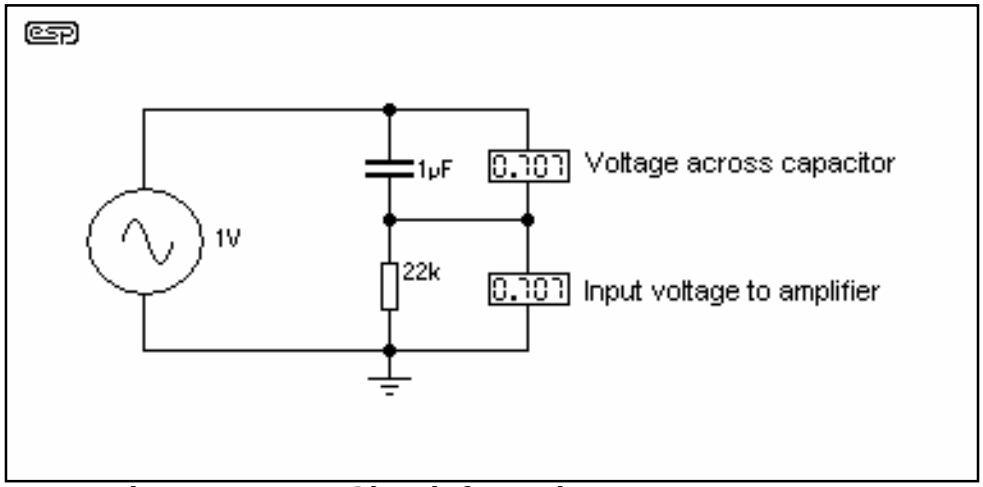

Figure 4 - Test Circuit for Voltage Measurements

Now, the caps used in a simulator are 'ideal' in that they do not have dielectric loss, series

resistance, insulation resistance (leakage) or any other undesirable parameters of a real capacitor. A simulated cap with these real parameters included is shown in Figure 5. The ESR (equivalent series resistance) is much higher than an actual cap, ESL (equivalent series inductance) is about typical, leakage resistance (via the parallel resistor) is much lower than reality at 100Megohms, and the dielectric loss components (the string of smaller caps with series resistance) deliberately exceeds that of most normal capacitors. This sub-circuit behaves like a capacitor with quite high losses - certainly it would be completely unacceptable as a tuning cap in a circuit operating at very high frequencies. In short, this is a dreadful capacitor. Perhaps these shortcomings might make it 'sound better', but it would need to be very expensive and perhaps unreliable to gain true acceptance. Just do a Web search for 'Black Beauty' capacitors - these are notoriously unreliable (especially early 'NOS'), sometimes unbelievably over-priced and should be avoided for anything more technologically advanced than land-fill (and yes, I do have personal experience with them).

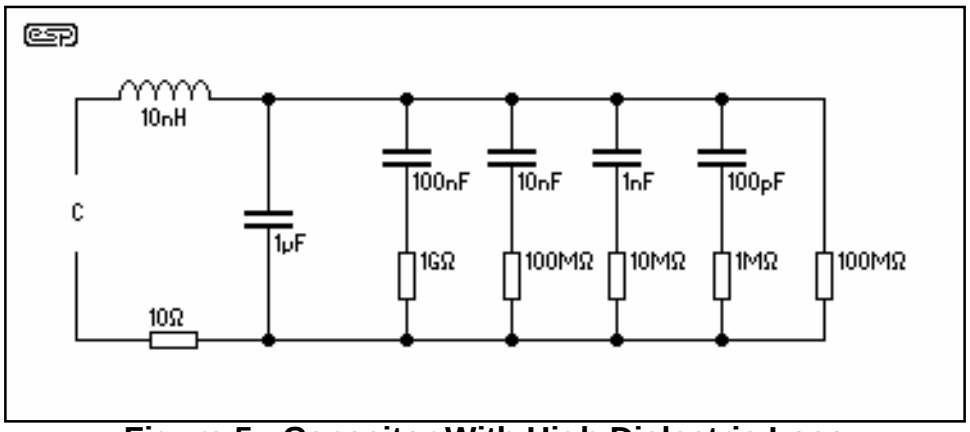

Figure 5 - Capacitor With High Dielectric Loss

This lossy capacitor (which is worse than any typical real-world component) is next used in the same circuit shown in Figure 4. When we look at the amplifier signal (across the 22k resistor) the frequency shifts up by 11mHz (milliHertz) and there is a loss of 3.3mdB (yes, milli decibel) at 10Hz, with a loss of 4mdB right through the audio band and up to 1MHz. This can be considered utterly insignificant. The vast majority of all loss is caused by the series resistance (which is exaggerated for clarity). Lest anyone think that the dielectric loss or leakage resistance may cause a phase variation, that too is insignificant. The phase angle at 10Hz is just under 36°, with the lossy capacitor being 0.047° different. Again, at higher frequencies there is no significant difference.

Ok, so there is very little change in overall performance when the lossy cap is used for coupling, but the losses should really mess up a filter circuit, right? Wrong, actually. There is virtually no difference at all. Although the difference can be seen with the simulator, most affordable real instruments don't have sufficient resolution to be able to see it. The difference between a 24dB/octave crossover filter built using ideal and lossy capacitors is so small as to be insignificant. The frequency changes by 1Hz, and the voltage difference at the crossover frequency is 0.044dB (44mdB). Many times this variation will result from normal

component tolerances, and even stray capacitance on the PCB itself could easily exceed the variation seen by the simulator. There is little to be gained by showing graphs with perfectly overlaid curves, but should anyone want to do their own simulations there is more than enough information here to allow that.

It is important to understand that the lossy capacitor appears (electrically) as an infinite number of small capacitors, each with its own series resistance. This can be built using real capacitors, with a lumped parasitic capacitance of perhaps one tenth of the value of the actual capacitance. Use a 1 megohm resistor in series with the 'parasitic' cap, using the general scheme shown in Figures 2 and 5. The 'losses' in this capacitor are far greater than any metallised film cap, yet using it in a circuit will not degrade the performance one iota. Dielectric absorption simply does not affect the way a capacitor passes the signal. Dielectric loss becomes a problem when significant (high frequency signal) voltage appears across the capacitor, but is rarely even measurable as a loss at audio frequencies and at levels typical of audio systems.

2.1 - Dielectric Absorption

So, we can conclude from this that the dielectric losses do *not* cause massive variations - in fact the variations are infinitesimal. But ... what of the charge storage of the dielectric? This is the phenomenon that allows a cap to recover some of its original charge due to 'dielectric absorption' (also known as 'soakage' [6]). This is part of exactly the same phenomenon that creates capacitor 'losses'. The lossy cap shown above has that effect too, and this is shown in Figure 6.

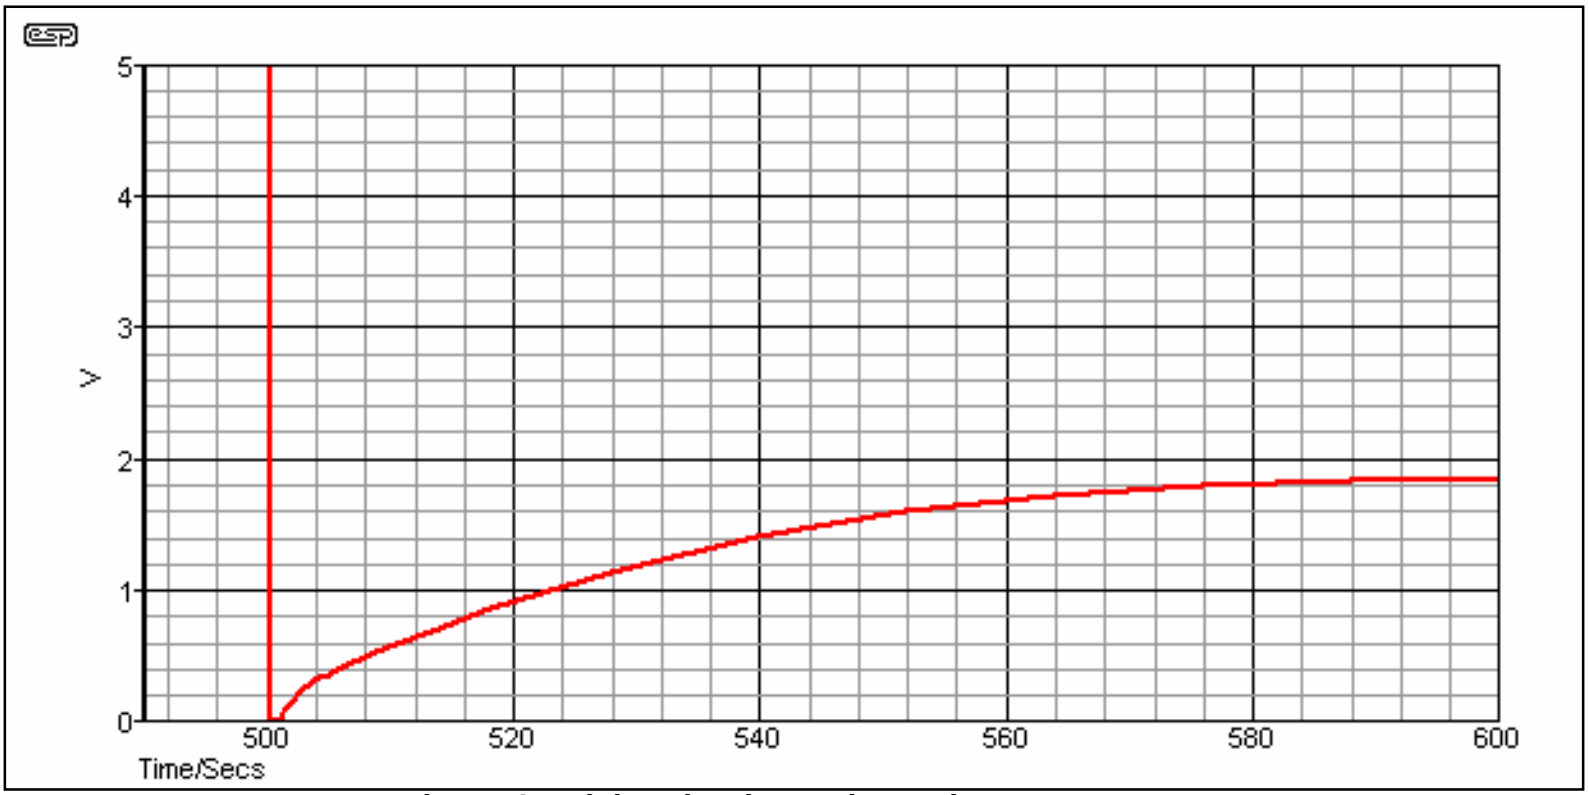

Figure 6 - Dielectric Absorption Voltage Recovery

The test circuit is shown below. This is a fairly standard test, but unless you are building a very low frequency filter or high accuracy sample and hold circuit, the effect is rather meaningless. It is interesting though. The simulated capacitor is the same as the lossy version shown in Figure 5. The official military specification test circuit for MIL-C-19978 (the test for dielectric absorption) uses an opamp wired to give almost infinite input impedance, because standard digital multimeters will not allow a useful measurement. The typical input impedance of a digital meter is 10 or 20 Megohms, and normal audio circuit impedances are much less than that - consequently any 'problems' caused by dielectric absorption will also be much lower than specifications indicate.

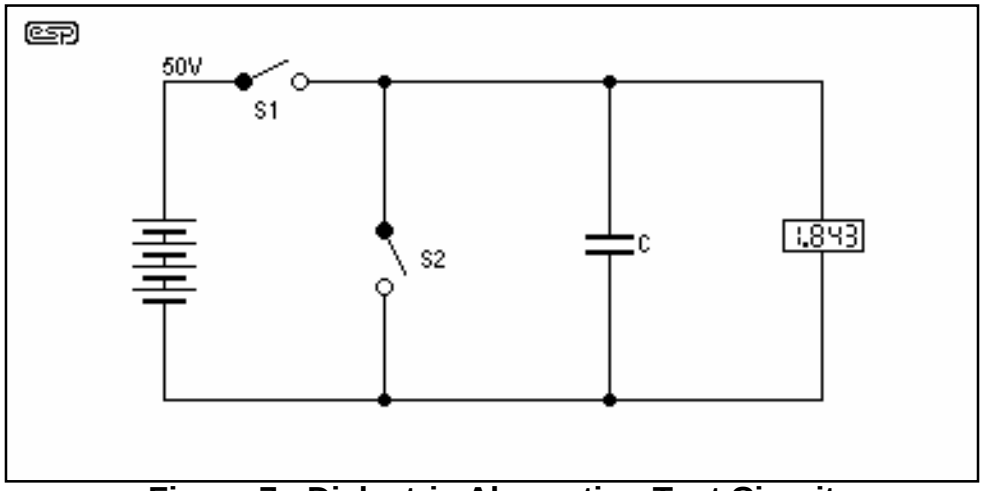

Figure 7 - Dielectric Absorption Test Circuit

The capacitor is charged for 500 seconds using SW1, then discharged (for one second) by

SW2. After the discharge, the voltage is seen to rise again, even though it was obviously zero for the duration of the short. Real caps do exactly the same thing, and if they were used in circuits having close to infinite impedance, it would be a problem. In long period sample and hold circuits, dielectric absorption *is* a problem, but in audio circuits it causes an almost immeasurably small loss of signal. Nothing more.

Once the cap is loaded with normal circuit impedances, the effect goes away almost completely. This assumes that caps will be charged then discharged in an audio system, but as covered above, that does *not* happen in normal audio circuits. Even in filter circuits, the effect is negligible - dielectric absorption does not magically create reverberation, sub-harmonics, background 'glare', 'whiteness' during silent passages, image smearing, ingrown toenails or cardio-vascular disease. Again, all this particular 'audio nightmare' (as some might have you believe) achieves is a tiny loss of signal.

With a 22k load resistor, the maximum 'recovered' voltage is 4.45mV, at 1.2ms after the short is removed (-81dB). Remember that this was after charging the cap to 50V for 500 seconds, then shorted for one second. This is not a normal audio circuit, and no audio circuit will subject a capacitor to anything even approaching the conditions used here.

Caps in audio circuits are simply not charged and discharged in this manner. To do so would cause signals to be generated that, after amplification, would mean instantaneous speaker disintegration. These tests are silly - they prove nothing, but are regularly hailed by some audiophiles as some kind of 'proof' that they can hear a difference because it can be measured. It is forgotten in the excitement that the signals and tests that form such proof will never occur in a real audio system that is not in the process of blowing up.

I have heard claims that the voltage recovery characteristic causes distortion similar to reverberation. What complete rubbish! If it were that simple to create reverb, one can be sure that no-one would have ever bothered with reverb springs, plates, or digital delays. Utter nonsense - it simply does not happen.

2.2 - Electrolytics

Electrolytic capacitors are definitely a problem though - there is any amount of proof ... Or is there ... ? Again, often claims are made based on tests that are irrelevant for audio. A popular myth is that electros have considerable inductance because of the way the foil is wound inside the can. This is nonsense - the foils are usually joined at the ends in the much the same way as with film caps. High frequency performance usually extends to several MHz [2], even with standard off-the-shelf electros and bipolar (non-polarised electrolytic) caps.

Electrolytics do have ESR (equivalent series resistance) as do all capacitors, but because of the nature of the internal chemistry of electrolytic caps it is non-linear. What is important here is not the non-linearity itself, but just how much signal is developed across the cap in normal (properly designed) circuits. We would be foolish to use electros in filter circuits, because they change their capacitance, ESR and inductance with varying temperature and frequency.

Electrolytics are not usually a problem with audio circuits, provided they are used only for coupling and decoupling applications. Because the AC voltage across the cap is so small (by design), the component's contribution is negligible. If you use electros for coupling, I would recommend that you use a value 10 times greater than needed for the design rolloff frequency. For example, if you were to exchange a 1uF film+foil coupling cap for a bipolar, the bipolar should be 10uF. This keeps the voltage across the cap to the absolute minimum at all frequencies.

2.3 - Distortion Tests

Imagine an electro, whose characteristics are so poor that it develops almost 10% distortion internally, with an applied voltage of 1V. This is a particularly bad capacitor, but it is sized so that the AC voltage dropped across the cap is 1% (10mV) of the applied voltage. This means that there is only 10mV AC across the cap, and the distortion across the load will be less than 0.1%. In reality, no electro will be that bad, so provided the voltage across it is kept to the minimum, distortion is not a problem.

Upon testing some 1uF 63V electros (polarised), the readings were interesting. My signal generator has a residual distortion of 0.02%, nearly all third harmonic. Connecting the 1uF electro directly across the output reduced the output voltage from 10V to about 5.5V RMS. This is because the generator has an output impedance of 600 ohms, and the cap was acting as a low pass filter. Figure 8 shows an equivalent circuit of the test setup.

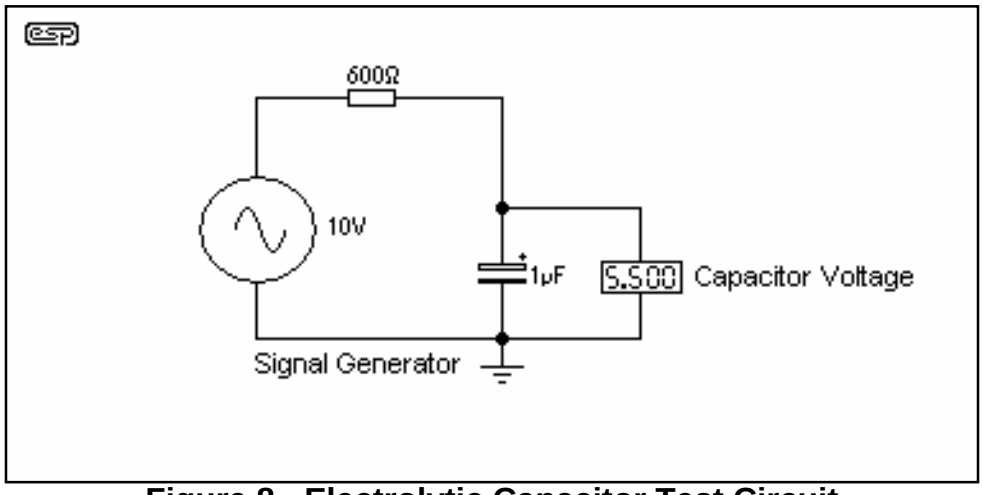

Figure 8 - Electrolytic Capacitor Test Circuit

The electro under test was unbiased, and with 5.5V AC at 400Hz across the cap, the distortion rose from 0.02% to 0.022% - a definite increase, but only small. At lower voltages such as 3V open circuit (about 1.6V RMS across the cap), the distortion *fell* to just over 0.015%. The reason the distortion appeared to fall is simple - the connection shown forms a low pass filter, which helps to remove the harmonics that make up the distortion component of the signal. A first order low pass filter will reduce the third harmonic sufficiently to make reading the difference quite easy. Based on a very similar test done using the simulator, the distortion should be about ½ the generator value, so the cap is still introducing some distortion. As the voltage (across the real capacitor) is reduced, so is distortion, until the noise limit of the distortion meter is reached.

Now, remember that this was using the electro in a way that was never intended. I subjected it to a relatively high applied AC voltage (where as a coupling cap it would have a great deal less - millivolts instead of volts), and it was unbiased as well. Even so, the increase in distortion was small, even with 5.5V AC applied, and it is safe to say that distortion was negligible below around 1.5V, and rapidly fell below the threshold that I am able to measure.

Attempting the same test described above with a polyester cap was a dismal failure - I was not able to measure the cap's distortion, only the attenuated distortion of the signal generator. As predicted by the simulation, measured distortion was about half that of the generator alone, using a 1uF cap at 400Hz, with 5.5V AC across the cap itself. I am satisfied that the polyester capacitor's contribution to measured distortion was well below my measurement threshold.

Various ceramics were a completely different matter though. A 0.22uF (220nF) ceramic was tried, as was a 100nF multilayer bypass cap, along with a few others. At any reasonable voltage, distortion was measurable - the worst measured distortion being 3% with 9V RMS across the cap. This was measured across the capacitor, so the actual distortion was worse than indicated because the capacitor was attenuating its own harmonics. I was unable to measure *any* distortion contributed by a 220pF 50V ceramic, even with 10V RMS at 100kHz across it.

2.4 - Capacitors in General

Electronics World did an epic series of articles written by Cyril Bateman [3], where he went to extreme measures to develop equipment to be able to measure the distortion of common capacitors. Again, this was done with an AC voltage applied across the cap, so the results are generally of far less importance for a coupling cap. The findings are useful for determining the usefulness of various caps in filter circuits (especially passive crossover networks) though, and he quickly disposes of a number of persistent myths, including (but

not limited to) the following:

- All ceramic capacitors introduce distortion
- Dielectric absorption compresses dynamic range and "smears" audio
- Polyester dielectrics are lossy and inefficient
- Capacitors look inductive at audio frequencies
- A capacitor's ESR is a fixed quantity

For anyone who wants to examine these findings in greater detail, I strongly suggest that you get hold of the original series of articles. In general, it was found that the distortion of capacitors was generally very low - well below that contributed by the majority of active circuits. There are very good and valid reasons not to use certain capacitor types in some applications, and equally good reasons to insist on their use in others.

For bypassing, so-called monolithic ceramics are very good, having a low impedance up to hundreds of MHz, assuring good supply bypassing at the highest frequencies. As frequency increases further, standard ceramics are usually preferred. Using them in an audio active crossover network would be a very bad idea though, because their capacitance tolerance is not good, and the value can also change with applied voltage and temperature. Some ceramics (high k types being the worst) may be microphonic due to the piezoelectric properties of the ceramic substrate. I have encountered this (many years ago) in some guitar amps, where large (19mm diameter) 0.22uF ceramic caps were used in the tone control circuit. While newer (and much smaller, both physically and electrically) caps are less likely to suffer from microphony, it is worth bearing in mind. As with dielectric absorption, microphony is more likely to be a problem in high impedance circuits. In most audio applications it will rarely be an issue, but ceramics in general are not recommended for filters, or as coupling caps in audio circuits. This is because of wide tolerance and capacitance variations with frequency and temperature.

G0G or NP0 ceramics have very low temperature coefficients, and are generally useful in many areas of audio where small values are needed. In particular, they can be used as RF suppression, or as the Miller cap in power amplifiers. While it is generally thought that polystyrene or silvered mica (for example) would be better, this may be more of an expectation than a reality. This is something I have tested, and have been unable to measure any difference in distortion between a polystyrene and ceramic cap. Frequency response is essentially unchanged, as is slew rate.

Electrolytics are excellent for power supplies, and most places where high values of capacitance are needed. They are unsuitable for filters, because they have wide tolerance, should be biased, and may change capacitance depending on applied frequency. Bipolar electros are excellent where high values are needed, and no polarising voltage is available. Because of wide tolerance, they too are unsuitable for filter circuits. The distortion caused by

bipolar electrolytic caps used for signal coupling (including their use in feedback networks to ensure unity DC gain) is low to immeasurably low if they are selected to have minimum AC signal voltage developed across them at all frequencies of interest.

When it comes to high current applications (such as passive loudspeaker crossover networks), there will be significant voltage across the cap and current through it. It pays to use high quality capacitors that can withstand the voltage and current that the caps will be subjected to - this generally means polypropylene, polyester, or perhaps paper-in-oil (if you must). This is an area where dielectric loss may cause the caps to heat up with sustained high power, and the devices used need to be stable with time and temperature. Do not necessarily expect to be able to hear any difference between these (high quality) types in a blind test though, as you may well be disappointed.

One thing that may be very important for passive crossover networks is the material used for the 'plates' of the capacitor. Metallised film caps may not be the best choice because of the resistance of the film itself. The film is usually extremely thin, and it may not have a low enough resistance to allow the full current required. I have not experienced any problems with this, but a film and foil type is more suited to high current operation than a metallised film construction. This topic is mentioned on capacitor manufacturers' websites, and I recommend a search if you want more information about current handling capacity.

Bipolar (non-polarised) caps are (IMO) simply unsuitable for use in passive crossovers, because they are so small for their capacitance that heating is far more likely ... whether because of power lost in ESR or dielectric losses. Wide tolerance also means that the network will probably not be right unless it is tweaked, and it will change with time anyway.

3.0 - Test Methodology

The standard (subjectivist) test method with capacitors (indeed, with many electronic components) seems to be to exchange a standard unit with one often costing a great deal more, then to proclaim that ... "Yea indeed, behold the huge difference", and "Lo, see how great is the improvement". As I have noted many times, this is flawed reasoning, and any such test is utterly invalid. Nothing can be gained from this except a continuation of the 'pure subjectivist' dogma.

In a properly conducted test, the test methodology will force the listener to determine if there is a difference between two pieces of equipment (or even any two components), and do so without knowing in advance which is which, and, to do so with *statistically significant accuracy*. This is usually taken to be around 70% - the listener must pick 'Part A' from Part B' correctly *at least* 70% of the time.

According to the claims one might hear from some people regarding their favourite capacitor (or anything else), any blind test should score 100% accuracy, such is the difference heard. Sadly, it seems that in any blind (or ABX) test, the difference fades to nothing, and test results are nearly always inconclusive - it cannot be said with certainty that a difference was heard or not. I cannot understand how something can be claimed on one hand to be 'chalk and cheese', yet cannot be reliably identified as soon as the visual cues are taken away. This should alert everyone to the fact that experimenter expectancy and/or desirability are the overwhelming factors, and that the components themselves are sonically virtually identical.

The actual testing of components must be done with care. The components must be tested in a manner that reflects the way they will be used in practice, or, if this fails to yield any measurable result, the degree to which the part is pushed beyond its ratings must be explained. The report should then extrapolate (in as far as practicable) the measured results at elevated operating conditions to the expected result at normal levels. That this is rarely (if ever) done is fair warning of the likelihood of erroneous data being propagated.

I have never been able to measure the distortion of a capacitor that is used sensibly in a real circuit. This is partly because the equipment I have does not have the extraordinary resolution needed to be able to measure such low levels of distortion, and partly because the active circuitry and system noise will usually predominate. There is little point trying to measure signals that are -100dB below the 1 Watt level, or even worse, at -100dBm (i.e. referred to 775mV).

For example, let's look at distortion at -100dB referred to full power of an amplifier. Assume that the loudspeakers are 90dB/W/m and the amplifier is 100W. The peak SPL is 110dB (unweighted) at 100W, and you might be blessed with an exceptionally quiet listening room - let's say 30dB SPL. If you have distortion artefacts at -100dB, then with a peak SPL of 110dB, the distortion will be at 10dB SPL unweighted (110dB - 100dB). Your very quiet listening room is a full 20dB noisier than the distortion components!

Based on my own observations, as well as those from many others (Bateman, Self, et. al.), capacitor distortion in any real circuit will generally be (much) less than 0.001% ... that's a level of -100dB. Testing and obtaining good results at these levels is highly problematical. Circuit noise, residual distortion and even a tiny bit of corrosion on a connector will increase the measured distortion dramatically. Cyril Bateman was forced to build specialised test equipment to measure the distortion, and while anyone can do the same, it is time-consuming and expensive to do so.

Returning to the use of a cap for signal coupling ... let's assume a seriously non-linear capacitor as shown in Figure 9. when used with significant current through the cap (A), the simulated distortion is 1.26% at V1. When used for coupling, distortion is zero - there is

simply not enough current through the non-linear circuit to cause a problem. Real tests show the same behaviour - the 1uF polarised cap that so happily gave measurable distortion before shows none that I can measure. The simulator also shows zero distortion at V2 when the non-linear cap is connected as a coupling capacitor (B). It is not until the load resistor (22k) is reduced sufficiently to cause significant voltage across the cap that distortion becomes measurable. For example, when the 22k resistor is reduced to 1.5k, distortion rises to 0.0076%. At 600 Ohms, distortion is 0.85%. The diode shown is 'ideal', so it will conduct at very low voltages.

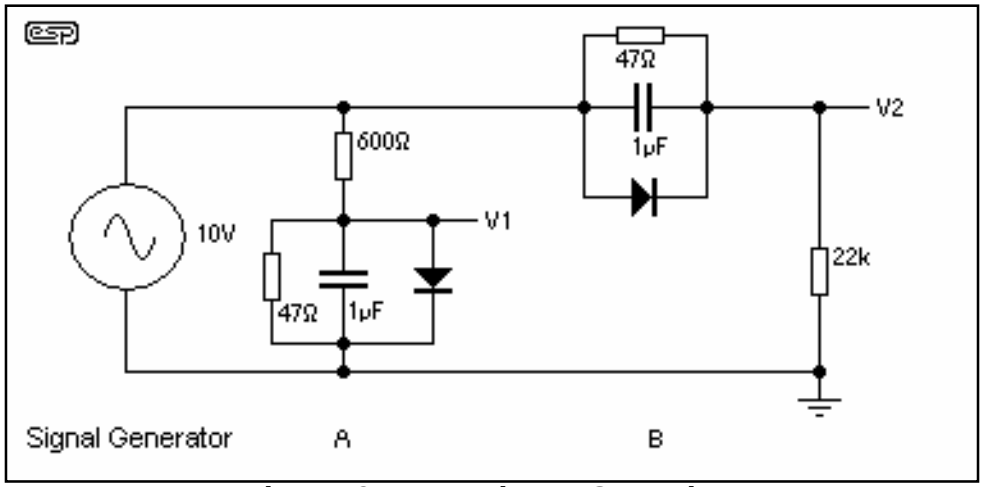

Figure 9 - Non-Linear Capacitor

Although this is obviously a simulated experiment to show the general principle, reality (including test results on the same electrolytic cap that produced measurable distortion before) is very close. If a capacitor is going to cause measurable distortion, then the signal voltage across it (and also the signal current flowing through it) must be significant. If neither of these is true (little or no voltage across the cap, and little current through it), then it is quite reasonable to expect that the contribution of the component at that frequency is negligible, and any inherent distortion it produces must also be negligible.

4.0 - Parasitic Inductance in Bypass Applications

All capacitors have some inductance, but what is often overlooked is that the leads are the primary cause for this. To minimise the inductance, keep the leads as short as possible, and keep them as close together as possible. When two conductors are run in parallel, they form a capacitor. By maximising the (capacitive) coupling, you automatically reduce the inductance. Loudspeaker cables have been produced that have extraordinarily low inductance, despite the fact that they are quite long, and should (in theory) have high inductance as well. Not so. They have high *capacitance* (sufficient to give many amplifiers severe heartburn), but inductance is low. The closer the conductors are spaced and the greater the physical area, the greater the capacitance and the lower the inductance.

Now, consider a conventional wound film and foil (or metallised foil) capacitor ... even if the plates were not joined at each end to form a (relatively) solid block (see figure 1B, or do a Web search for capacitor construction), the capacitance would be at the required value, and inductance would *still* be negligible. The mechanism that supposedly causes internal inductance has never been demonstrated for film caps, but a great many measured results have neglected the capacitor lead length, resulting in erroneous figures. The errors can easily exceed an order of magnitude with a poorly set up experiment.

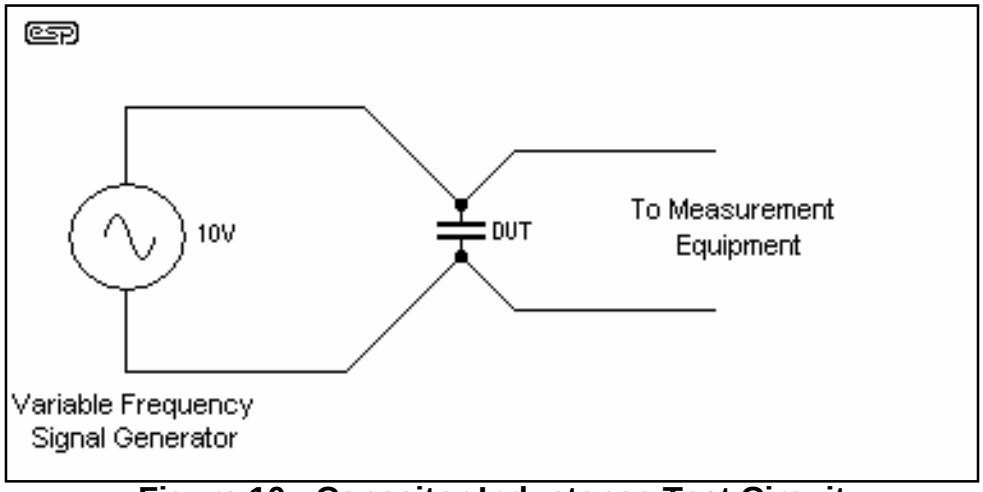

Figure 10 - Capacitor Inductance Test Circuit

The measurement must be taken from a point as close as possible to the capacitor. If the measurement is taken even a few millimetres away from the capacitor itself, it will include the lead inductance. This is made worse by spreading the legs of the cap to allow convenient connection. The inductance of the leads can be calculated by [4] ...

> $L_{dc}= 2L[\ln(2L/r) - 0.75]nH$ where L_{dc} is the low-frequency or DC inductance in nanohenries, L is the wire length in cm, and r is the wire radius in cm.

The inductance is not great ... about 5-6nH per cm (centimetre), but it is still significant at very high frequencies. With a 1uF cap (hardly massive), a mere 10mm of lead length (6nH) creates a series resonant circuit at close to 2MHz. Increase the capacitance to 10,000uF, and it is now 20kHz. This is not capacitor resonance, it is a resonant circuit formed by the capacitor and the *external* inductance of the capacitor's leads. For bypassing applications, the resonant circuit so formed *does not* reduce the effectiveness of the bypass capacitor if it is 'too big'. In reality, power supply bypass capacitors will supply the current required by the circuit regardless of the 'self resonant' frequency, so small values of capacitance do *not* mean better bypassing.

Figure 11 shows a simulated power supply and switching circuit, with inductive leads to the MOSFET and its load. Given the 'self resonant' frequency of the capacitor and lead inductance (about 35kHz with a 1,000uF cap), one would expect that the pulse performance

would be woeful, but it is essentially unchanged as C1 is changed from 1uF up to 10,000uF. If the value is reduced (less than 1uF), then performance does suffer. Lower capacitance *does not* give better bypass performance.

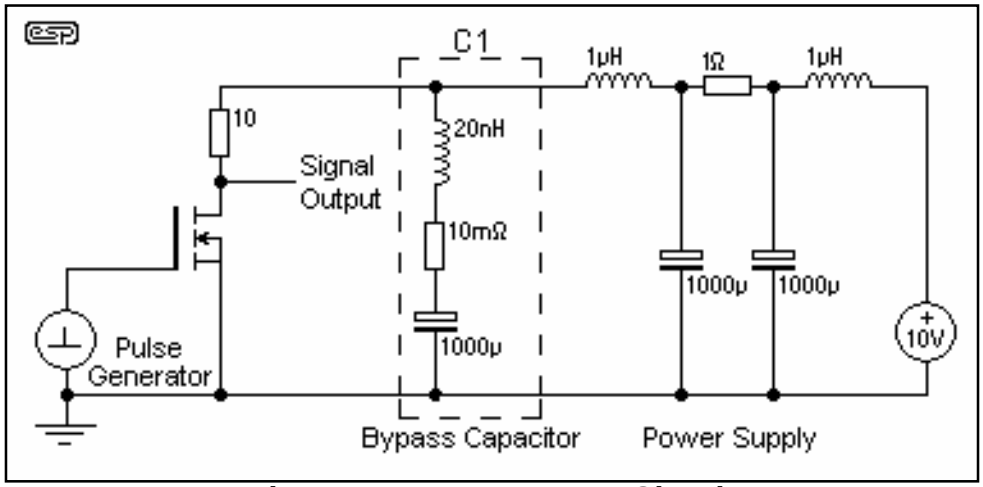

Figure 11 - Bypass Test Circuit

In Figure 12, you can see the waveform of the switching pulse with (red) and without (green) the series inductance and resistance - a comparison between a real and a perfect capacitor. Note that there is very little difference. This, despite the fact that in theory the 'combination' capacitor has a series resonance of 35kHz, and the switching speed is many, many times that. Using a much smaller capacitor (such as 100nF) is a disaster, allowing the circuit to ring, and develop excessive back-EMF. Feel free to perform the test using real components - you will get very similar results!

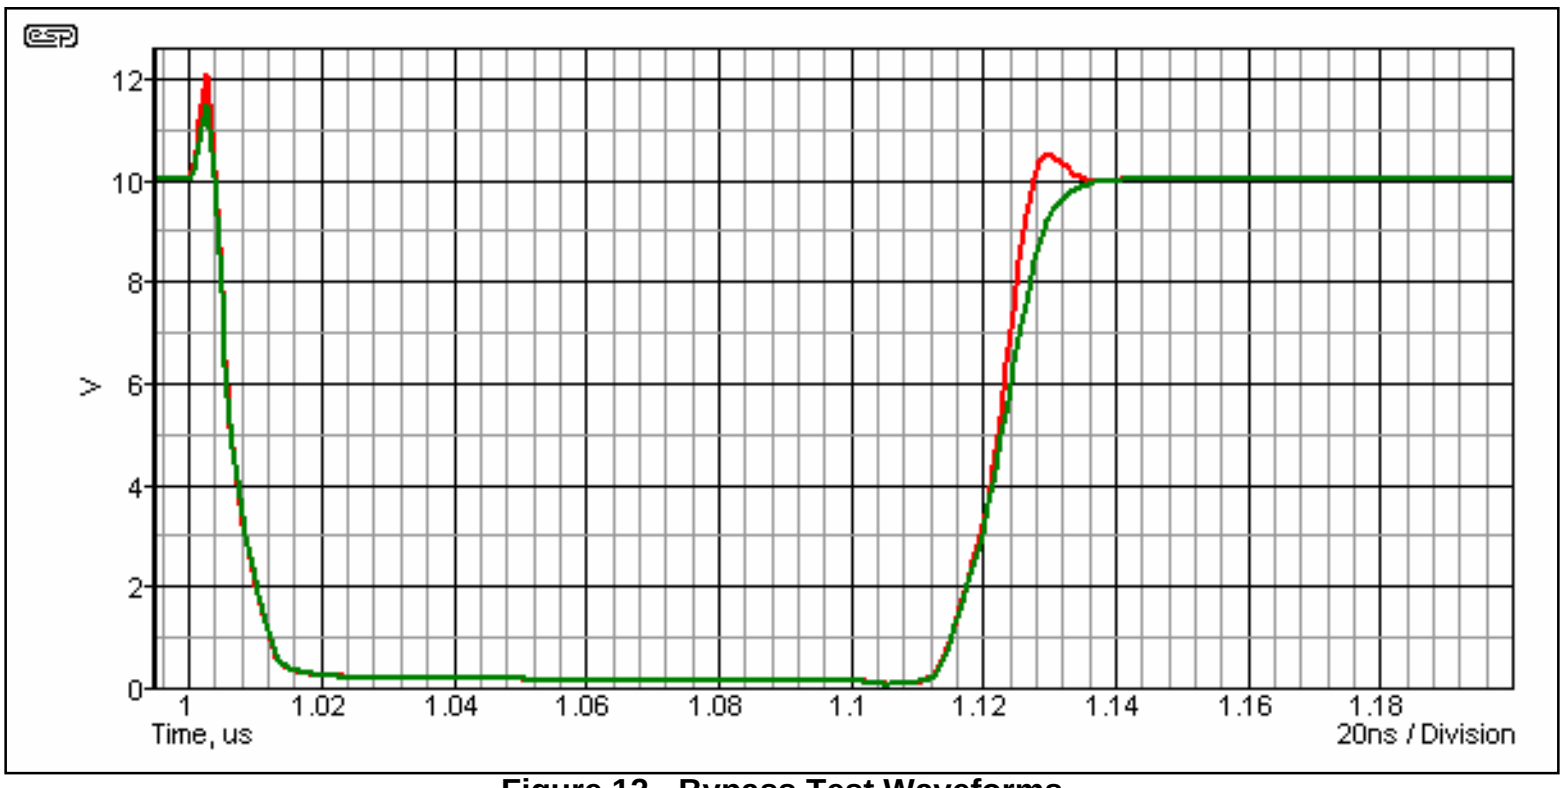

Figure 12 - Bypass Test Waveforms

An important thing that is often missed is that the resonance formula ($f_o=1/2\pi\sqrt{LC}$) only *implies* that higher capacitance values cause lower 'self-resonance' and worse high frequency performance. This is largely untrue - the ability of the larger capacitor to supply instantaneous current demands is not impaired, so the idea of using a small cap ("they have a higher self-resonant frequency") in parallel with a big cap is essentially nonsense - more capacitance equals more energy storage. The concept of 'self-resonance' in this context is flawed thinking, and leads to silly designs (100nF caps in parallel with 10,000uF electros for example) that generally achieve nothing useful, other than using more components.

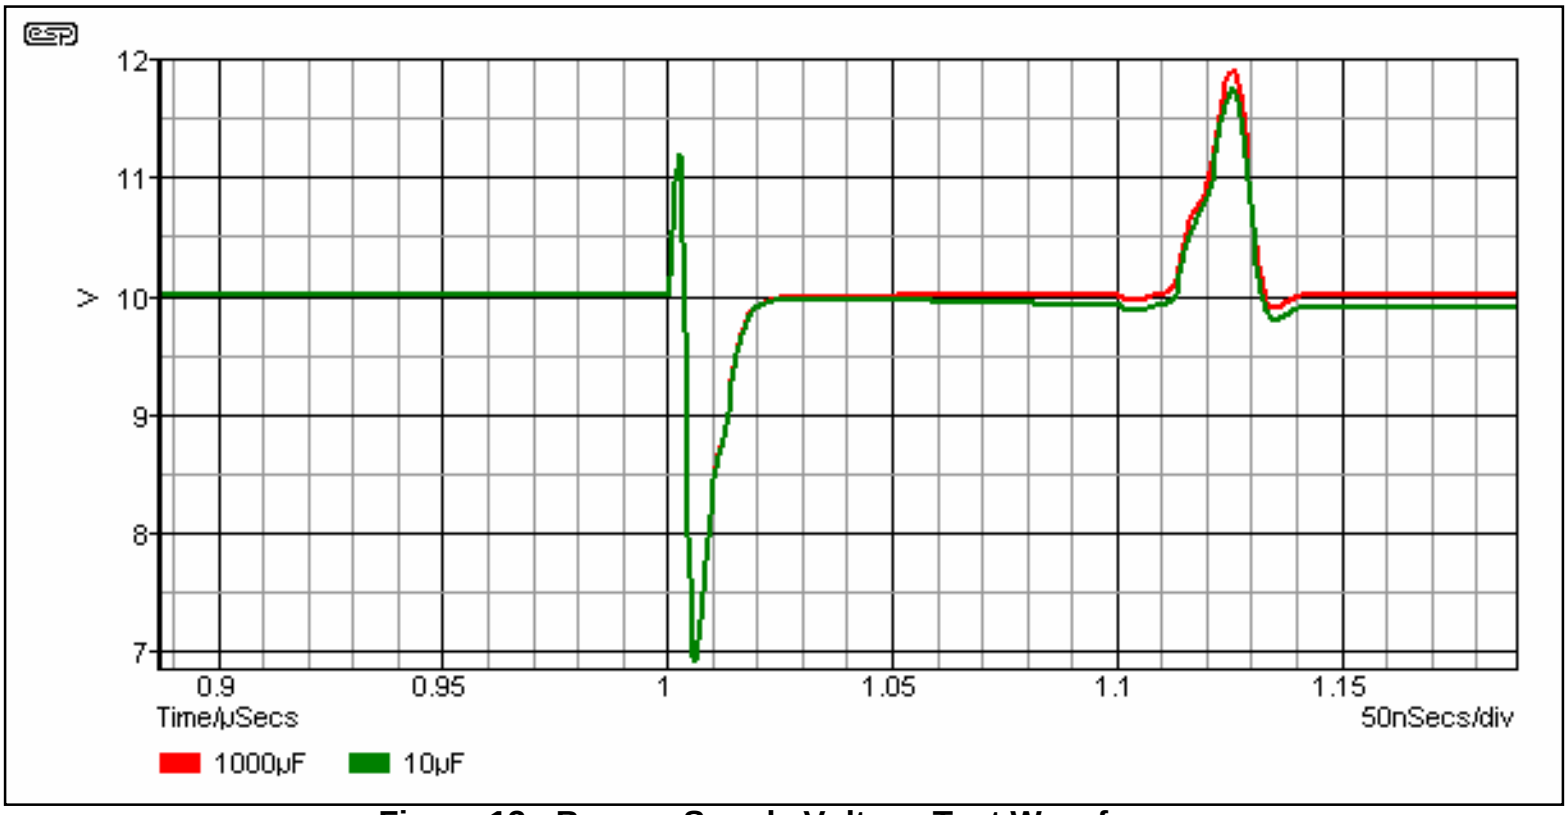

Figure 13 - Bypass Supply Voltage Test Waveforms

In Figure 13, you can see the difference between using a 1,000uF (red) and 1uF (green) bypass capacitor, measured at the positive supply to the switching circuit. The 1,000uF cap *should* show a sluggish response because its 'self resonant' frequency is so low. As power is demanded (MOSFET switched on), there is no difference at all, although recovery is a tiny bit slower. Not fully visible is the fact that the low value cap causes a damped oscillation, whereas the higher value does not. So, do low value caps 'work better' as bypass? ... No, they most certainly do not.

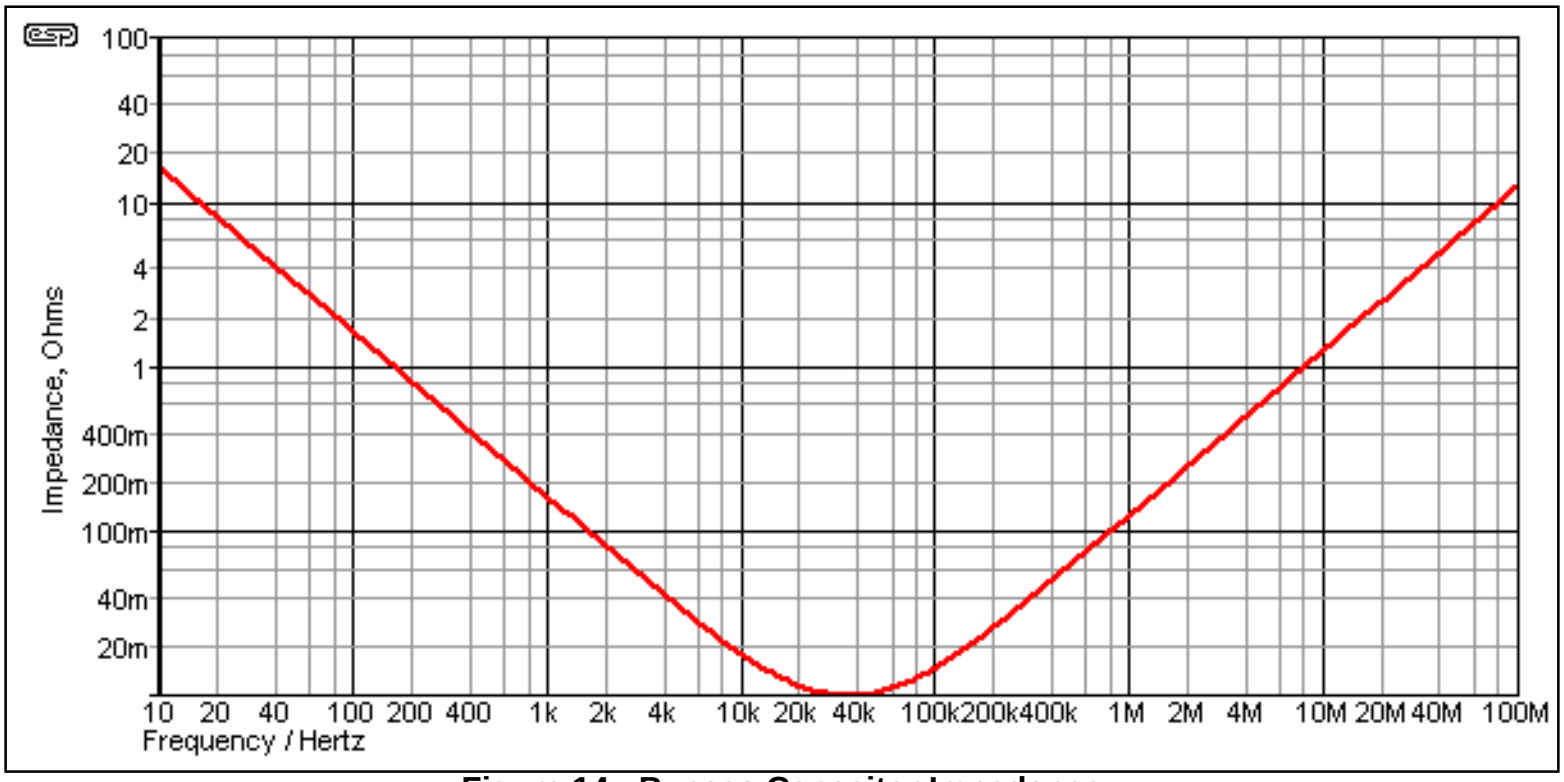

Figure 14 - Bypass Capacitor Impedance

Figure 14 shows the impedance of a simulated 1,000uF capacitor with 20nH series inductance and 10mΩ series resistance. The 'self resonance' frequency is 35kHz, with a minimum impedance equal to the series resistance (ESR). Even at well above the resonant frequency it is *not* an inductor, despite appearances. This is commonly claimed, but is false logic. The impedance is increasing, but until such time as the inductive reactance becomes significant (with respect to the circuit impedance) the composite circuit is still a capacitor. Even at 1MHz, the total impedance is only 125 milliohms. Although the 125mΩ is almost all inductive reactance, it cannot be considered significant - that is a somewhat vague term that is usually taken as around an order of magnitude compared to the load. In this case, the load is 10 ohms, so 1 ohm is 'significant'. This occurs at 8MHz. It is very important to understand the difference between a supply bypass application and a tuned circuit or other electronic function.

In a normal circuit (such as a series tuned circuit for example), when the applied frequency is the same as the resonant frequency of a capacitor and inductor (including leads, PCB tracks, etc.) the tuned circuit is no longer reactive - it is resistive! The resistance is equal to the sum of all component and lead resistances (including ESR). Below resonance, the circuit is capacitive - above resonance, inductive. Series resonance in a capacitor may result in rather unexpected behaviour in high frequency circuits (including digital), depending on the specific application.

It is obvious that capacitor leads should be kept as short as possible, and it would be an advantage if manufacturers stopped spreading and kinking the leads of monolithic ceramics

in particular, as this introduces a (small) additional inductance because of the lead length and reduces the maximum operating frequency. It is quite obvious that lead (and PCB track) inductance must be considered for very high frequency circuits - or for circuits that are capable of very high frequency operation even though they are used at much lower frequencies (audio amplifiers come to mind).

Some interesting observations are made by Ivor Catt [5], where it is maintained that the vast majority of capacitor claims are false. His information on bypass caps (in particular) goes against all 'conventional logic', yet the simulation described above validates his theory. A couple of his more notable quotes are ...

- If you cut off a capacitor's legs at the knees, you will double its self-resonant frequency
- A well behaved capacitor keeps its legs close together

Ivor is considered eccentric to many in the electrical/electronics fields (some may say that is an excessively generous description), but his data cannot be dismissed out of hand. Particularly when a simulation shows that a capacitor, even with series inductance, *can* supply the instantaneous demands of a switching circuit. This is despite that fact that the switching occurs at a frequency that is well above the 'self resonant' frequency of the capacitor.

Another of Ivor's contentious claims is that a capacitor is a transmission line. Based on the tests conducted (see ESL & ESR below), there is much to commend this model, even though it has been scoffed at by many who (in my opinion) should have been thinking more clearly. A length (any length) of coaxial cable appears to be capacitive at low frequencies, and at a frequency determined by its length, shows series resonance - it becomes (almost) a short circuit for that frequency. Above the resonant frequency, the cable is inductive. The primary difference is based not on any of the counter-claims that I saw to the suggested model, but because the very construction of a coaxial cable is such that it has vastly lower capacitance than any real capacitor, so the resonance is very high Q. In addition, the cable's capacitance and inductance are optimised for the circuit impedance. Capacitors are optimised for capacitance (what a surprise), so generally use a dielectric that is far thinner and has somewhat greater losses than coax. That does not change the basic model though - it simply means that the characteristic impedance of any given capacitor is dramatically lower than that of any 'normal' transmission line.

It is probable that if a capacitor were to be laid out flat rather than rolled up in the normal way, its inductance will not increase by anywhere near as much as the pundits might imagine. This, despite the fact that when it is rolled up, the entire edge of each plate is joined, so the 'length' of this transmission line is the *width* of the metallised film (or separate foil). This agrees quite well with the measured or calculated internal inductance of almost all capacitors, and this is easily verified by anyone with access to basic RF test equipment.

Electrolytic Series Resonance

The series resonance of an electrolytic has to be considered in conjunction with the circuit impedance. In real life devices, it is actually quite a broad null, often extending over several decades of frequency. This is readily apparent from looking at manufacturers' data, or by measurement. Measurement is actually quite difficult, since a significant current must be applied to be able to see the results. This requires an amplifier with very wide bandwidth indeed, and although some esoteric audio amps may be capable of providing sufficient current to obtain a worthwhile reading, most cannot.

Something that is somewhat easier is to apply a squarewave at (or near) the approximate series resonant frequency. Although the graphs in Figure 15 are simulated, the simulation is based on actual measurements, using a 15,000uF 35V electrolytic capacitor. This component has a series resonant frequency of around 40kHz, however, this comes with caveats. It is a very broad resonance (as expected), and with 10V RMS applied via a 10 ohm resistor, I was able to obtain a readable trace on the oscilloscope.

The following graphs show two traces ... the first (red) is the waveform across the cap with 50mm of lead between the cap and the measurement point. The second (green) is with the oscilloscope probes placed as close to the capacitor as possible. A mere 50mm of lead equates to approximately 20nH of inductance, but as seen in Figure 16, that is enough to double the amplitude of the spike at the leading edge of the waveform. It is also enough to lower the 'self resonance' quite dramatically - the low frequencies are unchanged, but the high frequency (where the impedance starts to rise) is moved up by nearly 400kHz. The minimum amplitude difference is because of the lead resistance (simulated as 10 milliohms).

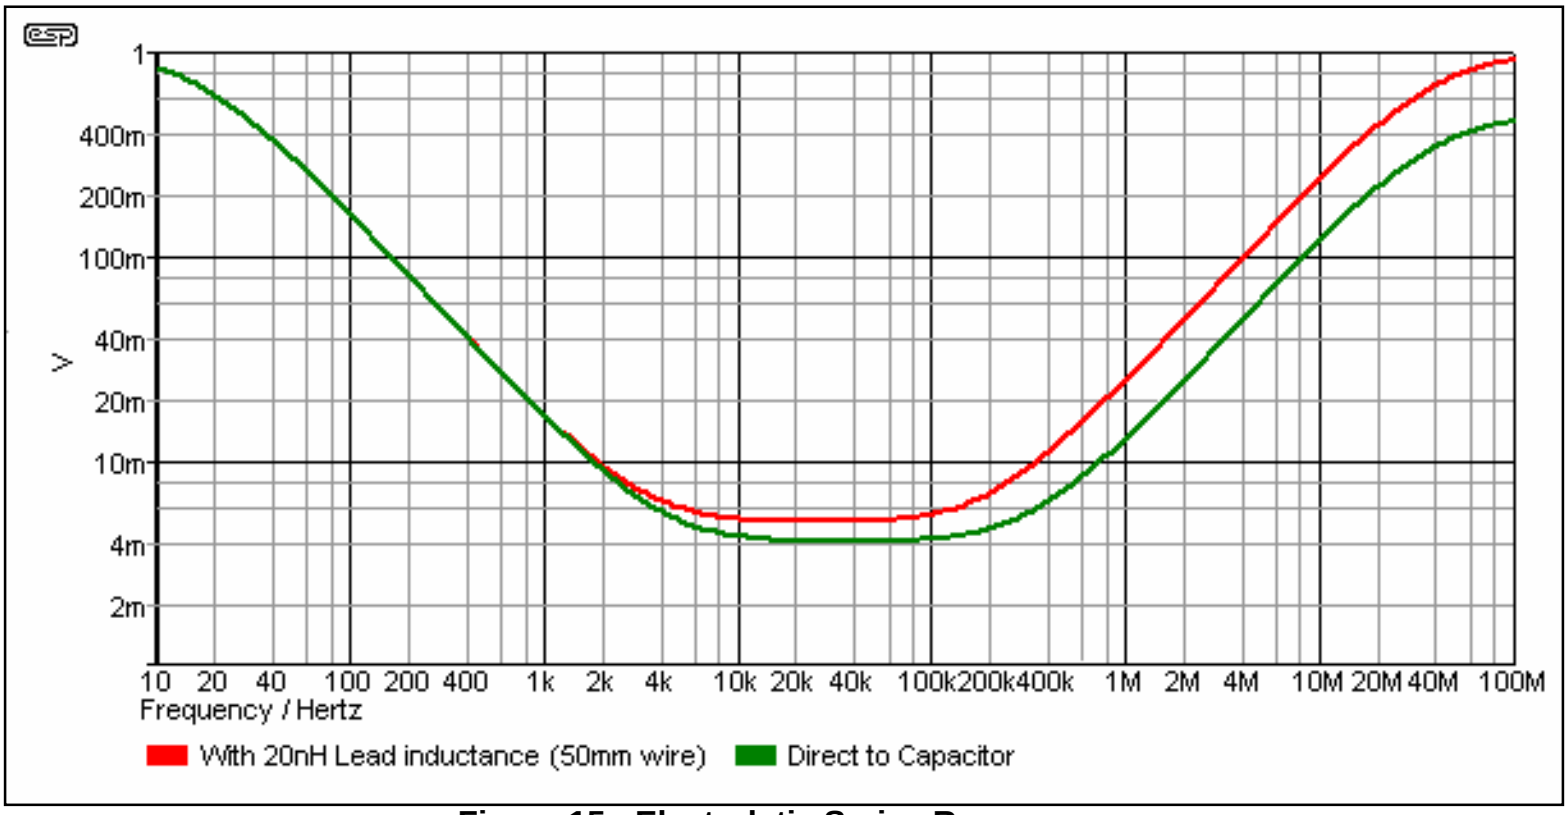

Figure 15 - Electrolytic Series Resonance

These simulations agree quite closely with the measured results, so even though there will be some variance, it will be less than that obtained from different samples of real-world components. As with the pulse response, there was zero measurable difference when a 220nF film cap was added in parallel - either with the extended leads or without. The simulation agrees for the most part (but only if a 'real world' capacitor with losses is used), and I have not included these data.

In a real circuit, there is a possibility that a small film capacitor in parallel with a large electrolytic may cause ringing (damped oscillation) at a frequency determined by the series inductance of the electro and the capacitance of the additional film cap. This is more likely to degrade performance than improve matters. It is possible to simulate this easily, but it is not so easy to measure because the frequency will be very high, and the impedance still very low. Because this possibility is rather remote, if it makes you feel better, by all means add a parallel film cap. Don't expect to hear a difference in a blind test though, because you almost certainly will not.

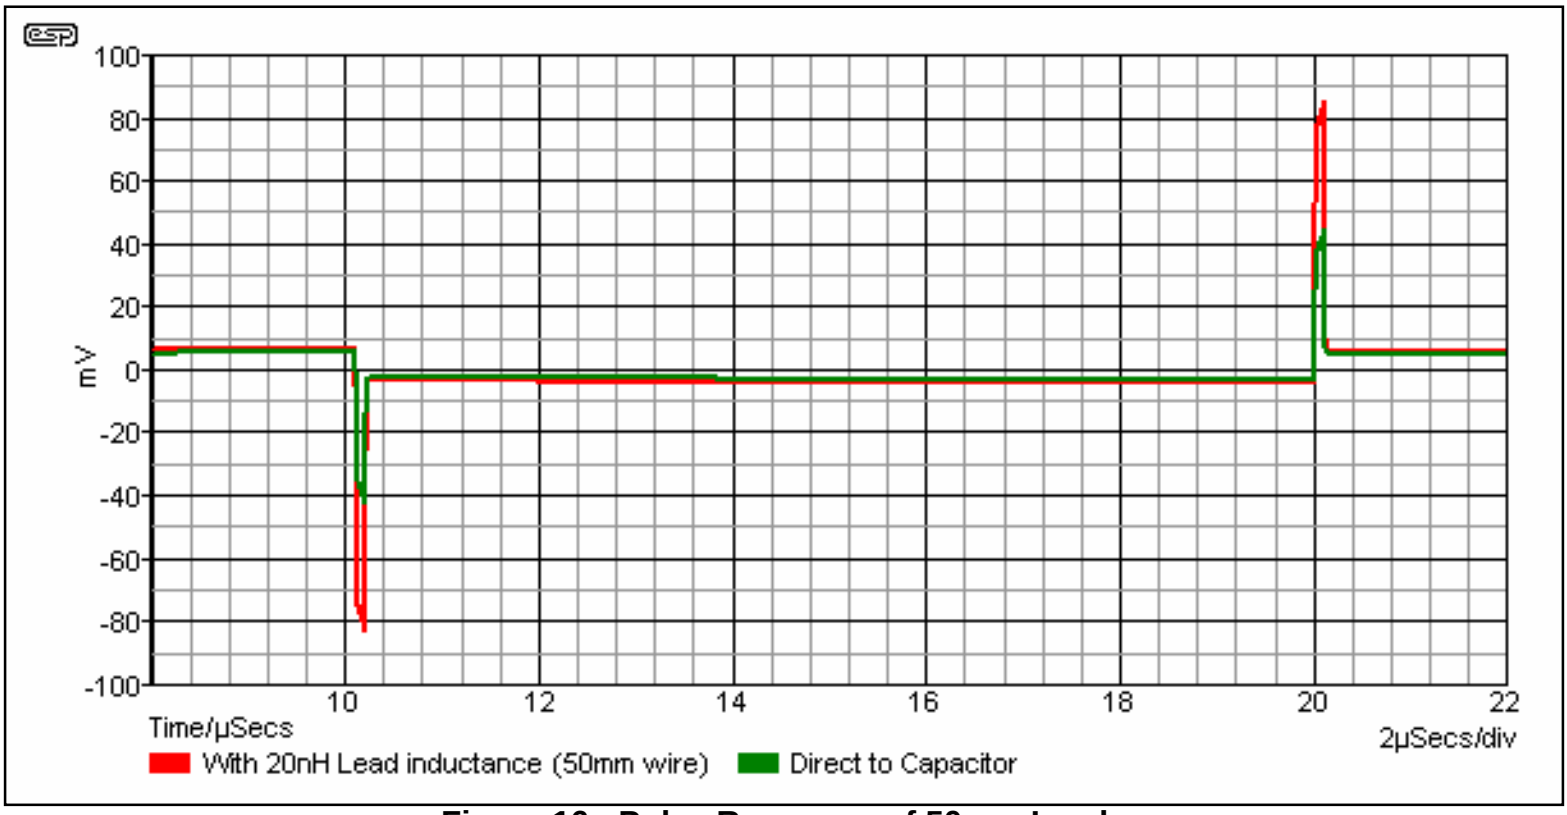

Figure 16 - Pulse Response of 50mm Leads

The pulse response is interesting. This is as close as I could get to the actual measured waveform, and contrary to common belief, adding a parallel capacitor (in this case 220nF) *did not change the measured pulse waveform one iota*. The impedance of the film cap is simply much higher than that of the electro, so it cannot have any significant effect on the end result. There *is* an effect, but it is immeasurably small. The impedance (capacitive reactance) of an ideal 15,000uF cap at 1MHz is 10mΩ, but we must add the ESR to that result. According to the simulation, the total impedance is 134mΩ at 1MHz - inductive reactance is responsible for most of that. By comparison, an *ideal* 220nF capacitor will have a reactance of 723mΩ at the same frequency - more than 5 times that of the electro.

Earlier, I made the comment that for resonance to actually work as expected, the circuit impedance must be 'significant' compared to the resonant impedance. It is time to examine exactly what is significant, and what is not. The resonant frequency of a capacitor and inductor is given by the equation

$$f_o = 1 / 2 \pi\sqrt{LC}$$

This is a general formula, and while it holds true in all cases, the Q (quality factor) of the resonance is dependent on the circuit impedance and component losses. In the case of electrolytic capacitors (especially large ones, where the resonant frequency is comparatively low), the capacitance is massively dominant compared to inductance. For this reason, electros will rarely (if ever) appear as a resonant circuit in any power supply or coupling

capacitor application.

The coupling cap is a good one to examine, because this is an area where it is often thought that a parallel capacitor will assist with high frequencies. If we assume a 4,700uF capacitor, having 100mΩ ESR and an inductance of 100nH (this is much worse than a real capacitor), its 'resonance' is at 7,341Hz. The test circuit is shown in Figure 11. As a coupling capacitor, it might appear to have inductance above the self resonant frequency, or so it would seem. Not so, as Figure 12 shows. In fact, the frequency response into an 8 ohm load remains substantially flat up to 4.5MHz (0.5dB down), and is -3dB at 12.7MHz.

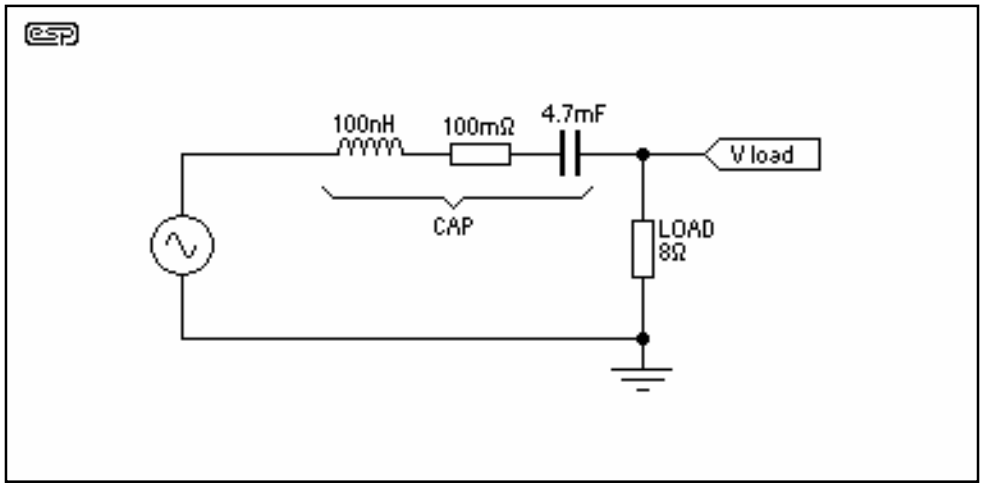

Figure 17 - Electrolytic Coupling Capacitor Test Circuit

In Figure 17, the 100nH of inductance in the capacitor is totally insignificant compared to the circuit impedance (4 ohms) and the capacitance. The speaker lead will have a great deal more inductance that the capacitor, so the frequency should be even lower than calculated. It doesn't happen ... well, actually it *does* happen, but the effect is so infinitesimally small that it can only be measured by simulation. In the example given, the difference between the voltage across the load resistor at 100kHz is reduced by less than 250udB (micro decibel), compared to the 7.3kHz 'self resonance' frequency.

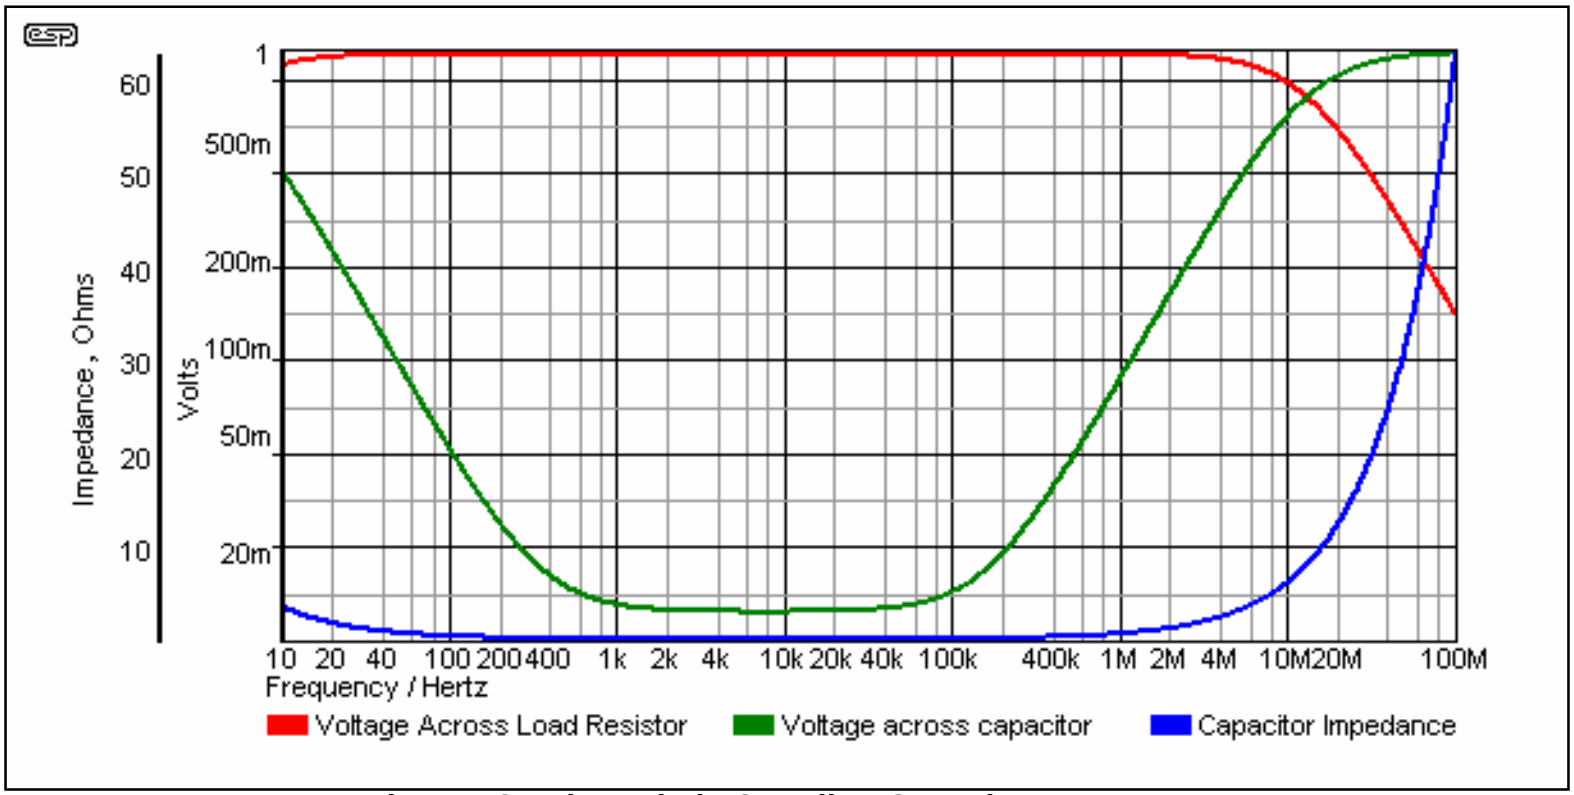

Figure 18 - Electrolytic Coupling Capacitor Response

For self resonance to be noticeable, the circuit impedance needs to be in the same general range as the capacitor's inductive impedance at resonance. As can be seen from the graph, the inductive reactance only reaches 8 ohms at 12.7MHz (the upper -3dB frequency). Will a 100nF polypropylene cap (or any other type) in parallel be of any use whatsoever? From the above, we can safely say "no". Its reactance will be equal to the 8 ohm load at 198kHz, but at that frequency, the electro has a total impedance of about 200mΩ, making the influence of the small parallel cap insignificant.

5.0 - ESL and ESR

ESL - Equivalent Series Inductance

Claims have been made that most capacitors *must* be inductive, because they are made from a wound sandwich of film and foil, or metallised film. Because it is usually wound (in a flat coil), logically, this leads to inductance. The problem with that theory is that it assumes that the termination is made to the foil at the end only, but a quick check of manufacturer data will show that this is generally not the case. The vast majority of capacitors are made so that the foil or metallisation projects from each side (one 'plate' on one side, the other 'plate' on the other side). Each end is then connected so that all sections of the plate are joined together. There is no longer a 'length' associated with the plate, and only its width becomes significant for inductance. When distortion is measured in a film capacitor, it is almost always the method used to connect to the foil that causes the problem, rather than the dielectric or foil material.

Aluminium is the most common metal for both foil and metallisation, and aluminium is notoriously difficult to attach to anything with good and reliable conductivity. That cap makers have made them as good (and as reliable) as they are is testament to the effort that goes into capacitor manufacture.

The ESL (equivalent series inductance) of any given capacitor is related more to its physical size than anything else. A larger capacitor will almost always have a greater inductance than a smaller version of the same capacity. Usually, the lead length is of far greater importance for high frequency operation.

To check the general principle, I decided to test a roll of telephone jumper wire as a capacitor. This is a fairly large roll of twisted pair (Cat-3), with the diameter of the roll being about 130mm, and 51mm high. The wire is twisted (as you would expect for twisted pair), and the roll contains about 80 metres of wire. Insulation is 0.25mm PVC, and wire diameter is 0.5mm. All in all, this should be an appalling capacitor.

Being a coil of wire, one would expect a high inductance and therefore low self resonance. The measured values were ...

Capacitance	9.67nF
Dissipation Factor	0.059
Self Resonance	303kHz
Inductance	28.5uH

The capacitance was measured at 9.67nF with two different meters, and DF (dissipation factor) was 0.059 ... not especially wonderful, but far better than I expected. Remember, this is a *coil* of twin wire, with the connection made at one end only. Inductance is calculated based on the self-resonant frequency - it is obviously much greater than a normal capacitor, but that is expected due to the physical size of the 'capacitor'. Needless to say, the fact that the connection was made at only one end doesn't help matters, but remember that this is a physically large coil of wire - one would expect that self resonance (and inductance) would be far worse than was the case.

Joining the ends together gave the following ...

Capacitance	9.73nF
Dissipation Factor	0.059
Self Resonance	1.0MHz

Inductance	2.6uH

This is a significant improvement to the inductance (roughly an order of magnitude), and also gives a small increase in capacitance. As you can now well imagine, by joining the entire edge of each capacitor plate, inductance is reduced to almost nothing, and only the physical size of the cap will influence the inductance. This can't be applied to my 'coil capacitor', because I only have access to each end, rather than the edges of the 'plates'. I think it is safe to assume that the wire coil performs far better than might have been expected, especially with the ends joined together. It also has far thicker insulation and smaller plate area than any real capacitor, both of which increase inductance and reduce capacitance.

In case anyone was wondering, the inductance of the coil used above is 15.6mH, with a series resistance of 6.4 ohms. This was measured with the two wires connected in parallel. Self resonance is at 27MHz. Not useful in the context of this article, but worth including.

ESR - Equivalent Series Resistance

While inductance is not affected by the dielectric material, ESR is - it is dependent on the dissipation factor (DF) of the insulation material, as well as the resistance of the leads, plate material and plate terminations. Because DF varies with frequency in most common dielectrics, so too does ESR. However, ESR is rarely a problem in most audio circuits. It is important in passive crossovers used in high powered systems, or for other applications where capacitor current is high. ESR (like all resistance) creates heat when current is passed, so for high current circuits the ESR is often a limiting factor.

ESR is very difficult to measure with low value capacitors, because the capacitive reactance is usually a great deal higher than the ESR itself. In general, it is safe to ignore ESR in most electrolytic and film caps used in signal level applications (such as electronic crossovers, coupling capacitors and opamp bypass applications). ESR becomes very important in high current power supplies, switching regulators/supplies and Class-D amplifiers, many digital circuits and any other application that demands high instantaneous currents that are supplied by the capacitor.

6.0 - Food For Thought

The above is food for thought indeed. I have had several e-mails from readers (within a day of the article being published), and further comments should be made to clarify a couple of important points. Much ado was made above about coupling caps, and these are a favourite of the upgrade brigade. It is not uncommon to see circuit boards where the constructor (or 'upgrader') has used caps for which the PCB was never designed. As an example, look at

Figure 19. This is not at all uncommon, but what is not understood is the potential for possibly major problems to be introduced.

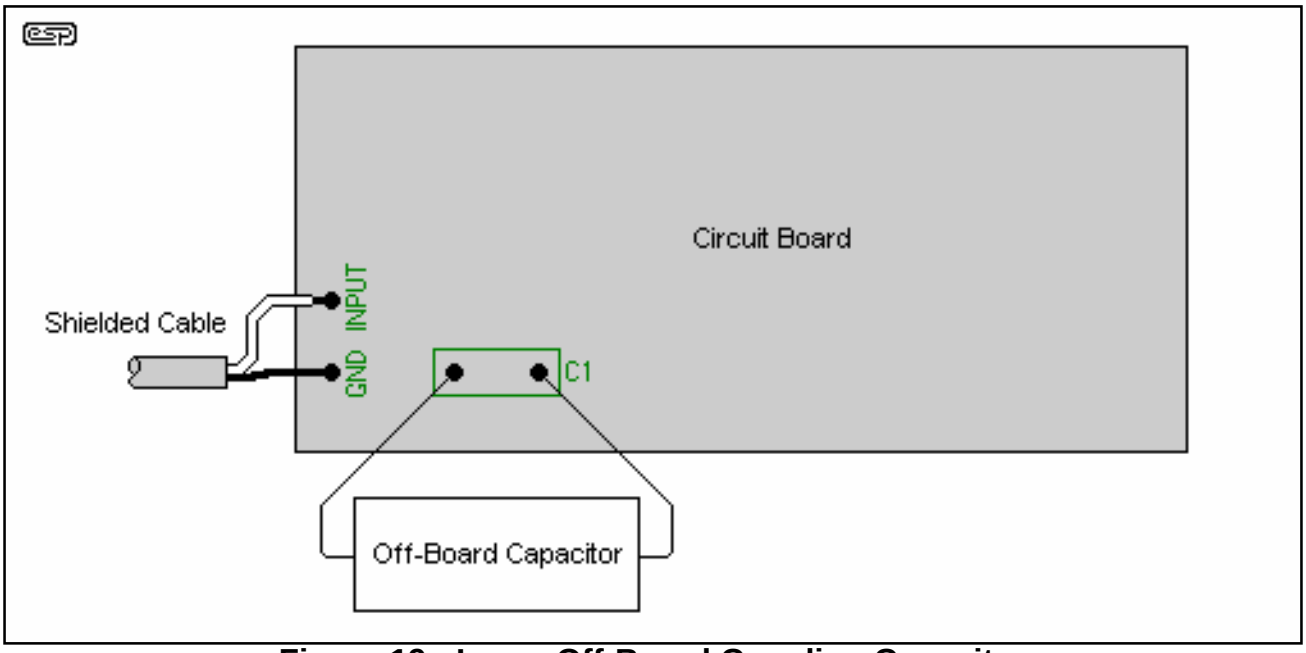

Figure 19 - Large Off-Board Coupling Capacitor

At first glance the diagram looks alright. Everything is connected where it should be, so where's the problem? Notice that the input signal is connected to the PCB via a shielded lead. The PCB may have a ground plane, but even if not, the connection between the shielded input lead is nice and short, and connects to C1 on the board. The space allowed is sufficient for a cap as originally designed.

Now, someone comes along with a massive (physically) cap that was sold as polypropylene (but could easily be polyester). It won't fit on the board, so is installed as shown. Look at the length of unshielded lead between the input terminal and the rest of the circuit on the PCB. Remember that the *entire* capacitor is part of the unshielded circuit, not just its leads. Even if the cap is marked so you know which is the outer foil, that doesn't help either, as any noise picked up will be coupled through regardless (this is what the cap is *for*!). This arrangement has the potential to pick up considerable noise, and if part of a power amplifier may even be sufficient to cause oscillation. It goes without saying that noise or oscillation will *not* improve the sound, even though the owner may think that it has done so.

The likelihood of noise or oscillation depends on many factors of course, and these may not be an issue (or not at a level that is audible). The mechanical reliability is also highly suspect, especially if the oversized cap has not been fastened such that it cannot move relative to the PCB. Had the on-board cap been installed in the position shown, its size is much less, and the board would have been tested with it in position - any problems would be immediately obvious.

Another point made is that series resonance can be used to your advantage. In the presence of a strong RF signal, normal bypassing may be insufficient to prevent the RF signal from getting through an audio system. If you know the frequency, then it is not difficult to tailor a ceramic cap and appropriate lead length to create almost a dead short for the interfering signal.

For example, if there is an AM CB transmitter (these operate in the 27MHz band) nearby that insists upon interfering with your audio system, you need to know exactly where it is getting into the audio path. Once this has been determined (not easy, but certainly possible), you can deduce the necessary capacitance and inductance using the standard formula ...

$$f_o = 1 / 2 \pi\sqrt{LC}$$

If we assume (say) a 1.2nF capacitor, then it works out that a series inductance of 28nH is needed. With roughly 6nH/cm, the cap needs to have leads about 46mm long, and with two leads than means 23mm each. The leads need to be as widely separated as possible, and some adjustment of the frequency is possible by pulling the leads wider apart or pushing them closer together. In its basic configuration, the combination of cap and leads has an impedance of less than 1 ohm between 25MHz and 30MHz, and is resonant (effectively a short circuit) at about 27.5MHz.

Maximum effectiveness is achieved when the circuit is tuned as accurately as possible, but this normally requires specialised RF test equipment. In general, a calculation will get you close enough for the circuit to be effective, and a bit of tweaking should enable you to get almost total rejection of an unwanted signal.

This last point is only made as a generalisation - RF is by its very nature sneaky, and deliberately using capacitor+lead resonance to solve a problem is just one of many techniques that need to be tried to solve an RF interference problem. No one method will work in all cases, and serious problems may need a combination of different suppression tricks. This applies both for preventing RF getting into a circuit, or preventing it from getting out (and therefore causing interference elsewhere).

7.0 - Conclusion

If wine or pharmaceuticals were tested the same way as audio, we would be in a very sorry state indeed. To be valid, all tests must be conducted blind, where the tester does not know which product they are using, or preferably double-blind, where neither tester nor controller knows which is which. That sighted tests are not only tolerated but encouraged is testament to the level of disconnection from reality that many 'magic component' believers obviously

suffer.

Unfortunately, there are many who will search the Net for 'proof' of their current theory, and will use or misuse any data they happen across to further their argument. That the data quoted may be out of context, flawed, or simply a load of codswallop is immaterial. Once these rumours start they take on a life of their own, and it then becomes almost impossible to get the discussion back into the land of reality. This technique has been shown many times with the 'great cable debate(s)',and much the same has happened with capacitors and other generally benign components.

A popular piece of disinformation that really irks me is the claim that ceramic caps should not even be used for bypass applications in audio. This is drivel, and is totally unfounded drivel at that. The purpose of bypass caps is to store energy that ICs need on a short term basis, swamp PCB track inductance to ensure that opamps don't oscillate, and to ensure that digital circuits don't generate supply line glitches that produce erroneous data. There is absolutely no 'sound' associated with DC supply rails. Opamps don't care if the DC comes from a battery, solar cell, or rectified and filtered AC (sine or square wave, any frequency). DC is DC - it has no sound, and it contributes nothing to sound unless it is noisy or unstable. Supplies may be completely free of noise, or might be relatively noisy (especially where digital circuitry shares the same supply). Provided all noise (including voltage instability) is of low enough level that the opamp's (or power amp's) PSRR (power supply rejection ratio) prevents the noise from intruding on the signal, supply noise is immaterial. As always, a blind test will reveal any genuine difference, and a sighted (non-blind) test will reveal the expected result - real or imagined.

To reject ceramic bypass caps, which have the best high frequency performance of nearly all types, is sheer lunacy. This is especially true when discussing simple DC power supply lines. PCBs have capacitance too, and the standard fibreglass material used is fairly lossy - it is certainly useless for very high frequency work at several GHz. Maybe that ruins the sound too - I *have* heard such tales, and they can be discounted out of hand. Still, these fairy stories circulate, are perpetuated by those with a vested interest in separating people from their money, and will continue for as long as anyone is silly enough to believe it.

Just as misleading are claims that all/most electrolytic caps are resonant within the audio band (or at least below 100kHz). Again, while this may be true, it is meaningless without context and simply indicates that the person conducting the test is leaving it up to the designer to determine if that will cause a problem in the circuit being developed. Always remember the importance of the lead inductance - that is usually far more important than a few nH of capacitor inductance.

Large electrolytic caps may well resonate (if a very broad impedance minimum can be considered resonance) within the audio band, but with impedances of well under 0.1 ohm

overall, this can hardly be claimed as a problem. Adding a film cap directly in parallel achieves nothing, because its impedance is many times greater than that of the electrolytic for all frequencies of interest. If there is *any* distance between the large electro and the film cap (for example leads running from the power supply to an amplifier PCB), the caps are no longer in parallel. They are separated by an inductance determined by lead length as well as some resistance, and the extra cap will help to damp out the effect of the inductance. Again, the larger the local bypass cap, the better it will perform.

One thing you can count on ... if anyone wants to sell you 'special' capacitors, designed to replace 'inferior' types (such as polyester, aka PET, Mylar®, etc.), then you know that there is a problem. These vendors are cashing in on the audio snake-oil bandwagon. Like cables, many of their offerings are likely to be of good quality, but at many times the genuine value of the part. Others will be perfectly ordinary parts that have been re-badged. For example, there are many capacitors sold as polypropylene that are actually PET or Mylar. It seems that no-one has ever heard the difference, simply believing that it *is* polypropylene, so therefore sounds 'better'.

I have never seen the specifications for snake oil as a dielectric, but I expect it to have rather poor performance overall. With 'magic' components, in the end everyone loses. DIY audio is supposed to be fun, not an endless search for the mystery component that will make everything sound wonderful. Sad news ... that component does not exist.

"The best cap is no cap" is claimed by some. I would much prefer to ensure that no DC flowed where it is unwelcome by using a cap than to allow a fully DC coupled system to try to destroy speakers given the chance. Perform all the blind tests you can with capacitors used in real circuits. Having done this, if you still think there is a difference (and can demonstrate it to others in a blind test), then you will probably be the first to do so.

If you wish to let me know that I am wrong, feel free to do so ... but *only* if you have conducted a blind A-B test and can provide some verifiable data to substantiate your claim. I regularly get e-mails from people who claim that they can hear the difference between components, leads or whatever, but in every case thus far, no blind A-B test method was used. I am not the least bit interested in hearing about the results of *any* sighted (non-blind) test, because such tests are misleading and simply verify existing opinion. In fact, the 'result' of the entire test is only an opinion, as there is never any data to substantiate the claim.

Electronic equipment is designed using facts and mathematics, not opinion and dogma.

Elliott Sound Products **CD vs. SACD vs. DVD-A**

by Niklas Ladberg

Introduction

For a while I have been interested to find out how good the new high resolution formats Super Audio CD and DVD-Audio really are? I have visited some demonstrations, but not been impressed which may be due to other causes than the sound formats.

After reading many replies at different forums, it seemed like many audiophiles considered SACD to be better than DVD-Audio. I also thought so until recently read what Ing. Öhman wrote in the Swedish Audio Technical Society * journal.

(*A non-profit organisation for sharing interest and knowledge in audio and sound reproduction)

The following are quoted from what Ing. Öhman wrote in the journal:

"It is nothing less than a tragedy that Sony/Philips system SACD still is considered to be a real competitor to DVD-A, though it has lower real resolution than the CD-system in the highest octave.

DVD-A does absolutely offer a much higher dynamic range than CD, but it is very questionable if SACD does.

SACD is in the high frequency range quite mediocre, even compared to a good CD-system one-bit DAC, and of course clearly inferior to a CD-player with a real multi-bit converter.

On the contrary, DVD-A is in theory 250 times better than the CD-system at all frequencies!

In today's reality though, it is hard to achieve such hyper-resolution, but maybe in the future? If the potential exists, recording and playback technology can evolve. Today the DVD-A resolution is about 16 times better than the CD-system and the bandwidth extends up to 100 kHz to be compared with 22,050 Hz for CD."

Now I became curious! This is the opposite of what I thought. I asked Öhman for a follow up ...

Niklas Ladberg: How did you come up with these conclusions?

Ing. Öhman: DSD (the coding technique used in SACD) is much better than CD in the low frequency range. The problems occur at higher frequencies. The noise level in the ultrasound register is more than 100 dB higher (-40dB under maximum output level, using narrow band analysis) when compared to DVD-A (-144dB under maximum output level, full spectrum noise).

Another way to describe the difference: The noise [power] from SACD is more than 20,000 million times higher than from DVD-A!

But maybe it is more relevant to know that this ultrasound noise from SACD is enough to warm up the tweeters voice coil with some detectable influence on reproduced sound. Besides, the ultrasonic may also affect the audible sound by down mixing in the air, at least at higher sound pressures.

A comparison with CD is harder because of the limited bandwidth of the CD-system. Signal to noise ratios in the range above 22,05 kHz can therefore not be determined, but noise level from CD can be as good as DVD-A – one can always use low pass filter! Then no ultrasound comes out from the CD-player.

The problem with SACD can be shown by theoretical calculations, measurements and by listening. I have done lots of all these three and every one of them points clearly in the same direction: SACD has not more resolution than CD above 10kHz. Our early estimations some years ago have now been confirmed by measurements and listening, made both by us and others. Today, many studies have been done, for example by Stereophile who has tested SACD players several times and confirmed our estimations.

NL: What does Stereophile say about the limitations of SACD?

IÖ: Oh, not much in the written tests. Stereophile is an advertisement dependant paper and they are a bit careful to say anything negative about anything, but they present their measurements, often done by the sharp editor in chief John Atkinsson. His comments are very informative! Although very careful, any equally sharp reader can decipher Atkinson's opinion from the text.

Stereophile also performed a large subjective listening test between some existing high performance recording formats and SACD was even considered to be inferior to PCM 16bit, 176,4 kHz.

Anyway, one should not take too much notice of "how many" said this or that. What is important is how things really are, not how many people believe this or that. Deciding truths by voting is seldom a good way. It can only show what people believe. Some peoples' beliefs might of course be right, but too often correct information and relevant listening experiences drowns in common misconceptions, preconceived notions and the media background noise.

This happens especially easy in this particular case since DVD-A and SACD never have been compared under equal conditions.

NL: I read in a technical paper about SACD. Sony writes:

> ***"The vast majority of A/D-converters used in PCM recording for conventional CD are 1-bit converters with high sampling frequency"***

Then it must be better to keep the signal in DSD-format (SACD) than convert the signal to PCM (CD/DVD-A)?

IÖ: Yes, that is correct, but is it relevant question? The CD-system seems worse than it is when used with a one-bit converter. The problem is not the conversion from a one-bit converter to PCM but the one-bit converter itself!

Besides, the one-bit converters used in CD-players usually have higher resolution than DSD, which only samples 64 times faster than CD-system sample rate (i.e. DSD sampling rate = 2.8 MHz). The low sampling rate in DSD is used because of the systems ineffective coding and lack of storage space. By packing the information it becomes a bit more effective but it still is ineffective compared to PCM.

One-bit converters for CD-players often use sampling rates between 11 and 50 MHz. The best one-bit converter probably is JVC's PEM-DD and it is much better than DSD.

This said with reservation, I might have missed some even better one-bit technology than PEM-DD. But as far as I know this is the technology that comes closest to true multi bit technology in resolution.

NL: I presumed that SACD uses DSD-technique for recording and mastering, but that turned out to be wrong:

> *Press release:* ***"A big surprise at the AES was the confirmation by Sony that DSD technique, used in SACD, uses multi-bit PCM during recording and mastering processes and that only uses one-bit technique as it applies to consumer playback systems. Jim Johnston of AT&T Research speculated that DSD and DVD-A data streams might be able to co-exist if output from different points within the same microprocessor."***

Apparently they use PCM for recording and mastering, even for SACD. Now the advantage of no conversion between formats suddenly disappears.

IÖ: Several documents show this is the case. Sony/ Philips has even officially recommended using PCM when editing the recorded material. I think it is a wise recommendation, because every manoeuvre in the PCM-domain is straightforward, easy to make and will not degrade the quality if performed with high enough resolution. Only the DSD-problems remain!

Therefore DVD-A is a purer and more straightforward system. No conversion between different formats and 144dB resolution at all frequencies up to 100kHz. Could it be better? Well of course it can, it can always be better, but DVD-A is good enough. DVD-A is what the CD-system should have been from the beginning!

NL: Back to the Sony technical paper:

> ***"On the playback side, most CD-players utilise one-bit D/A-converter to convert digital signals back to analogue."***

Is this correct? Don't most CD-players utilise multi bit-converters?

IÖ: Though some fine multi bit CD-players exists, unfortunately most CD-players today utilise one-bit converters. It is probably a price question. A so-called 24 bit one-bit converter (working with one bit technology inside but accept 24 bit input) costs about 2-4 dollars including 2 channels and digital filter.

A real 24 bit converter with 96 kHz sampling frequency and 8 times over sampling costs

about 10-15 dollars per channel – without the digital filter. For two channels and digital filter it ends up to approximately 40 dollars.

So multi bit technology is ten times more expensive as one-bit technology. Most manufacturers find it easy to choose ... Especially since Hi Fi-magazines and Hi Fi-stores never take a stand and point out the difference.

NL: From Sony again:

> ***"Although the bit numbers is just 1/16 of that used for the CD-format, the sampling frequency is 64 times higher. DSD can accommodate more than 4 times the information as the current format."***

4 times more information could not be wrong? Or is the depth of bits more important?

IÖ: The number of the bits is much more important. Actually the DSD-system is theoretically less dense in information than the CD-system. Even when the data is packed (as it is on an SACD) it is still not much better.

When Sony declares that DSD-format can store 4 times the data, they probably mean that there is 4 times the space on the SACD-disc compared to CDs. But since the DSD-coding is so ineffective, the real information is considerable lower.

The resolution/ information doubles when you double the sampling frequency (it is possible to be more specific, but for this example it is enough). But to double the resolution using PCM, you only have to add one more bit. If you go from 1 to 16 bits (adding 15 bits which use approximately 15 times more storage space), the resolution increases 65,536 times (from one step to 65,536 steps).

There is also another essential difference; the increase in resolution you achieve from raising the sampling frequency will be frequency dependant. A one-bit system will therefore have high resolution at low frequencies (where the information theoretically is low) and have low resolution at high frequencies (where the information theoretically is high).

By the use of noise shaping of high order, it is possible to increase the resolution at "quite high frequencies" at the expense of resolution at very high frequencies, but *only* for static, non transient signals. Transient signals will have poor resolution in a one-bit system. If the signal does not endure for a long enough time, the error will not be minimised by the noise shaper of the one bit system.

That's why you can read in documents from Burr Brown (who manufactures both one-bit and multi-bit converters) that you should use multi-bit converters for "*waveform synthesis applications requiring very low distortion and noise*". They have not written this for nothing.

A one-bit converter (i.e. the DSD system) cannot regenerate a short pulse with stringent form. It will change form from moment to moment. Every identical recorded pulse will show up with a new form.

One can always discuss the audibility of such behaviour, and if it is audible, one can discuss how much it disturbs. Objectively good reproduction is not important for everyone. So if the presentation of music is changed in some way, some people might see this as a minor problem, others think it is more serious.

It is beyond discussion that the lower resolution of one-bit systems is a problem under circumstances more precision demanding than audio. When you need both super precision and stability, when you need to know that a generated waveform looks like it is suppose to, nothing but multi-bit converters will do.

My entirely personal opinion/experience is that audio actually demands very high precision, and that the reproduction suffers from the lack of precision from one-bit converters and the DSD-system.

Perhaps I even prefer the old 13-bit PCM-based Denon system from the 70s. It was not a super high-resolution system, but it was as stable as it was consequent! I have a lot of these recordings (reissued on CD) and they actually sound fabulous!

NL: From Sony's paper ...

> ***"In general, the quantisation noise floor resulting from PCM is flat, according to the number of bits. With Delta Sigma modulation the noise floor is subjected to noise shaping. Because the DSD method uses a high sampling frequency, the quantisation noise is shifted to a higher frequency range. This reduces the amount of noise in the audible range for humans, which is relatively low."***

Is this correct?

IÖ: Yes, the first part, but one should be careful not to underestimate the hearing, as Sony does – or you end up with systems like SACD! Of course we can only hear single tones up to 20kHz but this does not implicate that we can allow any kind of noise

pollution above this frequency. Multiple tones in the ultrasound can create clearly audible phenomenon at higher sound pressures.

It can be discussed if we can tolerate the ultrasound noise generated from SACD. The noise from SACD just above 100kHz is higher in level than most of the treble in the audible range, at least when listening to the majority of acoustical music. It can also be discussed if DSD uses a "high" sampling rate. But apart from that: Yes, without noise shaping it will not work at all and that would be a lot worse. Now it is only a little bit worse than CD in the highest treble.

But why introduce a new super high-resolution system, that is "a little bit worse" than CD? Of course there are advantages when compared to CD also, but the drawbacks of SACD/DSD are completely unnecessary. Shouldn't a new system be better than CD in all aspects?

The noise level in the range above 100kHz is –40dB under maximum signal level (and is thus even visible on an oscilloscope!). The noise is in fact much higher than any possible music signal in the same frequency range. This can be compared to DVD-A where the noise level is –144dB in the whole audible range and also in the ultrasound range.

In reality these figures have not yet been reached in commercially available DVD-audio players, but the potential for future improvements is there. Today, the best DVD-A players reach a signal to noise ratio of about 120dB (0 – 100 kHz). The figure will be even higher when measured with small band analysis. This is far from 144 dB, but still very good.

I think it is a little embarrassing that no good DVD-A recordings have been released so far. They have all been of inferior quality. This has of course not made it easier for ordinary people to make a relevant opinion about the differences in the systems. The SACD recordings from Jan-Erik Persson at Opus3 are far superior everything released from DVD-A.

Now, when looking at "recordings in holistic view", the debate of the storing media/ system is much less important than the skills of the recording engineer – a good recording stored on compact cassette is far superior to a bad recording stored on DVD-A. But every debate has its time and place. It is not relevant to point out more important issues when we are about to choose a new storage media.

This time the storage media (SACD versus DVD-A) is the question, and it can very easily be distorted by comparing the systems on different recordings. The better

recording will always win.

The music is even more important of course, than the recording, but it is entirely subjective – not much to debate about. As an example; my taste in music is disputably deplorable. At least according to some people!

NL: I continue to read from the press release:

> *http://tinpan.fortunecity.commarrfield/216/pag_eng/oct2000.htm)*
>
> ***"The watermarking issue is having a big impact in the 109th AES convention at L.A (for the moment only at professional level, but in a future also at a domestically level). A big and increasing number of professionals have pointed out the fact that the actual methods of watermarking introduce sound quality degradation into the supposed high quality recording formats. While the watermarking promotion groups are pushing hard these methods, a group of very well known audio firms (Chesky records etc) and well-known engineers (Tony Faulkner of GRP) are very disappointed of what they consider an audible degradation of the sound quality. The first tests conducted recently in UK and USA (btw, not as impartial as supposed to be due to the use of ultra low quality recordings) using DVD-audio with the watermarking, have shown the fact of this degradation."***

Is the watermarking of SACD sound degrading?

IÖ: Well that depends on which watermarking is used! The so called "psychoacoustical water markings" are all sound degrading in various degree and are not associated with any specific storage system.

You can use it with any system of your choice, but it is unclear to what extent they are used in respective system. As far as I know, no released SACD recordings have used this type of watermarking, but I can be wrong.

The only thing I know for sure is that lots of CD-recordings have this kind of watermarking. But watermarking is a separate problem. It has nothing to do with the either of the recording and storage systems. You can choose not to use it. But the problems built in the DSD-system cannot be excluded!

Just to avoid misunderstandings I want to make a reminder that SACD has higher resolution below 5-10kHz than the CD-system. Exactly where the limit is, where each system (CD or SACD) is better, depends on if you are looking at a static or dynamic signal.

At frequencies below 100-600Hz the SACD-system could theoretically be even better

than DVD-Audio, but in reality this is not important. We are talking about so small flaws, far below the hearing threshold, so they can be disregarded. Any specific player however, can be very bad at low frequencies, but not due to the system if SACD or DVD-A is used.

Anyway, in the practical life, it seems like DVD-A wins over SACD at all frequencies, cleaner sound, lower noise, and a completely stable system, free from potential noise shaping algorithmic oscillations.

NL: How close to the potential resolution do we come with the player existing today?

IÖ: If we look at the players you can buy today, then the resolution is about 15-30 times lower than the full potential of DVD-Audio. That means 8-16 times better than the CD-system. A big improvement, but still a lot more is possible.

All these comparisons between systems made in "times" are based on pure technical specifications. If you want to have "worst case" audibility, take the logarithm and multiply it by 20, then you get the figures in dB. "15 times better" corresponds to a 23.5 dB lower noise level.

If these figures should be of any use for you, you must have a feeling for "how it sounds when an error signal changes X dB below the music signal". If the changes of the error signal take place below the threshold of hearing, naturally you will hear no difference at all.

Also, different errors have different audibility. Some are easier to detect. Others are more difficult. Some faults/errors are therefore more tolerable even though they are higher in level.

Who said it is supposed to be easy to form relevant opinions?

Relating technical performance to the experienced sound quality should be done with utmost care. My experience is that the quality improvements coming from using more bits are valuable only for high dynamic music material. An 11-bit recording will do fine for extremely compressed "radio-sound".

How people experience sounds in the ultra sound region seems to be quite individual. The most sensitive listeners seem to manage music better with no ultrasounds/ overtones at all, than with music plus ultrasound pollution. Probably no one minds a nicely reproduced ultra sound range (like in DVD-A), but when using such a very capable system, there is no guarantee that recording engineers manage to keep the

ultra sound "unpolluted".

When it comes to comparing CD, DVD-A and SACD against each another, it becomes much easier, because at optimum implementation, all error signals in these systems are in the form of noise. But you have to look at every frequency register alone, since the noise character of each format displays different spectral behaviour. I mention this again as I might not have been clear enough earlier in the text.

NL: Thank you for your time and for answering my questions!

IÖ: Hope I could straighten out some of your question marks.

Editor's Note

This article is reproduced with the kind permission of Niklas Ladberg and Ing. Öhman, with translation from Swedish into English by Marten Kihlberg. No changes have been made to the text other than by way of translation, and the actual words used herein are as accurate as translation allows.

The editorial "content" has been limited to the creation the web page (in standard ESP format) from the original article, a small number of grammatical corrections and the addition of one word [power], when referring to the noise level differences between SACD and DVD-A (i.e. 20,000 million is the power difference, not voltage difference).

I would like to thank Niklas Ladberg, Ing Öhman and Marten Kihlberg for making this information available.

Introduction

The term compression has several meanings in audio - there is lossy data compression (e.g. MP3), lossless data compression (a wave file compressed using a Zip program), and level compression and/or limiting. In this article, I concentrate on the last form, although a few words about MP3 are in order (later).

I recently read a wonderful article by a mastering engineer by the name of Bob Katz (see references, below). Bob was adamant that many producers, engineers and musicians have joined a new race to see who's CD can be the "hottest" (i.e. loudest). There is a mistaken belief that this makes the sound more exciting - it doesn't - it makes it boring, and very tedious to listen to ...

Just like commercials on TV, which are compressed to within an inch of their lives. Does anyone find the sound satisfying? I'd be very surprised to hear someone (other than the producer) say yes - they are annoying, seem to be much louder than the programme you were enjoying, and cause a great many people to hit the mute button on the remote the instant they start (I'm one of them :-)

Compression Versus Limiting

So what is the difference between these two effects? Depending on your outlook, either not much or a great deal. A limiter is usually set to a fixed threshold, and any signal that attempts to exceed the threshold is pulled back (attenuated) by exactly that amount needed to maintain the predetermined level. If the input gain is set way high, then all signals below the threshold (including noise) are boosted - in the extreme case so everything is the same volume (again including noise!). Limiters are "hard" compressors - the absolute level is fixed, and the compression ratio may be as high as 100:1 or more. This means that the input signal must increase by 100 "units" to make the output increase by one unit. Many limiters claim that the ultimate compression ratio is infinity, however this is probably an over estimation of the true figure.

A compressor uses much the same (or at least similar) circuitry as a limiter. While some compressors boost the level of signals below a preset threshold by a predetermined amount and reduce the level of signals above the same threshold, this type of compressor is most commonly used in noise reduction systems - an expander is used at the playback end to return the original dynamic range.

The majority of compressors use a threshold setting (like a limiter), and reduce the gain progressively once this is exceeded. Compression ratios of perhaps 2:1 are common, so the output will rise (or fall) by one unit for every two units of input change. A 50dB dynamic range (above threshold) is therefore reduced to 25dB (from softest to loudest signal). Unlike limiting, the compression threshold is typically set lower than the peak level - the actual threshold level could be anything from +8dB to -40dB, depending on the effect desired.

For example, a guitar (after suitable amplification) may produce transients of perhaps 5V peak, but yield an average level of only 500mV. This represents 10:1 or 10dB peak to average ratio. The peaks are produced as the pick strikes (or releases if you prefer) the strings, and the average is predominantly the normal decay of the note before the next is played. The VU meter (I refer here to real ones, not the stupid things you so often see that bear no resemblance to a proper VU meter) gives a good indication of the average level, and therefore the perceived loudness (VU = Volume Unit).

A PPM (Peak Programme Meter) shows the peak levels - no surprise there. Some meters, mainly electronic versions, provide both indications. A bar shows the average (VU) level, and a dot that "sticks" at some higher level shows the peak amplitude.

By using compression, the same guitar may have the maximum level reduced to perhaps 1V - the average level will now be higher as well (softer sounds are amplified, loud ones attenuated). Peak to average ratio may be reduced to 6dB or less, and the note will seem to just hang on forever ... well not quite, but you get the idea.

This sort of compression is common on percussion, strings, vocals - in fact almost anything. It is appropriate if (and only if) it provides the *sound* the artist wants - when compression is used just to make something sound louder, then it is better to just turn up the volume. This way, the original dynamics are preserved. Incorrectly used, compressor/limiters will flatten the sound, and remove the life and soul of the music.

Additional Features

Compressor/limiters are usually fairly complex electronically. Since they already have a voltage controlled amplifier (VCA) circuit that must be of the highest quality to satisfy audio professionals, this can be used for other things as well, with little real increase in cost or complexity (they are already complex, so a little more won't hurt :-)

A common addition to these audio tools is a noise gate. This is provided with compressor/limiters, and is used to gate (or switch off) any signal below a preset minimum. Noise gates are used to remove unwanted low level signals, but are sometimes used to mess up the sound completely by removing the ambience. Better a little noise and a complete sound than a quietly decaying ambience that suddenly just stops. Used properly, a noise gate can seem to eliminate background hiss completely, while letting the signal through (the hiss is still there, but you can't hear it when the signal is present). Used improperly, the initial parts of sounds are cut off, and the natural decay is not present. This is (fortunately) rare in pro studios.

One final feature offered in many units is a "de-esser". The sibilants ("ssss" sounds) in vocals are often over emphasised by close microphone placement, mic characteristics, the vocalist, or equalisation - and often a combination of these. This can be very unpleasant, so the de-esser does exactly what its name implies - it reduces the sibilant sounds by an amount that the recording engineer can set according to need (or taste)

Why Use Compression?

Compressors and limiters are used in music for a multitude of reasons. The first (and should be the only) reason is for the sound. Used properly, a compressor - or more correctly a limiter - will place an absolute cap on the maximum level that can be passed. This is invaluable for preventing a large PA system from distorting, or making certain that the ADC (Analogue to Digital Converter) does not clip (exceed the maximum conversion voltage). Digital distortion is extremely unpleasant, and is to be avoided, as with all forms of hard clipping.

There are many other reasons to use compression or limiting. Many instruments do not have the sustain that the musician desires, and this can be corrected by using a compressor to extend the note. As the signal fades, the compressor increases its gain, so the note lasts longer.

Another reason is to restrict the dynamic range. Movie soundtracks are a prime example. If the maximum level of a car bomb exploding or a shotgun fired at close range were to be reproduced, and all conversations were at the normal level, no-one in the theatre would hear anything that was said, or would be deafened instantly by the explosions. By reducing the dynamic range, both can be accommodated at levels that are appropriate, but limited to an acceptable maximum and minimum loudness.

By contrast, many trailers and theatre advertisements are heavily compressed - they have a consistent loudness that is greater than that of the main feature. This technique can work for a limited period (it gets your attention), but becomes very tiring very quickly.

The over use of compression results in a flat, lifeless reproduction. In his article, Bob Katz refers to "wimpy loud sound", and at some stage we've all heard it. You put on a CD, and it is LOUD, so you turn it down, so the loud parts don't leave you loudspeaker cones on the floor. You wait, you listen, you wait some more ... it never happens! There are no loud sections! There are no quiet sections. Everything is at the same volume from beginning to end, and the result is indeed wimpy. Certainly the CD is louder than others

you own, but it is the same volume from start to finish and leaves you as flat as the sound.

How to make music bereft of life - compress it until it bleeds (to death). No hi-fi, regardless of cost or sophistication can make rubbish like that sound good, since there is virtually nothing that can be done. An expander (essentially the opposite of a compressor) may restore some vestige of what the artist intended, but compression is not easily undone unless you can obtain the exact reverse of the original settings - this is both difficult and time consuming to even attempt, assuming that you have the equipment in the first place (very few hi-fi systems incorporate an expander, so most of us are well and truly screwed).

Contra Indications

Compression is commonly used in the final mix, and this is where things can go seriously wrong - everything is at the same volume, peak to average ratio is minimal, and the resulting sound is *almost always* worse than it was before the compression was applied. Used correctly, a small amount of compression may be useful with some musical styles, but it is completely unsuited to others. I have several CDs that sound "exciting" at first, but the sameness of having a constant barrage of sound at the same level becomes extremely fatiguing in only a short time. On some, I can hear the compressor/limiter acting ("breathing" or "pumping" are terms commonly used for this effect), which means that it has been over used, and the CD is then relegated to the "don't bother listening to this" pile. Most unfortunately, this pile is getting bigger, and many of the modern CDs are worse than older ones because of the stupid, unnecessary and pointless game of one-upmanship by the record companies, all trying to get the "hottest" CD on the block.

I don't want it to be "hot", I want it to sound the way it should, with real dynamics, soft and loud passages, and things that make me jump! Fortunately, I am not alone, but unfortunately, record companies are still producing material for people with crap systems - "Make it sound good on a crap system - we'll sell more". This is rubbish - people with only a boom box don't care that much, otherwise they would strive for something better. Those among us with good or excellent systems should not have to listen to something that was mixed on a pair of near field monitors with the quality of a transistor radio, and compressed so heavily that it has lost all of the dynamics that make music what it is - or should be!

If the CD is a little quieter than expected, then I simply turn up the volume - even without

a remote control, this is hardly an arduous task. Better that than have a whole pile of "hot" CDs that I can't bear to listen to because they have had all their life removed by an over zealous compressor-head.

Peak to Average Ratio & Dynamic Range

All music has a peak to average ratio (and dynamic range - see below), since there are peaks and dips in the level (even when heavily compressed), and the average level must be lower than the peaks. The trick is to know what the peak to average ratio should be. It is commonly quoted as being between 10dB and 20dB (a power ratio of between 10:1 and 100:1). By this reasoning, music with a 10dB P-A ratio will need perhaps 50W to handle the peaks, but will provide an average power of only 5W. This is typical of a lot of music, and even some orchestral music will be at this ratio without any compression (relatively uncommon, but Bob Katz has experienced exactly this).

A ratio of 20dB is at the other extreme, so the same 50W amplifier will only produce an average power of 0.5W - this is where the use of high powered amplifiers for hi-fi is important - by the time the average power is high enough, the peak power is massive. A quick example ...

You want to listen to music at 90dB (SPL). Your speakers are rated at (say for convenience) 90dB/m/W, so with two of them, the effective sound pressure (at 1 metre) is 93dB SPL with 1W into each channel. You (the listener) are some distance away, so the level may be 3 to 12dB lower at the listening position. We shall assume 6dB as a reasonable guess for a typical listening room (although it may be considerably more than that, depending on room treatment, furnishings, etc.).

For 1W per channel, your SPL will be about 87dB SPL, so to get the extra 3dB, the power must be doubled to 2W per channel. If you have music with a peak to average ratio of 20dB, you will need 200W per channel to reproduce the music without distortion - assuming that you have that much power, the peak SPL will be in the order of 110dB ...

(90dB + 20dB P-A ratio = seriously loud).

Compression is your friend! Such a high P-A ratio will cause most high end systems (and their owner's ears) grief at high levels, so some degree of compression will make the reproduction less arduous on your system (and a lot less likely to frighten the cat to the point where it perches tightly on your head :-) The magic is to find the ratio that keeps the ratio to a reasonable figure (and there are no absolutes here!), while

preserving the soul of the music. It can be done, and I have many CDs and vinyl albums that do it very well (Bob will also tell anyone who cares to listen how to do it well, too).

It can also be done very badly, and so many new releases do just that. Mind you, a lot of old releases were just as bad - this is not a new phenomenon, but has been happening ever since the compressor was first invented - or at least used in anger.

Dynamic Range

Is there a difference between peak to average ratio and dynamic range? The answer depends entirely how long the averaging period is. Generally, the two are considered separate, but with enough compression they become equivalent. The dynamic range of a piece of music is the difference between the softest passage and the loudest - it takes little imagination to realise that if it is sufficiently heavily compressed there will be no difference at all.

With a good mix, and a compressor/limiter that is correctly adjusted, the difference between the two will be less than in "real life", but great enough to create excitement - this is where experience and careful adjustment come in. The range of sounds we can hear (and will be assaulted by) is enormous, from the faint rustling of leaves on a very quiet night through to jack-hammers or jet planes (and certain motorcycles!). To expect to reproduce this range from a home hi-fi or theatre system is generally not possible and is undesirable anyway.

The difference between the two is blurred - there is an almost infinite grey-scale, rather than any black and white distinction between the two, so I shall leave it at that.

Typical Specifications

A discussion of compressor/limiters would be incomplete without a brief explanation of the features and controls typically offered. A typical unit may offer the following (adapted from real specs for a typical unit) ...

Max. Input Level:	10V RMS (+22dBu)
Dynamic Range:	118dB
Signal to Noise Ratio:	>100dB
Headroom:	18dB <0.05% at +4dBu, with 6dB compression
Distortion:	<0.05% at +4dBu, with 6dB compression

Limiting Threshold:	-40dBu to +20dBu
Attack Time:	0.1ms - 200ms
Release Time:	50ms - 3s
Compression Ratio:	1:1 - 100:1 with selectable hard or soft compression knee

Some of these terms are self-explanatory, while others may need a little more information.

- **Maximum Input Level**
  This is the maximum signal (in Volts RMS and/or dBm or dBu **). If this is exceeded, the input stage will distort due to clipping. This indicates that a unit with the above specification cannot be used for a direct speaker feed (few can, and a Direct Injection box is nearly always needed).

- **Dynamic Range**
  The range of the quietest sound (signal) to the loudest. The spec above is misleading, since it ranges from the noise floor to the maximum input level. The effective dynamic range is limited by the minimum signal to noise ratio the engineer will accept, so subtracting (say) 50dB from the above would be reasonable.

- **Signal to Noise Ratio**
  The level of noise referred to a specified output level. Again, the output level is not specified above, so we don't know if the actual noise floor is better than -100dBu or -78dBu, since the reference input or output level was not defined. Many manufacturers use A-Weighting for these measurements, which is also misleading for most applications. A-Weighting should be used only where the sound source is some distance from the listener (possibly hundreds of metres), or is expected never to exceed about 70dB SPL near field.

- **Headroom**
  This can be tricky, since there are many different ways to describe it. Most commonly, headroom is the difference (in dB) between the typical or specified output level, and the maximum the unit can provide without distortion.

- **Distortion**
  Another can of worms! Distortion measurements are not really meaningful if the level and frequency are not stated. It is even harder with anything that uses a VCA, since their distortion can vary considerably depending on the degree of amplification or attenuation. Distortion (probably) should be worst case - the frequency, amplitude and amount of gain that produces the most distortion. This would probably look bad in the specs, so is not used.

- **Limiting Threshold**
  This is the range of signal level where the unit can be set to function. Below the threshold, a limiter does nothing - it just passes the signal straight through (with maybe a little fixed gain or loss, as appropriate). Above the threshold, signals are attenuated by an amount determined by the compression ratio (see below).

- **Attack Time**
  A measure of how long it takes before the unit changes the gain when a signal is applied. This may be very fast to prevent *anything* from exceeding the threshold, or deliberately slowed down to allow a percussive attack to the instrument. A relatively slow attack might be used with drums to increase the apparent dynamics, whilst actually reducing them.

- **Release Time**
  The release time determines how long the gain takes to return to "normal" after it has been reduced. A short release squashes the dynamics of the sound completely, and a very long release time ensures that all material remains at a constant fixed peak level, while still allowing normal variations. The overall dynamics (of a musical piece) are still compressed, since the soft passages will allow the unit to apply the maximum gain. This is all controllable.

- **Compression Ratio**
  As discussed above, this can be low (1:1 means no compression), almost infinite, or anywhere in between. An infinite (or high) ratio is a limiter, anything between 1:1 and about 10:1 is a compressor, although some would argue (correctly) that 10:1 is really limiting. Some units also offer a "soft" or "hard" knee (the threshold). A soft knee means that the onset of compression or limiting is gradual, ranging over a few dB, while a hard knee means that once the threshold is reached, the limiting action is immediate, with no gradual onset.

** dBm is a reference level based on 1mW into 600 ohms. This represents a voltage of about 775mV. dBu is based in a reference level of 1V RMS (also sometimes seen as dBV).

What To Listen For

An excellent way to hear compressor/limiters in action is an outside broadcast on TV. While the presenter is speaking, the level is constant, with very little variation - even when they are off-axis from the microphone. When there is a break in the commentary, the background noise can be heard to increase at a (relatively) fixed rate, until it is as loud as the presenter's voice, or someone starts speaking again. It is then instantly reduced to where it was before.

As you get used to what to listen for, you will hear many CDs where the level of the backing track falls when the singer (or someone else) starts making their noises - this (to many audio professionals) is quite normal, but it is not - it is a typical case of over application of compression in the final mix. When an additional sound is added to those already present, it is *supposed* to get louder - this is called dynamics (or even "micro-dynamics" - a reduced scale version of the real thing).

These effects are especially noticeable with commercials on radio or TV - listen for them

so the sound can be identified. Should you purchase a CD that does the same, complain to the record company - they have ruined your music!

What About Lossy Data Compression?

MP3 - love it or hate it, it is here (probably) to stay. As can be determined from a multitude of sources, MPEG Layer 3 (or MP3 for short) discards information that theory (and a lot of experimental testing) indicated would be inaudible. It uses a well known characteristic of our hearing called "masking", where it is known (and can be proven) that certain frequencies and levels are completely inaudible when accompanied by another signal at a higher level. The points where masking take effect are beyond the scope of this article, but differ according to relative levels and frequency, and the frequency band itself. An MP3 encoder breaks the signals into sub-bands using filters, and each is treated differently according to a set of rules built into the encoder signal processor.

While it is generally considered that a high bit rate (128kb/s or above) MP3 track is of "near CD quality", many people will dispute this vehemently. My own experiments and listening tests indicate that imaging is poor, and the precise placement of instruments and vocals is missing. Some instruments - especially the harpsichord (so I hear) sound completely different when encoded, almost regardless of the bit rate. A good test is to "rip" some pink noise (preferably generated by an analogue source), and compare the difference.

There should be no difference - or at least it should be inaudible, but this is not the case! At 320kb/s the difference is barely audible - one has to listen carefully to hear it, or figure out just *what* to listen for ... but there is a difference, and it also shows up very clearly on the analyser of Winamp. The peaks are flattened, so the dynamic range (or peak to average ratio) is degraded, and the sound of the noise lacks "life" compared to the original recording.

If we can hear a difference with noise, why would music be any different? It isn't! Ok, noise has a relatively constant bandwidth (DC to daylight in the extreme), and excites all frequencies more or less simultaneously. Well, so does a lot of music, albeit for short periods at a time.

Will my comments here make MP3 go away? Of course not, and nor should it go away, because it is a useful way to archive recordings, or provide people (who insist on *not* hearing approaching traffic while they run or cycle) a convenient medium for portable

sound.

Even Worse Things That Can Happen

On a final note (pardon the pun :-) a reader recently sent me an out-take of a CD. It was clipped! Not just compressed and limited to the maximum (that too), but with actual clipping - flat tops on some peaks. I asked him to check his setup very carefully to ensure that the record level was not set too high, and he assured me that he had at least 3dB of headroom above the peak CD level.

At some stage, I shall check some of the CDs I have that annoy me because of the constant loudness to see if they have the same problem. Probably not, since the clipped CD was from an "indie" (independent producer) so would not have had the controls in place one would expect from an established mastering house.

Be that as it may, there is not really much point in setting up the "ultimate" hi-fi system, with headroom to spare and almost zero distortions of any kind, only to have the music CD pre-distorted, compressed, limited and bent so far out of shape that it is no longer useful for anything other than a coaster.

References

- Compression - A most excellent article by Bob Katz, on the perils of using compression or limiting on the final mix. As Bob says - leave this to the mastering engineer, and if you don't like the result - complain!
- Some examples of specifications were extracted from Alesis and Behringer information - no material from either manufacturer has been directly used or copied - merely representative information on performance and functionality.

Introduction

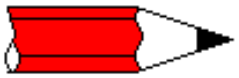
It is not uncommon to see hi-fi equipment with the earth (ground) disconnected from one piece of equipment or another, usually to prevent a hum loop which ruins the listening experience. However, there is nothing quite like being electrocuted to *really* ruin the experience should something go wrong!

Electrocution

First, a quick word on electrocution. It is not fun, and electricity kills a great many people worldwide every year. A current of 50mA (barely enough to make a low wattage lamp even glow) is sufficient to send your heart into a state called "ventricular fibrillation", where the heart muscles are all working out of synchronisation with each other. Little or no blood is pumped, and you will die within about 3 minutes unless help is immediately at hand.

Sometimes (but less often), your heart will simply stop. If this happens, it is possible that with external heart massage that it might re-start, and occasionally it might even re-start by itself - rare, but it can happen. The result of fatal electrocution is that you will no longer be able to enjoy the hi-fi that you have spent so much time and money putting together, and all other earthly activities are similarly curtailed :-(

This article has been prompted by many e-mails I have received asking about hum, earthing and what should be done to ensure that equipment is safe, and does not hum. There are other causes of hum in a sound system other than electrical (safety) earthing issues, but I will contain this particular article to the basic issues of safety and eliminating hum loops while maintaining a high degree of safety.



The regulations regarding safety earth connections vary from one country to the next, and I do not have the details for each case. This article is general, and if unsure, you should consult the appropriate electrical supply authority in your country to obtain the rules that apply to you.

I have used the terminology I am familiar with - the live conductor is called the 'active' and the return conductor is called 'neutral'. The safety conductor is called 'earth' or sometimes 'earth ground' (particularly in the US). These terms differ, so make sure that you know what they are called where you live.

How The Safety Earth Works

The basic idea of an electrical safety earth (or ground) are pretty much the same everywhere. The case (chassis) of the equipment (and except for special situations, the internal electronics) is connected to an earth pin on the mains outlet. This is then connected through the house wiring and switchboard to an electrically solid earth point, which is commonly a (copper) water pipe, or a stake buried deep into the ground.

Should a fault develop within the equipment that causes the active (live) conductor to come into contact with the chassis, the fault current will flow to earth, and the equipment or main switchboard fuse or circuit breaker will blow. This protects the user from electric shock, bypassing the dangerous current directly to earth, rather than through the body of the unsuspecting poor bastard who just touched it. If this experience does not kill, it will invariably enrich the vocabulary, but regrettably the new words will be useless in polite company.

Earth leakage circuit breakers (RCD - residual current detectors - see below) measure the current in the active and neutral conductors. If these differ by more than a few milliamps, the circuit is disconnected. The principle is simple - if the current in the two wires differs, some of it must be going somewhere that is undesirable, so the supply is interrupted almost instantly. While these are mandatory in some countries (or under some circumstances), it is best not to rely on any advanced technique, but provide a system that is intrinsically safe - this is extremely difficult in reality.

There are exceptions to the basic earthed equipment method of protection. Some equipment is designated 'Double Insulated', and usually has a symbol of two concentric squares that indicates that the equipment is double insulated, and that an earth connection is not needed (or in some cases *must* not be used). The common plug-pack (wall-wart) power supply is nearly always double insulated, and such equipment has reinforced insulation, designed to ensure that it is not possible for the live AC connection to connect to the secondary electronics in any event - including a complete meltdown. The electrical safety tests to verify that a product meets the Double Insulation standards are rigorous and expensive, and are very difficult to meet with high powered equipment, and even more so when the equipment has a metal case. Nearly all power amplifiers (for example) are *not* double insulated, and require an earth connection.

Colour Codes

The common colour codes for mains wiring are shown in Table 1, below. The Active (or Line) is the

'live' conductor, and carries the full AC supply voltage. The Neutral conductor is not live, but is intended to be the return path for all current in the active lead. Although this has caused great confusion to a great many people, it is sensible and logical (I will not go into the reasons here). The safety earth (or ground) conductor is intended to provide protection against electrocution, and where fitted, must not be disconnected.

Conductor	IEC	US	Alternative
Active (Line)	Brown	Black	Red
Neutral	Blue	White	Black
Earth	Green/Yellow	Green	Green

Table 1 - Common Mains Colour Codes

These colour codes are not standardised, and some variations may be found in different countries. The column headed 'Alternative' refers to an old code that used to be used in Australia and several other countries prior to the IEC codes being adopted. The one common theme of these codes is that they have been designed so that colour-blind people will not get the wires mixed up. The use of green with yellow stripes for the earth makes this even more secure. I have no information on the history of the determination of the colours used, but it is of little consequence since we can't change it.

Earth Loops

Figure 1 shows a typical connection of two hi-fi components, and includes the house wiring and main earthing point. As can be seen, there is a loop (indicated by the dotted line), which includes the interconnect cable, power leads, and a small part of the house wiring. Such loops are a major cause of hum in systems, and it is not uncommon for people to remove an earth wire from one or the other mains connectors to break the loop and stop the hum. The situation is much worse if different wall outlets are used for different parts of the sound system. In this case, the loop may extend all the way back to the main switchboard, making it longer, and more likely to have a significant voltage between individual earth connections.

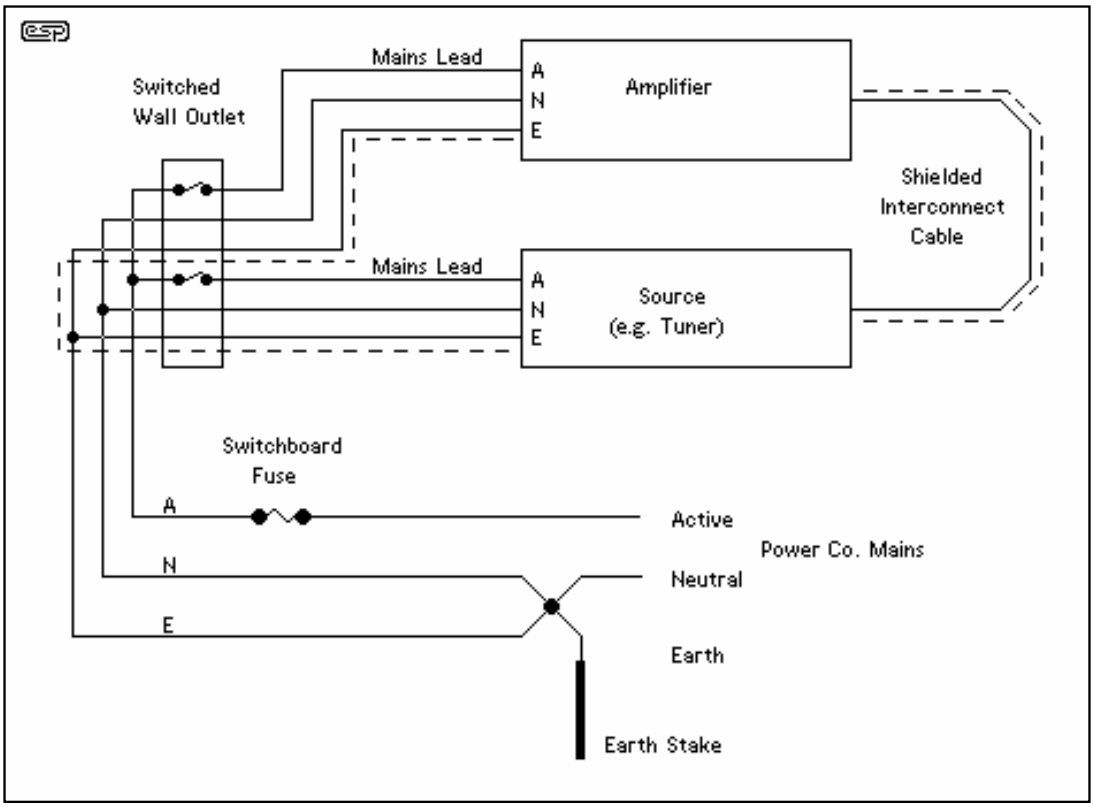


Figure 1 - The Formation of an Earth Loop

Also note that the neutral (return) conductor is attached to earth at the main switchboard. This is standard in Australia and many other countries, but might not be the case where you live. Check with an electrician who can tell you how this is done (if you really want to know).

What happens if the amplifier develops an electrical fault that allows the live AC conductor to come into contact with the chassis? The current will flow from the chassis, through the earth connection, and the fuse will blow in the switchboard or in the equipment if a fuse is fitted.

Should the safety earth be disconnected from the power amp (for example), if a fault occurs in the amp, the only earth return is now via the interconnects (assuming that the source is earthed). These interconnects are not designed to withstand the fault current that can occur with a major electrical fault, and may disintegrate before the fuse. You now have a live chassis on the amplifier - just waiting for someone to touch it and die!

Residual Current Detectors

Many new installations use an 'Earth Leakage' or 'Residual Current' detector, a device that will disconnect the AC supply if the current flowing in the active (live) conductor is not exactly matched by that in the neutral. Any imbalance means that current is going somewhere it should not be, and the device will trip.

These safety circuit breakers are very fast acting, and have saved many lives since their introduction. The 50mA that will kill you is detected by the breaker, and the power is disconnected - fast! Most of these type of breakers will operate on as little as 20mA, so you are not only protected against major faults, but also against excessive AC leakage caused by faulty insulation or moisture.

This does not mean that you can now go around disconnecting earth connections to stop hum - the safety devices that may be fitted to your house wiring are designed to trigger on a fault *before* you find it the hard way. In many countries, it is illegal to tamper with electrical (mains) wiring unless you are licensed - but in all countries, if it can be proven that you disconnected an earth that allowed a fault to kill someone else, *you are liable, and may be subject to criminal charges* ! Is that scary?

Main Earth Connection

For those who build amps (as is the case with many of the readers of these pages), a common question is "How should I connect the mains safety earth to the chassis?". As I stated above, the regulations change from one country to the next, but the principles are the same. Figure 2 shows a view of the basic connection, which is very safe. The lug used must be an approved earth lug (or one that meets any standards that exist where you live).

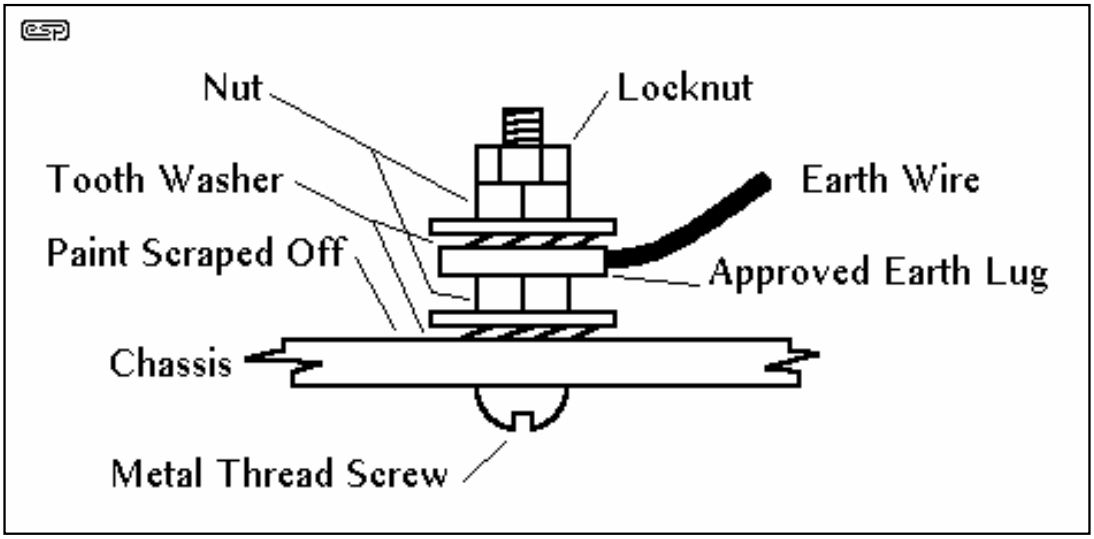

Figure 2 - Safe Method Of Connecting The Safety Earth

Any paint (or anodising, in an aluminium chassis) must be scraped away to expose bare metal, and the tooth washer ensures that there is a good 'bite' into the metal itself. The use of two nuts is strongly recommended, since the second one acts as a locknut, and prevents the first nut from loosening. The flat washers shown are optional, but highly recommended. They may be a requirement in some countries.

Do not use the earth connection as mounting for any other panel or component - it must be dedicated to the task of providing a safety earth point. If a component mounting bolt is used, at some stage it may be disconnected by a service (or other) person, which means that the apparatus is unsafe until everything is (hopefully) put back where it belongs - this does not always happen.

Make sure that the electrical connection between metal panels is also very well made. Some chassis are available in a kit form, and when screwed together, may not make good electrical contact with each other. Should the mains come in contact with a panel that has a flaky connection with the one that is earthed properly, the same potential for disaster is still present. All exposed metal must be properly and securely earthed.

The internal electronics of an amplifier should also be earthed, but now we have the problem of the hum loop again. There are two possibilities here ...

- Don't earth the internal electronics, or use a simple 'loop breaker' circuit to allow the case to act as a shield for radio frequency interference, but no solid connection is made (this is a common approach). This provides protection should there be a failure from the incoming mains to chassis, bit provides none at all if the transformer were to develop a fault between primary and secondary windings. Such faults are uncommon, but they can (and do) occur.
- Use a high current loop breaker circuit, ensuring that even major fault currents will be bypassed to the safety earth conductor. Such a circuit was described as a part of the 100W Guitar Amp project, but is shown again below. Be warned that this circuit (while safe) may not be legal where you live.

Use Of Loop Breaker Circuits

While very effective (and safe), as mentioned above such a circuit might not be legal where you live. If this is the case and hum is causing you grief, the use of balanced interconnects will solve the problem - but at some cost, and will require balancing circuitry at each end of all the interconnects. This is the approach taken in all professional equipment, and is highly effective, allowing all safety earth connections to remain exactly as they are to prevent electrocution of the artists or road crew. Suitable circuits for home (or professional) use are shown in the projects section.

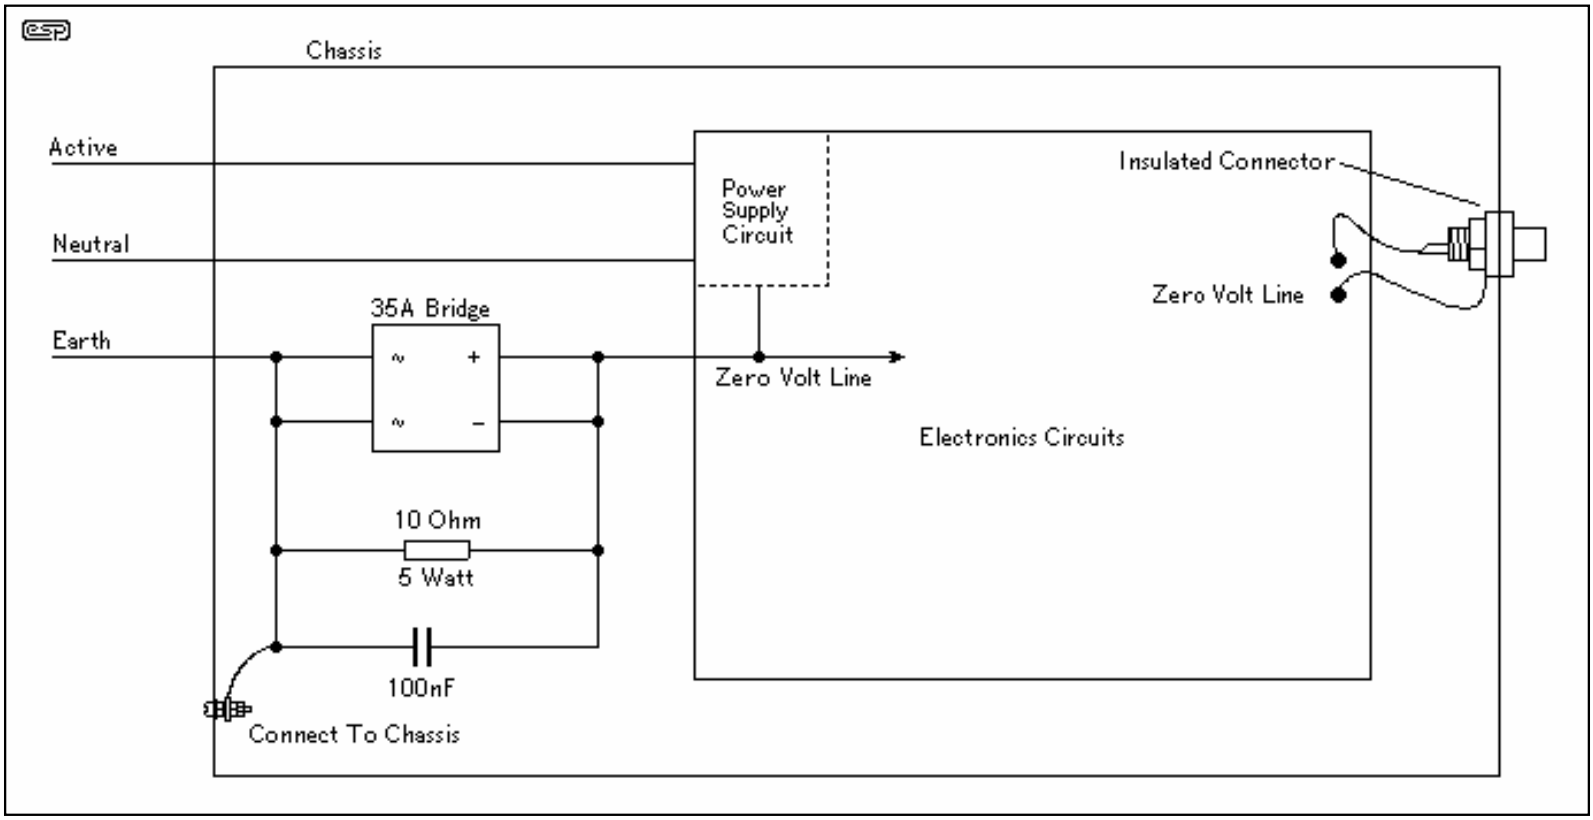

Figure 3 - A High Current Safety Loop Breaker Circuit

I have simply shown all internal electronics as a box, with the only connection to the loop breaker being the zero Volt line. This is most commonly taken directly from the centre tap of the main amplifier filter capacitors, but should always be connected to a point where there is high current wiring back to the transformer. It is the transformer that provides isolation from the mains, and the possibility of an internal transformer fault must be catered for.

The only exception is if a double insulated mains transformer is used, but these are rare. Should the transformer be of "conventional" construction (not a toroidal), then the transformer body - the steel core - must be connected to chassis directly. *Do not use any loop breaker circuit to isolate the transformer core, as it is unnecessary and dangerous to do so*.

The loop breaker works by adding a resistance in the earth return circuit. This reduces circulating loop currents to a very small value, and thus breaks the loop. The capacitor in parallel ensures that the electronics are connected to the chassis for radio frequency signals, and helps to prevent radio frequency interference. Finally, the diode bridge provides the path for fault currents. The use of a large chassis mounting (35A) type is suggested, since this will be able to handle the possibly very high fault currents that may occur without becoming open circuit. Note the way the bridge is wired, with the two AC terminals shorted, and the two DC terminals shorted. Other connection possibilities are dangerous, and must be avoided.

In the event of a major fault, one (or more) of the diodes in the bridge will possibly fail. Semiconductors (nearly) always fail as short circuit, and only become open circuited if the fault current continues and 'blows' the interconnecting wires. High current bridge rectifiers have very solid conductors throughout, and open circuit diodes are very rare (I have never seen a high power bridge go open circuit - so far at least). Use of the bridge means that there are two diodes in parallel for fault current of either polarity, so the likelihood of failure (to protect) is very small indeed.

When a loop breaker is used, it is vitally important that all input and output connectors are insulated from the case. If not, they will instantly defeat the loop breaker by providing a direct connection from the zero Volt point to chassis, and no benefit is obtained. (Electricity has an annoying - but perfectly logical - tendency to travel along the path of least resistance, and a direct short circuit will always have less resistance than the loop breaker.)

It is not uncommon to have a voltage of 1 or 2 Volts between the earth connections of power outlets that are wired separately back to the switchboard. This small voltage, with a total resistance of perhaps 0.5 Ohm, will cause a loop current of 2 to 5 Amps, all of which flows in the shield of the interconnect. This is sufficient to cause a voltage difference across the interconnect, which the amplifier cannot differentiate from the wanted signal. By breaking the loop with the 10 Ohm resistor, the current is now less than 200mA, and the voltage across the interconnect will be very much smaller, reducing the hum to the point where it should no longer be audible.

An earth loop will typically inject a 50Hz or 60Hz hum into the signal - if you have a 100Hz or 120Hz hum (which often has a hard edge to the sound), you have done something wrong in the wiring of the power supply, and the technique above will not help.

Mains Filters

In some cases, a transformer may be fitted with an electrostatic shield, which are lamentably uncommon in hi-fi transformers. Where provided, these too must be connected directly to the main earth point, and not via the loop breaker. Again, this is unnecessary and potentially dangerous.

The purpose of the electrostatic shield is to intercept (and earth) any interference on the incoming

mains. It does this by preventing any signal from being capacitively coupled from the primary to secondary windings, so the only form of coupling in the transformer is via the magnetic field in the transformer core. Most mains transformers have relatively poor high frequency response and this helps to further reduce interfering signals.

This can dramatically reduce extraneous noises (clicks, pops, whirring sounds, etc.) that might get into the system via the house and supply company wiring. This has great potential to pick up noise, since there may be 50 to 100km (or more) of cable involved between your amplifier and the generating plant.

In some cases, a mains filter might be fitted to amplifiers or other equipment (such as specially designed mains leads or 'black boxes') to reduce any interference. Where fitted, if an earth connection is provided, it must be connected to the safety earth and chassis - never to the amp's zero volt line. Typical filters will use Metal Oxide Varistors (MOVs) to cut off any high voltage spikes, and a capacitor and inductor network to filter out anything that is not at the mains frequency.

A true 50Hz (or 60Hz) tuned filter will be a large unit indeed, so most line filters only work at frequencies above a few kiloHertz. This is generally enough to get rid of most interference, since a well designed power supply should be able to filter out the majority of noise from the mains. Mains filters usually use the mains earth as a reference, so it must be present for the units to work correctly. Not using the safety earth as a reference is extremely dangerous, since the filters have capacitors which can (and do) become short circuited if a high voltage spike manages to get through and punctures the insulation.

Conclusion

Electrical safety cannot be over emphasised. Hum is damn annoying, and everyone wants it gone. There is no good reason to sacrifice one for the other, since safety and hum-free operation can peacefully co-exist with care and the right techniques.

As I have said several times, make sure that you find out the legal requirements in your country, and don't do anything that places you at risk - either from electrocution or legal liability. Neither is likely to be a pleasant experience.

Where the mains is noisy (apparently a common occurrence in the US), use of a dedicated mains filter is useful to prevent mains noise from entering the system. This will generally be unnecessary if the supply is well designed (especially if an electrostatic shield is used on the transformer), but this is often the exception, rather than the rule.

The use of 'specialty' mains leads (unless fitted with a proper filter which will be in the form of a box in line with the cable) is unlikely to solve the problem - regardless of claims made by the manufacturers or reviewers (see The Truth About Cables, Interconnects and Audio in General for my comments on these - this article made a lot of audiophiles very unhappy, but advertising hype does *not* negate the laws of physics).

- 5 Final Assembly
- 6 Conclusion

Note: The basis for this article was originally written by John Inlow, and was available on his website up until 2002 (when the entire site disappeared). Drawings have all been substantially revised (and colour added to make them clearer), and are based on John's originals. The photo in Figure 1 is a cropped and cleaned version of John's original picture. Parts of this document may still retain original copyright. The text has been almost completely re-written.

1 Introduction

Build your own heatsinks? Absolutely - this page shows you how to build a heavy duty heatsink and chassis, suitable for Class-A or high power Class-AB amplifiers. While there is no claim that the end result will be cheap (nor are store-bought heatsinks), the performance can be as good or better than anything you can buy.

At only 20% efficiency for a Class-A amplifier, the wasted heat is enormous! Out of 100 watts of input power, only about 20 of those Watts are available as useful sound. The rest of the power (80 Watts) is dissipated as heat, and must be removed - all the while keeping the transistor junctions at a safe operating temperature. It takes big heat sinks to remove the excess heat from the power transistors. It can also be unbelievably difficult to locate affordable, large heatsink stock (and this seems to be worse in the US). So, this page describes a solution to the problem.

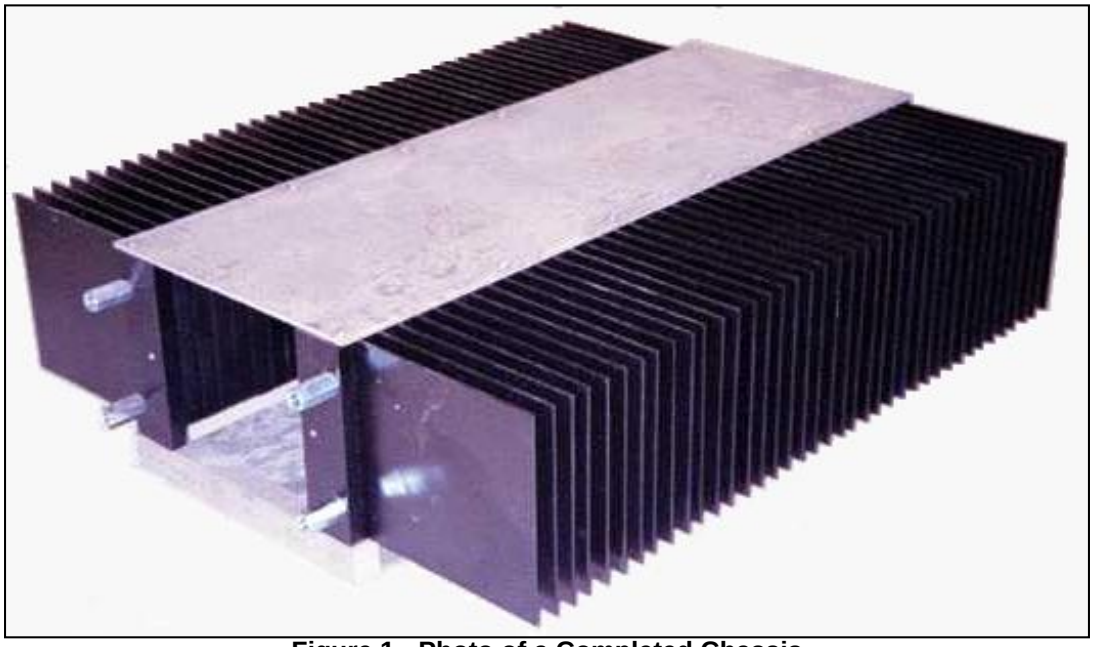

Figure 1 - Photo of a Completed Chassis

The pictured chassis (John Inlow's photo) will easily dissipate well over 160 Watts of wasted power - all as heat. If this meets your requirements, get ready to head for your workshop in readiness to make a significant amount of mess. The design is totally adaptable, so any size of heatsink can be produced, designed to fit any opening size or application. The chassis, although time consuming, is easily reproduced by anyone with basic construction skills. Use a drop saw (also known as a 'chop' saw in the US) with a carbide tipped blade designed to cut soft metals.

The saws and blades are readily available from most hardware stores, and are relatively inexpensive - actually, one can purchase the power saw for less than the blade (a very odd situation indeed). Be sure to use plenty of cutting fluid designed for machining aluminium. Denatured alcohol (methylated spirit) is excellent, but is highly flammable. On the positive side, there is no oily residue that can spontaneously combust if incorrectly stored. Take ***extreme*** care with all cutting fluids, as there are risks with all of them - especially anything that works well with aluminium.

---

2 Construction

Before going into great detail, it is important to look at the following drawings so you can see what is involved. There is no doubt that you will need some fairly serious tools to be able to tackle something of this nature. Apart from the drop saw and metal-cutting blade mentioned above, you will need a drill press - a power hand drill could be used, but the results will be disappointing or very, very time consuming (or both). You also need taps (for cutting threads, not whatever you might have been thinking). A decent sized work area is also needed, and be aware that you will create a vast amount of aluminium chips, powder and swarf. The kitchen table is not recommended.

You also need the usual array of hand tools and miscellany - a hacksaw, files, drill bits, G-cramps, and various bits of scrap material that can be used to construct drilling and assembly jigs, etc., etc.

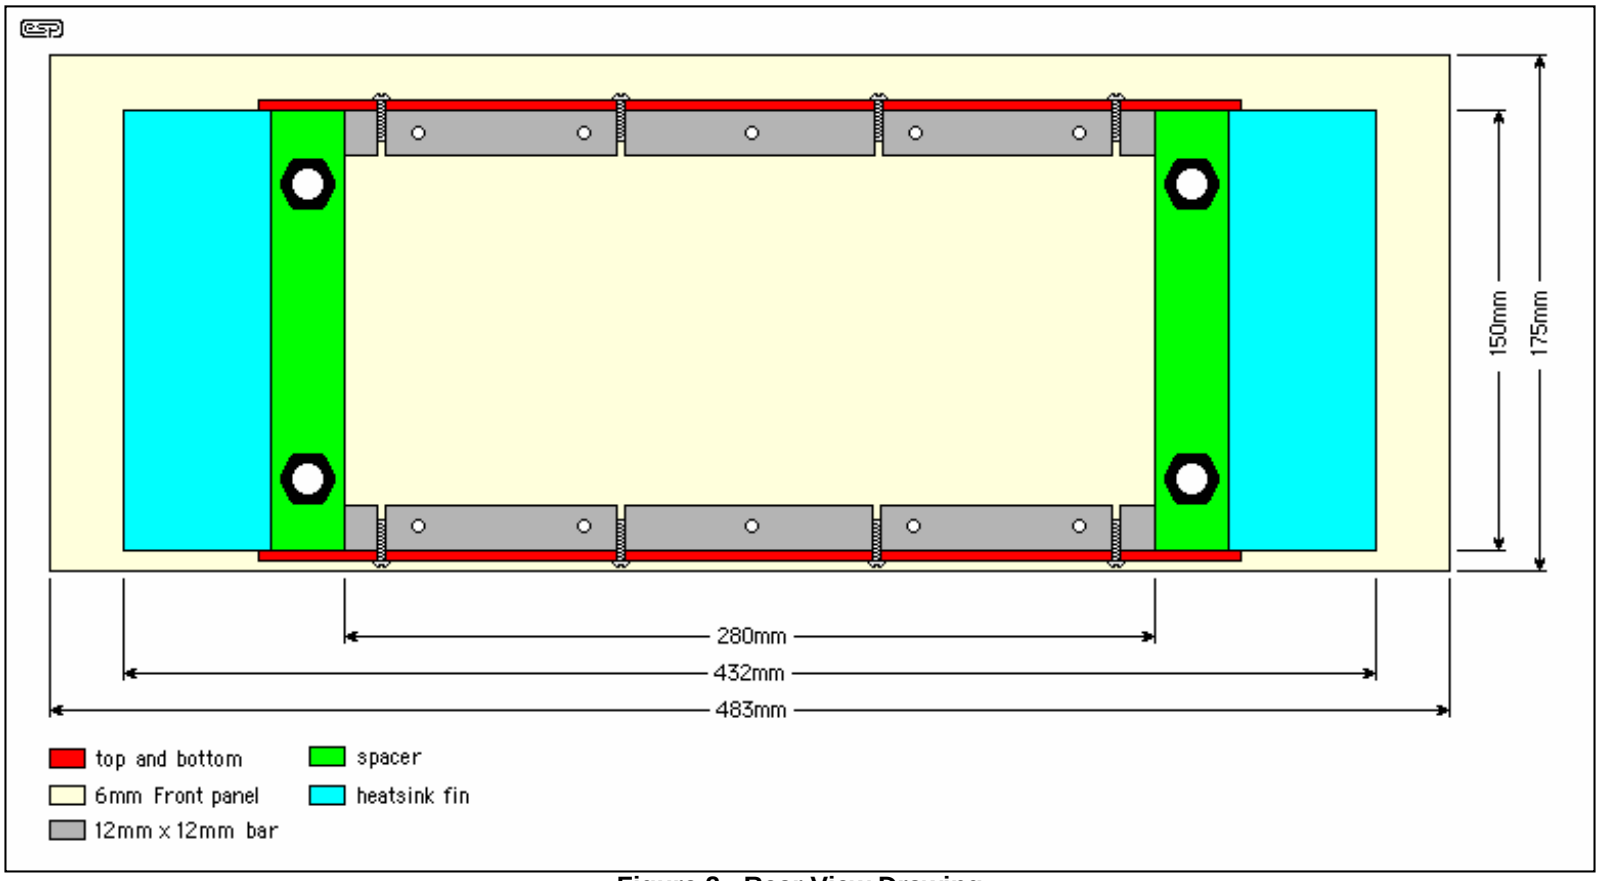

Figure 2 - Rear View Drawing

Looking from the rear, we see the two heatsinks, top and bottom covers, as well as the front panel. If you insist on using imperial measurements, then divide all measurements shown by 25.4 to obtain inches. The dimensions are not critical for the most part - adapt to suit your specific application.

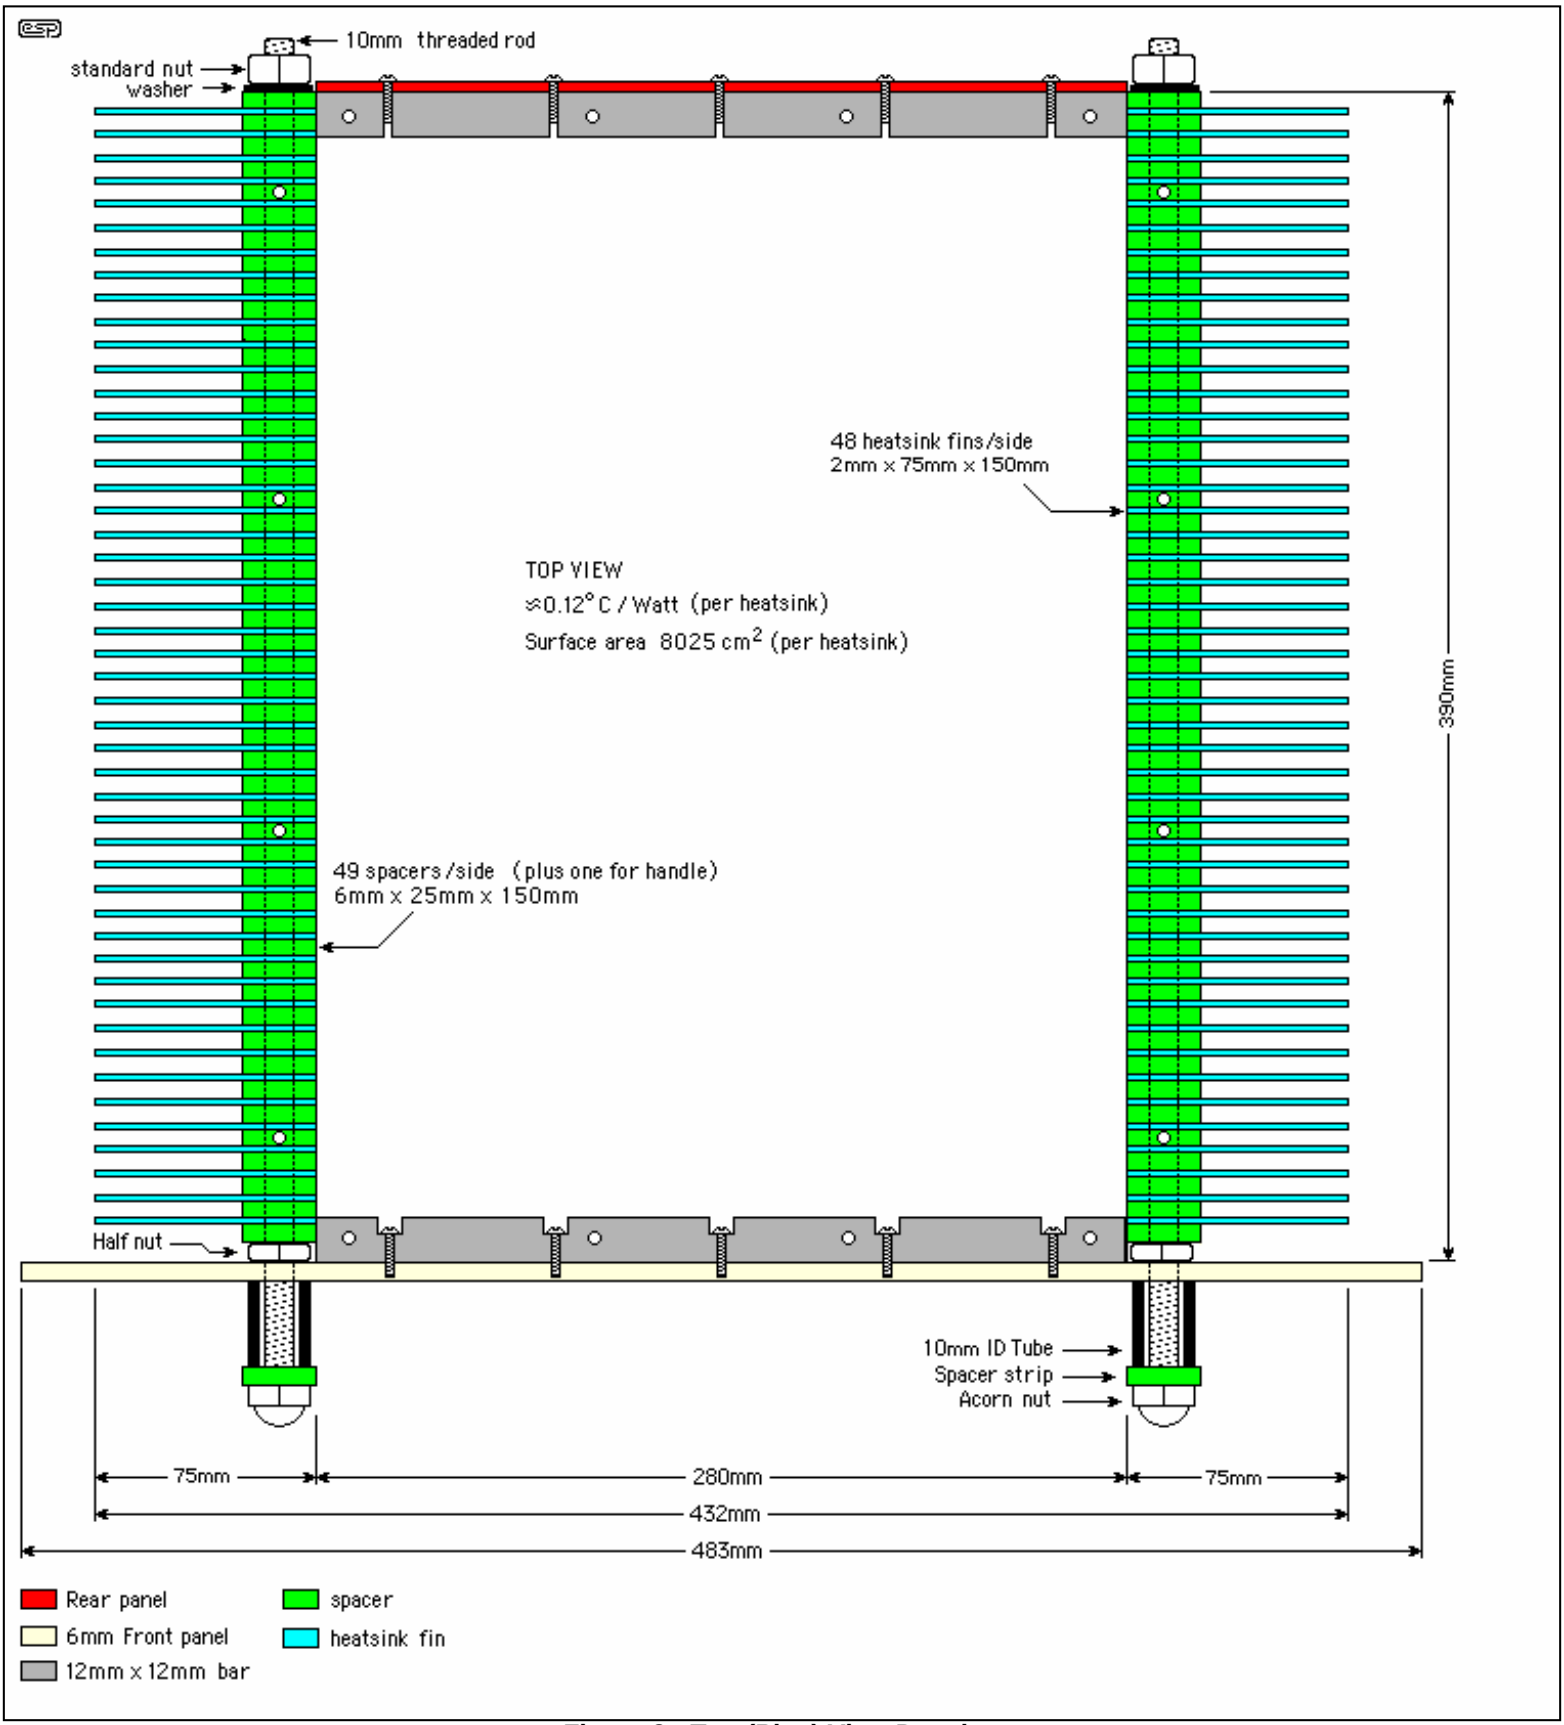

Figure 3 - Top (Plan) View Drawing

The plan view gives you the rest of the picture. Again, adapt the dimensions to suit your application. The heatsink sections can be as large (or as small) as you need, limited by available funds and your patience (as always).

It is suggested that you use 6 x 25mm (or 0.25" x1.0") bars for the spacers and 2 x 75mm (0.08" x 3.0") bar or cut

sheet for the heat dissipation fins. The length depends on your intended height - all drawings here are based on a 150mm (6") heatsink height. Starting with a spacer section on the outside, the two sections are repeated (spacer-fin-spacer-fin ... spacer) until you have the length you need. To achieve the desired depth for the chassis, the plates are bolted together onto four (two for each heatsink) 10mm (3/8") threaded rods. Drilling the holes is a tricky and time consuming job - they must be aligned perfectly. The difficulty of the process is reduced if you create a jig to position the material as you drill the holes. Although it adds time to the whole process, partially pre-drilling each section with a centre drill (a special drill bit with a thick shank and small stubby tip) will ensure that the drill bit does not wander, causing holes to be off-centre. It is very important to clean up the holes after the drilling is completed. Using either a larger drill bit or a de-burring tool, chamfer the holes to remove the jagged edges that form when drilling. Don't even think about avoiding this step - the plates will not touch one another evenly so heat transfer will suffer, and your assembled heatsink will never be straight.

If you use 10mm threaded rod, the holes should be drilled to 12mm. This allows for the occasional hole that is slightly off centre, and also lets you align the assembly perfectly before it is finally clamped up tight.

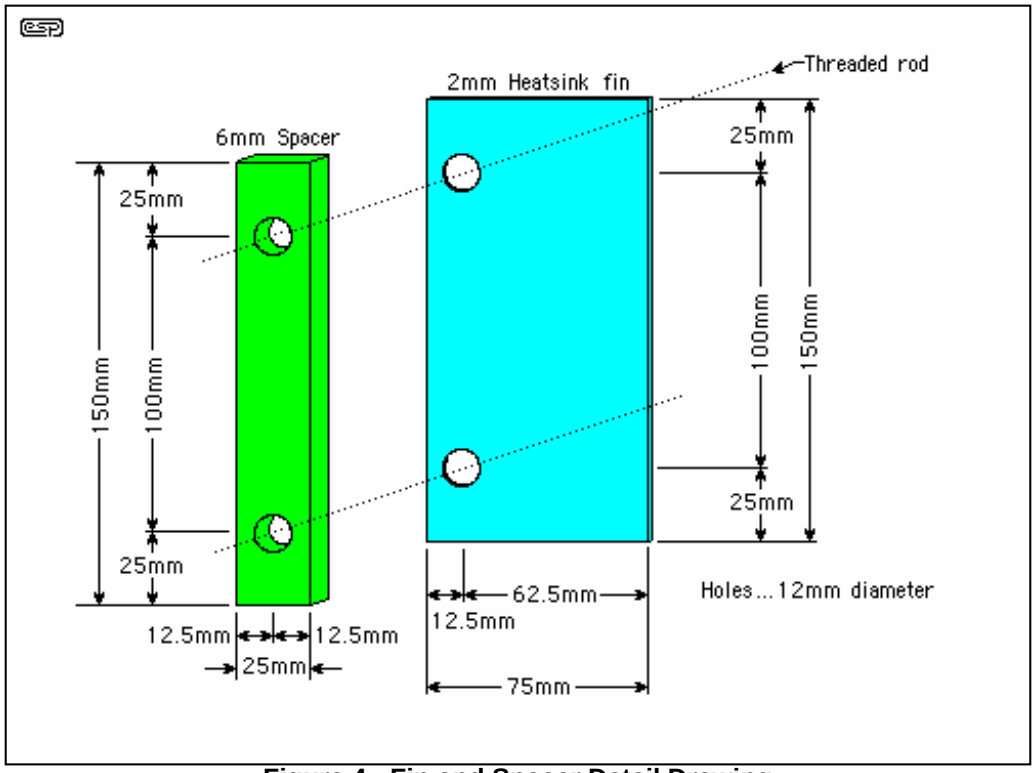

Figure 4 - Fin and Spacer Detail Drawing

Keep repeating the above pattern until you achieve the desired depth for your chassis. The same procedure is used for both sides of the chassis. The threaded rods must be long enough to pass through all of the spacers and heatsink fins, and still have sufficient left over for nuts. Optionally, the rods may be extended further to create a mounting for handles at the front of the chassis.

Make sure that all surfaces are flat after drilling. De-burr all edges before assembly to get the best possible contact between the spacers and fins.

---

3 Heatsink Assembly

When everything is machined, cleaned and ready to assemble, begin by screwing a half nut onto one end (to become the front) of the four threaded rods. Make sure that the distance from the end of the rod to the face of the half-nut is correct for your handle sections (allow for front panel, tube (or long nut if you prefer), handle section and acorn nut). Then slide on the first spacer, followed by a fin,then a spacer (etc.) in alternating fashion. When

completed, screw a full nut onto the remaining end (rear) of the rods - this should only be finger tight at this stage! You need to get the distance at the front dead right if you are planning on adding handles - the final acorn nut does not have much depth. Feel free to add washers at the front as well as the back, but make sure they are allowed for in the length of the threaded rod.

Alignment is critical. Because your heatsink is made from many separate pieces of aluminium, it is possible for it to assume many different and entertaining shapes, within the constraints of the threaded rod. None of the potentially entertaining shapes is useful - you need flat and square. Period.

To achieve this, you'll need a flat surface with a piece of scrap angle the same length as the heatsink assembly screwed to one edge. You also need a small hammer, a square, a scrap piece of aluminium and a piece of timber. First, lay the assembly onto the surface, with fins pointing upwards. Slide it across so that it contacts the angle. The alignment is by nature repetitive - each step will need to be repeated - possibly several times ...

- Using the scrap timber, gently tap the edge opposite the angle (tap towards the angle) until the heatsink lies dead straight along the angle. All fins and spacers should be level on both sides.
- Use the square to ensure that the ends are at a perfect right angle to the base board *and* the angle section. Adjust as needed.
- Tap the fins and spacers down (use the scrap aluminium to reach between the fins to get to the spacers). The idea is to ensure that every fin and every spacer is flat against your alignment surfaces.
- Tighten the rear nuts slightly, and repeat the above process.

Once completed and the nuts are firm, you can clamp a piece of wood on top of the assembly, thus clamping the heatsink to your flat surface. Be careful that you don't disturb any of your alignment during this process. Now the rear nuts can be tightened fully. They should be tight, but not ridiculously so - a stripped nut or threaded rod is not a bonus at this stage.

Upon removal from the assembly jig, the heatsink should be flat and square, requiring the minimum effort to obtain excellent thermal contact between the reinforcing bar or mounting plate (see below). If the nuts are tight enough, firm effort on your part to bend or twist the completed assembly will result in nothing more than heatsink imprints on your hands - the heatsink itself should remain nice and flat, with no bending or warping. If it *does* warp, you will have to repeat the final step, after loosening the nuts just enough to allow the assembly to be made flat once again. Although this is a frustrating step if things move, it is highly recommended - you will find out for yourself how rigid the heatsink is, and whether (or not) you need to add a reinforcing bar (or perhaps just tighten the nuts a little more).

If it is possible to distort the assembly (or it comes out pre-warped), then you must use reinforcing bars screwed to the back of the heatsink (all drilling and tapping must be into the spacer strips *only*. Alternatively, a full-length flat plate will also provide reinforcement, but at somewhat greater expense. These options are discussed below. Note that one or the other needs to be used anyway - at issue is how long it must be to achieve rigidity and good thermal contact.

---

4 Heat Spreader

After assembly and prior to fitting the heat spreader (either a reinforcing bar and/or flat spreader plate), it is advantageous to mill the rear of the heatsink to present the flattest possible surface. Given that few hobbyists have access to a milling machine, an alternative is to carefully file the entire rear surface - this will be an extremely tedious job, but will improve performance. A linisher (belt sander) can also be used, but the surface must be finished with a fine grit so it is as smooth as possible. The photo in Figure 6B shows the rear surface of a small heatsink I made, and the linishing marks are visible. I deliberately did not complete the job so the anomalies could be seen clearly.

Although the surface shown is very flat (better than 25um / 50mm), the surface finish will almost certainly not be good enough for direct mounting of semiconductors. This makes the heat spreader mandatory. You can check

surface flatness by trapping a thin hair (for example) at various places on the surface with the edge of a steel rule. It should be not possible to pull the hair from beneath the edge of the rule at *any* position under the heat spreader location.

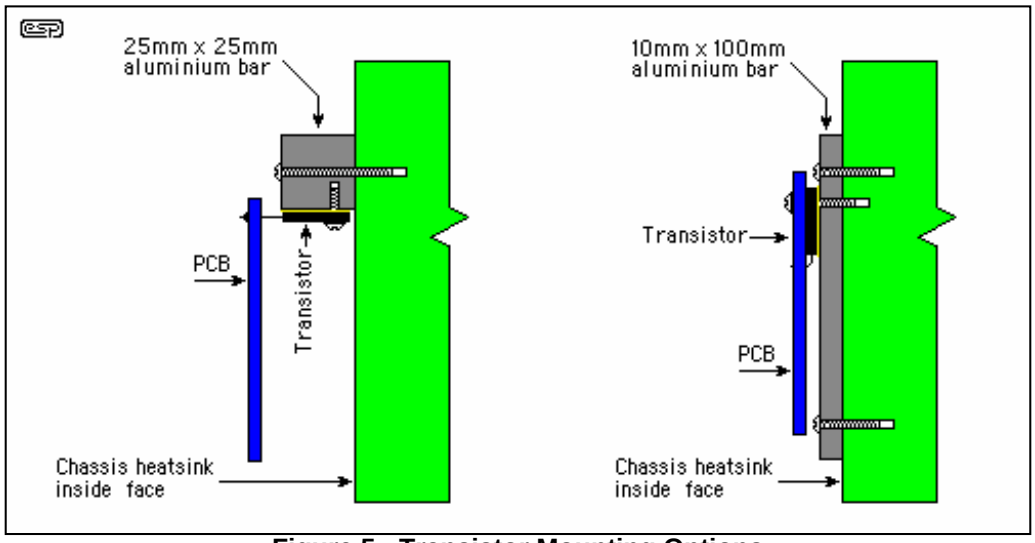

Figure 5 - Transistor Mounting Options

Before assembly of the heat spreader to the heatsink itself, apply heatsink compound between the spreader and the heatsink back. Apply a thin layer, and check that the two surfaces mate well by pressing the bar onto the heatsink. Remove it, and check that the heatsink compound is evenly distributed and shows signs of full contact. This will be immediately obvious upon inspection.

The transistors may be mounted directly to the reinforcing bar as shown. Normal transistor mounting procedures apply. Alternatively, attach a section of flat bar as shown in the right-hand drawing. This method produces a nice flat surface, ideal for mounting boards where the transistors (or MOSFETs) are under the PCB.

It is imperative that all holes for the bar or plate line up with the centres of spacer sections - drilling and tapping such that a hole is part way between a fin and a spacer will cause deformation of the assembly, resulting in potentially dramatic loss of performance.

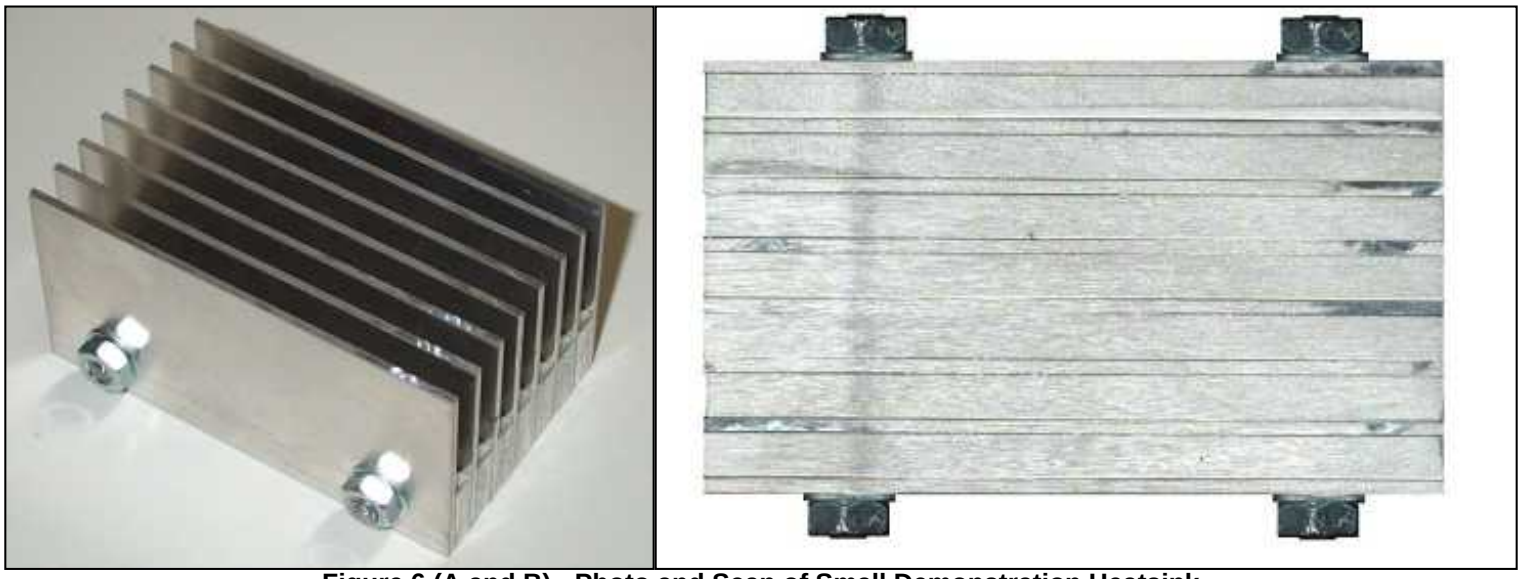

Figure 6 (A and B) - Photo and Scan of Small Demonstration Heatsink

The above photos are of a small demonstration heatsink I built. The left side (A) shows the general construction, while B shows the surface finish on the underside (the latter was scanned to get the best image of the surface). I

deliberately didn't complete the machining process so you could see the aberrations that you *will* get when the heatsink is assembled. The dark areas are actually the shiny (not sanded) areas of the fins. This was despite my following the instructions listed above, so you will also have the same problem. Attempting to remove every imperfection is futile unless you have access to a milling machine - it will be too boring and frustrating for words. The last 5% of the surface could easily take 90% or more of the total construction time.

This is the reason for using a heat spreader - it distributes heat over a much larger surface area than you will get with any transistor, but the surface still needs some basic attention or heat transfer between spreader and heatsink will be badly affected. This will lead to an excessive temperature on the spreader, and an even higher temperature for the transistors. This machining is the most important part of the exercise!

I used a linisher (essentially an upside-down large belt sander), but careful filing will also work very well. Yes, it will be tedious and hard work, but the results will be worth your efforts.

You will also note that I didn't follow the procedure, in that I have fins (rather than spacers) at each end of the heatsink. Feel free to break the rules too, provided you work out exactly what you need. The whole idea is that this process allows you to make a heatsink that exactly fits your needs. In case you were wondering, the overall size of the heatsink pictured in Figure 6 is 100mm (h) x 60mm (w) x 52mm (d). There are 8 fins, each is 32mm deep, giving a thermal resistance of about 1.16°C / W (if black enamelled) or 2.0°C / W (polished aluminium, as pictured).

---

5 Final Assembly

Once the heatsink sections are drilled and tapped to accept the top and bottom covers, the heat spreader has been drilled and tapped for the transistors, and no further work needs to be done in that area, you may start the final assembly. The bottom needs to be drilled for external feet and for all internal hardware that will be attached to it. As shown in Figure 3, the heatsinks (as well as top and bottom covers) are drilled to accept mounting screws. The heatsink holes are tapped to accept the size screws you will use, as will the heat spreader.

The front panel simply attaches to the two heatsink sections as shown in Figure 3, and the top and bottom panels attach to the heatsink and front and rear panels. Although no additional mounting for the rear panel to heatsinks is shown, this can be added if desired. You can use 12mm square section, or a piece of angle if you prefer. The extra is not really needed, but the rear panel will flex a little when the top is not in place without it.

If you find that you need the reinforcing bar(s), first assemble the heatsink as described above, then drill and tap the holes for the reinforcing bar (in both heatsink spacers and bar). Assemble the heatsink as described, carefully turn it over and file, sand or otherwise machine the rear surface so it is as flat as possible. Then, attach the reinforcing bar, and screw down lightly. You will quickly see if there is any misalignment, and this must be corrected before you permanently attach the bar to the heatsink. In general, it is expected that if the assembly process is carried out carefully, the heatsinks will be very rigid indeed - almost as if they were one solid piece of aluminium.

The unit as described is *very* heavy, so file and sand all edges and outside corners of the ribs to reduce the risk of being cut. It will be much easier to assemble if you drill and tap all the heatsink holes for mounting the reinforcing bars and / or heat spreader before final finishing.

Paint the finished heatsink with a spray can of flat (matte) black enamel. It should be a self-etching type designed for aluminium finishing for best results. Don't be tempted to try for a perfect finish between the fins, as you will end up applying too much paint which will reduce performance. You could get all the sections black anodised before assembly, but that would be an expensive option because of the number of pieces. Don't even contemplate pre-finishing the heatsink components - any paint between fins and spacers will degrade performance dramatically, and may cause the heatsink to bend or twist when it is assembled.

The front panel arrangement may look rather suspect, with the 12mm bar attached using screws into blind holes in

the panel. With a 6mm panel, this allows 5mm hole depth, and about 4mm of this can be threaded. Having done exactly this on many occasions, I can assure the reader that it works perfectly. You do need to be extremely careful to ensure that the holes don't go all the way through, but other than that, the process is straightforward. Tapping blind holes is a cow, but you can cheat and use self-threading screws. The latter must be square-ended - conventional tapered self-tapping screws will not work! If you are concerned, use a good epoxy resin (24 hour setting type - *not* 5 minute) as well as the screws for a permanent bond.

---

6 Conclusion

As described, each heatsink section will have a thermal resistance of around 0.12°C / W. This is assuming a middle-of-the-road value for emissivity of about 0.8 - typical of a flat black surface finish you will be able to apply at home. This is a very good figure, but it will be degraded if the heat spreader is too small, or makes ordinary (as opposed to excellent) thermal contact with the heatsink, etc. The distribution of transistors will also have a bearing on the thermal performance.

However, even if we were to assume the worst case and the thermal resistance is effectively doubled, it is still very good at 0.24°C / W. The 'typical' figure (0.12) was calculated using the ESP heatsink calculator program (see the downloads section of the ESP website). Heatsink temperature was taken as 60°C, at an ambient temperature of 25° C. Even using the worst case figure, this means that when dissipating 80W (as discussed at the beginning of this article), the heatsink temperature will stabilise at around 20°C above ambient (45°C at 25°C ambient) ... and that's *worst case!*

Because of the large thermal mass (as well as actual mass), this heatsink will take a significant time to reach full operating temperature. Each heatsink will weigh in at about 5.9kg for aluminium alone, and even the baby one I made (see Figure 6) weighs 480 grams (admittedly, that's with the steel threaded rod, washers and nuts). Both heatsinks will weigh about 12kg (over 26 pounds in the old measurements), and you have yet to add the panels, transformer(s) and other components.

The basis for this article was originally written by John Inlow, and was available on his website up until 2002. Drawings have all been substantially revised (and colour added to make them clearer), and are based on John's originals, as is the photo in Figure 1.

Introduction

We hear so much about damping factor, the effect of speaker leads (and how much better *this* lead sounds compared to an "ordinary" lead), and how amplifiers should have output impedances of micro-Ohms to prevent "flabby" bass and so on. But what does it all really mean?

Before an informed judgement can be made, we need to look at some of the real factors involved. There are a multitude of impedances involved in a typical amplifier to loudspeaker connection, most of them having a vastly more profound effect than the amp's output impedance alone.

For example, I have demonstrated a modified version of the 60W amp, which used current drive output. This version exhibits a damping factor of 0, since it has an output impedance of about 200 Ohms - the most common reaction was "Wow, that sounds just like a valve amp!".

Not really true, since valve amps actually have a damping factor of at least 1.5 or so, and exhibit other characteristics which are very difficult to emulate with transistors or MOSFETs, but this was the overwhelming critique of the amp's sound.

Indeed, my very own (bi-amped) hi-fi uses an amp for the bass-mid with a designed output impedance of about 4 Ohms. This provides a useful extension of the bottom end (I'm using sealed enclosures), without excessive peaking at resonance (there is a bit, and the correct impedance is probably 2 Ohms, but I just haven't gotten around to making the modification yet). To some, this is absolute nonsense - how can you have tight bass with no damping? Easy, damp the enclosure properly, and don't expect someone else (the amp) to do it for you.

For the purpose of this article, I shall assume an amplifier of 100W into 8 ohms nominal load, which is typical enough for a reasonable system.

Amplifier Impedance

It all starts with the amplifier. An amplifier will always have a defined (and measurable) output impedance, and this will vary depending on frequency. In some cases during measurement, it may appear to change with load impedance too, but that is most likely caused by protection circuitry. In many cases, measuring the output impedance is extremely difficult, but the majority of amps will give sensible results.

With commercial products, the output impedance is often quoted, but rarely with and further information. To be meaningful, the impedance should be quoted at at specific frequency, or preferably at a range of frequencies. It would be helpful if the power level were to be stated as well, but this is not often the case. If you really want to know, you will have to measure it yourself.

Although relatively easy to do, there is some risk involved, so never undertake this process unless you know exactly what you are doing, and accept the risk that you may damage the amp if you make a mistake. You will need a resistor of known accuracy, with a resistance equal to the amplifier's stated load impedance. It must be capable of dissipating either the amplifier's full output power, or a level of power that you will not exceed. A 10W wire wound resistor is recommended, preferably non-inductive for broad band accuracy.

For this exercise, we shall assume the amp referred to in the introduction - 100W into 8 Ohms. An 8.2Ω 10W resistor will be fine for the basic test. The amplifier output voltage should be kept below 9V RMS at all times (9V and 8.2Ω is 9.8W - within the resistor's rating). Measure the resistor's actual value - do not use the stated value, as this could have an error of up to 10%. For the exercise, I will assume the resistor is exactly 8.2 Ohms.

Set a signal generator to the desired test frequency, and apply the signal to the amp input. Adjust the level until you have a convenient voltage below the 9V maximum. Measure the voltage carefully. Call this V1 (let's assume 5.00V)

Now, connect the load resistor directly to the amp terminals, and measure the voltage again. Do this accurately and quickly - the resistor will get hot quite quickly if the voltage is anywhere near the 9V maximum. Call the loaded voltage V2. It should be less than V1. (Assume 4.88V)

Now, you can calculate the amp's impedance (I will do this the long way, as it's far easier to remember) ...

I = V2 / R = 4.88 / 8.2 = 0.595A

The amplifier is most easily represented as a perfect voltage source having zero Ohms impedance, with a series impedance that we see as its actual output impedance. Knowing the voltage drop in the amp's internals (Vd) and current (I), we can calculate the output impedance (Zo) ...

Vd = V1 - V2 = 5.00 - 4.88 = 0.12V
Zo = Vd / I = 0.12 / 0.595 = 0.2Ω, or 200 milliohms

The so-called 'damping factor' is simply the speaker impedance (Z_L) divided by the amp's output impedance ...

DF = Z_L / Zo = 8 / 0.2 = 40

This test will usually show highest damping factor (lowest output impedance) at low frequencies, with the impedance rising from around 500Hz and upwards. The actual frequency depends a lot on the amplifier's topology - it may be as low as 100Hz, or as high as several kHz.

In some cases (rare, but it can happen), you will find that the voltage *increases* slightly when the load is applied. This condition is usually an indicator of bad internal wiring practice, and the amp has negative impedance.

Since this is an inherently unstable state it should be avoided, although it is remotely possible that some misguided soul thought it was a good idea. It isn't. With the exception of special-purpose amps where there is a need to solve a specific problem, negative impedance is generally something to be avoided. See the article (Variable Impedance Amplifiers) that covers this exact topic for full details.

Speaker Leads

After the amplifier, we have the speaker lead itself. This has become (for reasons which I must confess I find entirely obscure) a subject of great controversy. There is actually nothing controversial about a piece of wire, despite the manufacturer's assertions to the contrary.

The purpose of the speaker lead is to carry the output current from the amp to the loudspeaker, preferably with as little power loss as possible. This implies that the lead should be capable of carrying currents of perhaps 5 amps or so for a distance of typically 2 metres. This is hardly a difficult task - the mains lead to a 2400W electric heater carries a continuous current of 10 Amps (assuming 240V operation), and usually manages this with little loss. The house wiring manages to carry this current from the switchboard through to the power outlet for far greater distances, still with relatively little loss. Then, of course, there's the cable run between the switchboard and the power station - ????

Power Loss

Some of the more expensive speaker leads (costing 10's of dollars per metre) are capable of carrying

currents far greater than can ever be drawn by a loudspeaker connected to our "typical" amplifier.

At the very worst, a nominal 8 Ohm speaker system may have an impedance at some frequencies (usually at or near the crossover frequencies) of perhaps 4 Ohms - some may be lower than this, and I would suggest that in such cases the designer should return to the drawing board forthwith, since a truly monumental error has been made.

So, let us assume that the truly monumental error has been made, and look at the current the amp might need to supply. To make life simple (for the time being) we will look at the maximum possible power on a continuous basis - this will never happen, but it is useful as a comparative figure. The figures below are rounded, and assume that the power supply is actually capable of providing the currents quoted - this is highly unlikely.

Impedance	Power	Voltage	Current
8.0 Ohms	100 W	28 V	3.5 A
4.0 Ohms	200 W	28 V	7.0 A
2.0 Ohms	400 W	28 V	14 A
1.0 Ohm	800 W	28 V	28 A

These figures take things to extremes - an 8 Ohm loudspeaker which falls to 1 Ohm would have to be the most ill-conceived possibility imaginable, but we will stay with this, since it is useful to demonstrate the point, and there is probably more than one of them out there already.

Now, let us imagine a speaker cable with a resistance of 0.1 Ohm - for a 2 metre cable, this will be the so-called "speaker" cable that is a very thin figure-8, and rated at 5A (low voltage only).

Even at the lowest impedance of 1 Ohm, where at one isolated frequency the poor amplifier will be attempting to supply a maximum current of 28A - but will it? The likelihood of this one frequency being driven to full power is extraordinarily remote, but we will use it anyway.

So, now we have 28V across 1.1 Ohm, so the current is reduced slightly, to about 25A, so 2.5V will be lost across the cable at this frequency. The amplifier is only attempting to deliver a mere 650W to the load, with the cable dissipating the rest as heat. A 0.9dB drop in level is nothing compared to the agony the amplifier will be suffering, with the real possibility of second breakdown in the output devices (which does not always result in the instantaneous destruction of the transistors) - can you imagine what that would sound like?

A small amount of resistance is inevitable - there is no super-conducting speaker cable available as yet, so you are always going to have a small loss. It will require very thin wire and a very low speaker impedance before you even lose 1dB, so I believe we can dispose of that myth (note that this is a very simplistic look at the issue - there is a *lot* more involved). For a more in-depth discussion of this topic, see the various cable articles.

Damping Factor

Having established that resistance within reason is not an issue as regards power loss, there is damping

factor to be considered. Quite apart from the fact that "damping factor" is a rather ill-conceived term, we need to look at the reality of what the amplifier is capable of controlling within the speaker cabinet.

According to the proponents of "damping factor should ideally be infinity +/- 3dB", the amplifier is in total control of the speaker, provided its impedance is low enough. What utter rubbish. The loudspeaker is an electro-mechanical device, and its sensitivity to external impedance is easily tested. Indeed, if the amp were in total control, with the amplifier connected (and turned on), you would not be able to move the cone at all by tapping it.

Try this experiment. Disconnect the speaker leads from the speaker, and tap the cone lightly with your fingers - listen very carefully to the character of the "thump" of the speaker. Now, connect a short piece of stout wire directly between the speaker terminals - this will have a resistance so low as to be considered 0 Ohms.

Tap the cone again, the same way as before. Can you hear a difference? I would expect that you can, because if not the speakers are either so well damped internally that the amplifier's contribution is irrelevant, or there is so much internal resistance that no amplifier can save them.

Now, remove the short, stout wire, and replace it with a 4 metre length of the cruddiest bit of wire you can find, bell wire or telephone cable is ideal, but thin fencing wire will do equally well. Tap the speaker cone again, and listen carefully to see if there is any difference between the sound with the "dead short" versus the piece of rubbish you just connected, which might typically have a resistance of 0.5 Ohm (maybe more).

Could you hear any difference? If you have access to an AC millivoltmeter, you should try to measure a voltage as you tap the speaker cone. You will typically find that very little change will be evident in the character of the sound between the dead short and the bell wire, and only a small voltage (a few millivolts) will be indicated.

This is a rather extreme test, and it is quite possible that a very slight difference in "tonality" will be observed. It is equally possible that you will not be able to hear any difference whatsoever, despite the fact that damping factor has been reduced to a small fraction of its former value with the dead short circuit created by the short wire.

Even the best amplifier in the world will have some impedance, as will the most expensive cable. These can actually be "removed" completely by building an amplifier with a negative output impedance, but having tried this approach, I can assure the reader that a horn compression driver is the only speaker I have ever tested which sounded better with negative impedance. All other speakers, whether horn loaded, sealed or vented box sound universally disgusting with negative impedance.

Negative impedance is exactly what it sounds like - the amplifier is modified so that the voltage output rises with increasing load. This is surprisingly simple to implement, but speakers seem to hate it - most seem to prefer a small but measurable amount of positive impedance. This is the equivalent of using a cheap speaker lead, but has other implications - there is no loss of power due to the resistance of the lead, and high frequencies are far better since there is none of the capacitive loss incurred by the really cheap speaker lead.

Have you ever wondered what it is about valve (vacuum tube) amps that has many audio enthusiasts drooling over the latest - usually extremely expensive - offering from this manufacturer or the other?

They will wax lyrical about the extended bass, and the sweetness of the highs etc. etc. One of the things about valve amps is their relatively high output impedance - this may be up to about 6 Ohms for an amp without any feedback, and will rarely be less than about an Ohm (8 Ohm output selection is assumed). The damping factor is obviously grossly inferior to that of a transistor amp, but the sound quality is generally considered more musical, or "sweeter" by a great many enthusiasts.

There are many other factors involved than simply the output impedance, but if this were so important (or as important as some would have you believe) then valve amplifiers would be universally condemned for their poor low frequency performance - phrases such as "woolly", "muddy" and "over-emphasised" spring readily to mind. Instead, we can read reports where reviewers have praised the low frequency performance, claiming an extra 1/2 octave or so of bass extension. This is in spite of the fact that very few valve amplifiers can actually make it down to 20Hz without rolloff and output transformer saturation distortion starting to be readily observable.

Well before transformer saturation distortion and other undesirable effects make themselves known, the output impedance rises. This is at the very frequencies where damping factor is supposedly most important. Yet these amplifiers continue to receive rave reviews from listeners - we must conclude that the damping factor cannot be as important as is so often claimed. Could it be that *all* owners of valve amplifiers have tin ears, and couldn't tell the difference between a symphony orchestra and a bag of cat litter? This is possible, I suppose, but I do believe that it is somewhat unlikely !

I shall not go so far as to say that the myth is disposed of, but I believe that an extremely low amplifier output impedance is not as important as many people think it is, and that in some cases a small (preferably controlled) amount of deliberately introduced impedance is useful for correcting the characteristics of a loudspeaker driver whose Q is lower than desirable for the enclosure design used. Indeed, I have made such modifications to equipment - raising the output impedance of the amp so that a studio monitor driver could be matched more exactly to the enclosure, and this was at the request of the speaker designer.

Please see the article Effects Of Source Impedance on Loudspeakers for more information on this topic.

For the Thiele-Small Parameter Set ...
This can be a useful trick if the total Q of a loudspeaker is too low (for example, because of a very low Qms - mechanical Q). Such a speaker is normally not suited to a vented box, but by raising the total Q (Qts) by means of increased output impedance from the amp (thus raising Qes), a very satisfactory result may be had.

An experimental plot of a Dynaudio 24W-100 driver shows that an extra full octave is obtainable by raising Qes to 0.9 (from the quoted 0.45). Admittedly, the box required becomes somewhat large, but this has always been the price we pay for extended bass anyway. A similar test on another loudspeaker with a very low Qts showed identical results, with a full extra octave obtainable at the low end, simply by raising the Qes of the driver. The results are shown in Figures 1 and 2.

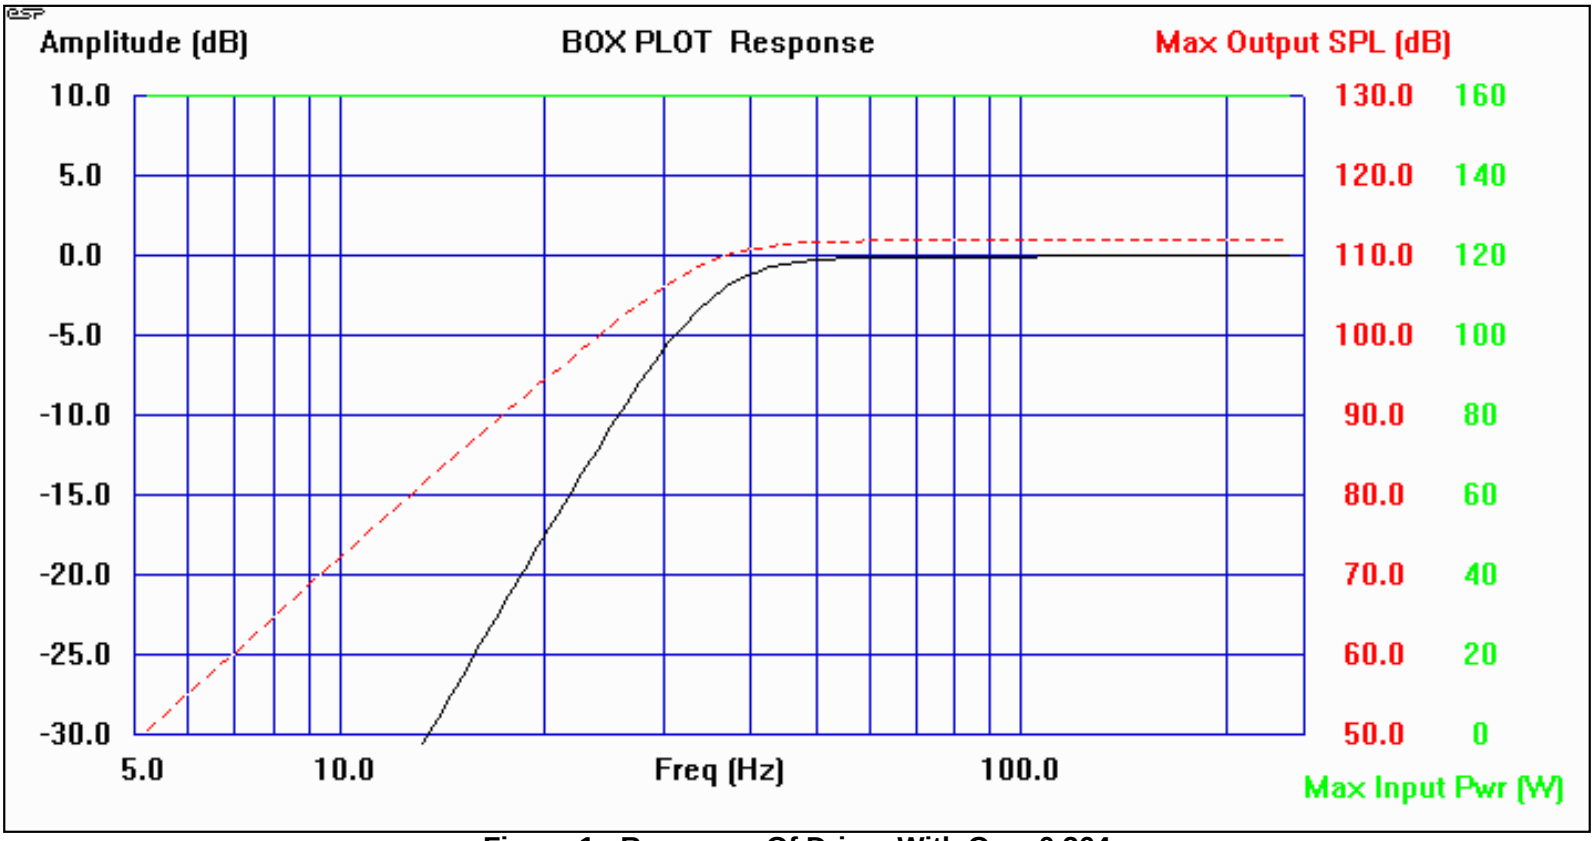

Figure 1 - Response Of Driver With Qes=0.364

As can clearly be seen, the lower -3dB frequency is about 35Hz which although acceptable, but can be improved. Box size is 61 Litres. By raising Qts (using the expedient of increasing Qes with a defined output impedance), we can improve matters in the low end department ....

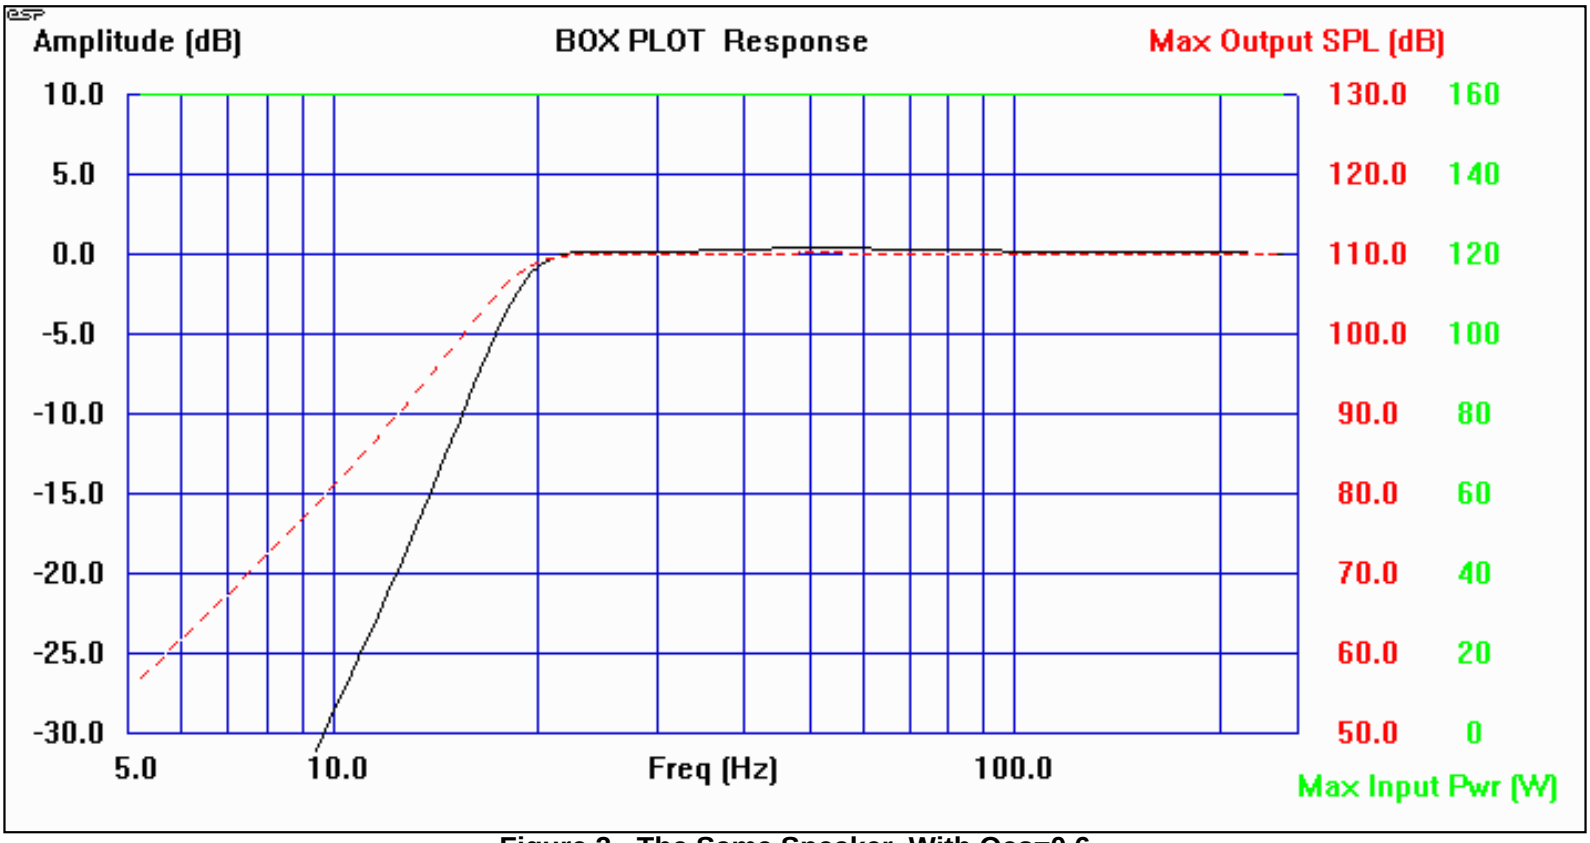

Figure 2 - The Same Speaker, With Qes=0.6

The lower -3dB frequency is now about 18Hz, which represents an extra octave of bottom end. Box size is now 271 litres (just a tad on the large side), but the principle is sound nonetheless. It is worth noting that these two plots are optimised for the given parameters, with no further fiddling with the parameters. BoxPlot (a very useful shareware program) was simply given the details, and made an optimised calculation from the details provided.

Modifying the output impedance is remarkably easy to do in any amp, but naturally the impedance selected must exactly match that required to increase Qes by the desired amount. If it is greater (or less) than optimum, then the box alignment is no longer valid, and bottom end response is unpredictable (at best). So too with boxes which have been designed with a zero Ohm source, since this will never be achieved in practice.

Speaker Impedance And Protection

Speaker systems are rated for a nominal impedance, which will be typically 8 Ohms for hi-fi systems. Many of these claimed impedances are very misleading, since the actual impedance varies widely with frequency. There will be two impedance peaks at low frequencies, corresponding to the driver and enclosure resonance (the upper peak), with the vent and enclosure resonance providing the lower peak. Sealed enclosures will exhibit only the speaker/cabinet resonance peak, since there is no vent used.

Then there are impedance dips, where the actual impedance may fall to 1/2 (or less) the rated impedance. These are nearly always caused by the crossover networks, and can impose a significant reactive load on the power amplifier. It is very difficult to design the perfect passive crossover network, which is a very good reason to use a bi-amplified system with a good quality electronic crossover network, whose characteristics are far more easily controlled than any passive design. (See Bi-Amplification - Not Quite Magic (But Close))

The reactive load imposed on the amplifier by a speaker load causes far higher dissipation in the output transistors than the simple resistive load generally assumed during testing. At the extreme end, consider a load which is completely reactive (i.e. inductive or capacitive). The voltage and current are 90 degrees out of phase with each other, and no power is consumed by the load - even though there is voltage and current present (and measurable). Assuming a voltage of 20V and a current of 2A, the actual power is zero, so the amplifier must dissipate not only the normal internal losses inherent in all power amplifier designs, but the 40 Volt/Amps reflected back from the reactive load. (Volt/Amps - or VA - is roughly equivalent to Watts - but only when the load is resistive, implying that work is performed).

In reality, the reactance is always accompanied by some resistance, so the amount of power converted into work (moving the loudspeaker cone to create sound) will always be non-zero. An additional quantity of the supplied voltage and current are converted into heat (another form of work) due to resistive losses in the voice coil and crossover network. The reactive (also known in electrical engineering as the imaginary) component is reflected back into the output of the amplifier, where it must be absorbed and converted into heat.

It is the reflected power from the loudspeakers which is responsible for a great many amplifier failures. Because of the low efficiencies of most modern speaker systems, more power is needed from the amplifier. This means that the amp will have to dissipate more reflected power and this can lead to overheating (or internal "hot-spot" localised heating) which leads to the destruction of the output transistors. Some amplifier protection systems are sufficiently sophisticated that they can prevent this form of damage completely, but

will generally provide an additional side-effect - the deterioration of sound quality. This is often noticed as a "grainy" or similarly described quality to the sound, and is difficult to eliminate when protection is used. A certain IC power amplifier I have tested has a very comprehensive protection circuit, which seems to work very well. However, as the amp reaches the point of clipping, the distortion component is multiplied tenfold by the protection circuit, with the result that what should be completely inaudible distortion becomes very audible indeed.

It will come as no surprise that I am not a fan of protection circuits in amplifiers, for this very reason. A little care on behalf of the listener to ensure that the amp has sufficient power for the highest listening level desired (plus a bit more for safety), together with being sensible and not shorting the speaker leads, means that protection circuits can be dispensed with in a hi-fi system. This is not the case with lo-fi (Ghetto-blasters and the like), but for true high fidelity sound systems active (or "real-time") protection should be avoided.

Speaker Protection Systems

Speaker protection circuits come in a variety of flavours, the most common being fuses, "poly-switches" and DC offset cutout relays. Looking at each in turn is useful.

Fuses - A fuse is the simplest protection device for speakers, but is not very effective. The fuse is usually capable of protecting a speaker, but is quite incapable of protecting the amp - the transistors will almost invariably blow far quicker than any fuse. The fuse will prevent the fault current from the amp from blowing (or setting fire to) the speakers, provided that it is correctly rated. Basic protection is all that is really offered.

Poly-Switches - These are basically thermistors (thermal resistors) which are normally low impedance, but when their temperature reaches a preset value they go into a high impedance state - thus limiting the current to a safe value. Because they are essentially a non-linear device, and have some resistance even when not activated, I cannot recommend that they be used for hi-fi applications. Their internal resistance adversely affects damping factor (which may be a "so-what"), but the fact that they are non-linear means that some degree of distortion must be introduced by their inclusion. The degree of added distortion is bound to be dependent upon how close to their limits they are being run, but in no case could this be considered negligible. When we are striving for amplifiers with less than 0.01% distortion, it takes very little non-linearity to raise that by an order of magnitude.

DC Offset Relay - This is one item that has no bad habits, provided that the relay contacts are capable of handling the output current of the amplifier without overheating. This is not as trivial as you might think, since few small (and/or reasonably priced) relays have a suitably high current rating, and many do not have sufficient contact separation to break the arc created by 50V DC being dumped into a speaker load.

With some of the relays I have seen used, one can almost guarantee that the relay will be destroyed if it were to be called upon to do its duty. However, the basic idea is sound, and introduces no distortion or other undesirable effects to the final signal. With a little extra circuitry, the relay can also be called upon to open under other fault conditions (such as excessive output current), and the only characteristic will be that the sound cuts out completely while the fault is maintained. This is a better solution than trying to provide active protection with its resultant sonic degradation.

Impedance Matching

If you are into RF (radio frequency) design, or perhaps telecommunications, this becomes an important topic. For hi-fi audio, it is a meaningless concept and will actually cause an increase in noise and distortion.

It has often been claimed that a 600 Ohm microphone should be matched to a 600 Ohm input for best performance. This is simply wrong, and microphone manufacturers specifications will support me on this.

Imagine a 600 Ohm microphone with an open-circuit output voltage of 5mV. If the mic preamp has an input impedance of 600 Ohms, the microphone output is reduced by 6dB to 2.5mV because of the simple voltage divider created. It helps to use the engineering "model" for a signal source of any kind, which is basically a "perfect" (meaning zero Ohms impedance) voltage generator, with a resistance + inductance or capacitance (sometimes in combination) in series with the output.

If the output is loaded, then the available voltage from the source drops, and that in turn means that more amplification is needed to obtain the final voltage needed. If the output is reduced by 6dB, this means that an additional 6dB of gain is required to compensate - therefore the circuit will have more noise.

The ideal for a microphone is to use a high impedance input, but this creates other problems, so a compromise is needed. Typically, a good mic preamp (for microphones of up to 600 Ohms) will have an input impedance of between 1.2k and 2k Ohms. This causes far less loading, and does not cause any problems for the microphone.

Generally, it is desirable that the output impedance is low, and the destination impedance high, and this is the case with the majority of modern equipment. Preamps usually have an output impedance of less than 1k Ohm, and power amps will have an input impedance of at least 10k Ohms, but more commonly 22k or 47k.

So why is impedance matching important for RF and telecommunications? The reasons are completely different, as we shall see.

Radio Frequencies: When an RF voltage and current are transmitted along a wire, the impedance of the cable itself becomes significant, and for any distance that is "significant" - which is to say any distance greater than about 0.1 of the signal's wavelength - matching is necessary. The wavelength is calculated from the speed of light (3 x 10 ^ 8 m/s, or 300,000km/s) multiplied by the "velocity factor" of the cable. This varies from about 0.7 up to 0.9, meaning that a signal travels more slowly in a cable than in free air or space.

Wavelength = C / f (where f = frequency and C = velocity)

A 1Mhz signal travelling in a typical coaxial cable (velocity factor of 0.8) will have a wavelength of ...

Wavelength = ((3 x 10 ^ 8) x 0.8) / 1 x 10 ^ 6 = 240m

Based on this, any attempt to transport a 1MHz signal further than about 24m will start to cause problems unless the send and receive impedances are properly matched - not only to each other, but to the cable as well.

In the hi-fi audio world, this is not an issue, since this is 50 times the highest frequency we can hear, and

few instruments create appreciable harmonics above 20kHz anyway. In theory, we could send an audio signal 12km without having to worry about impedance matching.

Telecommunications: Impedance matching is a requirement in telecommunications networks, but not for any of the reasons you might think. It is actually rare for an analogue phone line to run more than about 5km from the exchange (C.O.) to the user's location.

The impedance matching required is to enable the hybrid - a circuit that allows simultaneous transmit and receive on a single pair without interference - to function properly. If the impedances are not properly matched, you will hear too much of your own voice when you speak, and the far end speech will be too soft.

Because of the distances involved, the telecommunications network is balanced, to prevent noise.

Balanced Vs. Unbalanced

The conventional hi-fi connection is unbalanced. One conductor is earthed (the shield), and the other carries the signal. Except that this is rubbish. The shield also carries the signal, since without a return path, we have an "air-gap" problem, and no signal will pass - other than general noise and maybe a tiny bit of the desired signal due to capacitive coupling between the two circuits.

This unbalanced signal is actually fine for short distances - few hi-fi interconnects will be longer then a metre or so. Provided the source impedance is low, there will be very little noise introduced, and the signal will pass unscathed from one piece of equipment to the next.

However, if 10mV of noise were to be picked up along the way, then this is added directly to the wanted signal, adding hum or other undesirable noises to your music.

In contrast, a balanced connection uses two wires, one carrying the normal signal, and the other an inverted (but otherwise identical) version of the signal. At the other end, the two signals are recombined. Any noise that was picked up along the way will be seen to have the same polarity on both wires, and is not "seen" by the receiving equipment. Only signals that are in "anti-phase" (of opposite polarity) are picked up.

This noise on both wires is called common-mode noise, and a properly balanced circuit will amplify the wanted signal, but reject common-mode noise by as much as 60dB (i.e. 1/1000th of the noise gets through). This is known as common-mode rejection ratio, and is a figure quoted by all opamp manufacturers for the opamp inputs.

If the same 10mV of noise were picked up by a balanced cable, only 10uV of unwanted signal will be present at the output of the amplifier if the common mode rejection is 60dB. To look at it in a different way, the signal leads will have to "collect" 10 Volts of noise to allow a 10mV noise signal to pass.

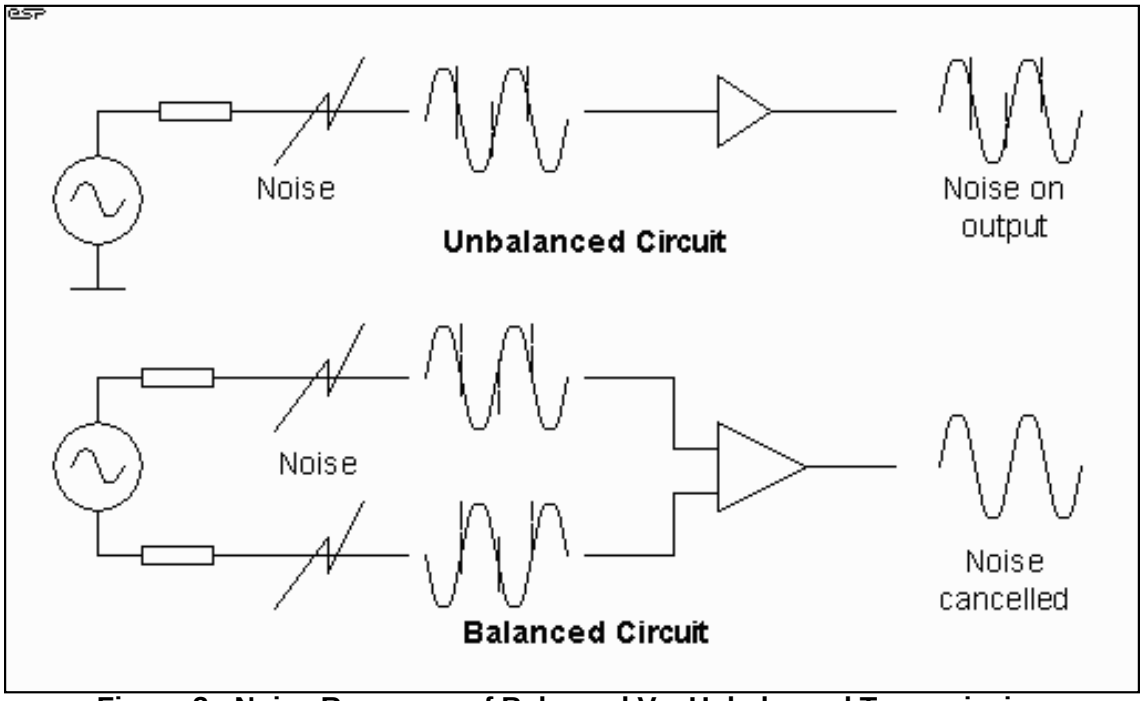

Figure 3 - Noise Response of Balanced Vs. Unbalanced Transmission

Figure 3 shows how the noise is cancelled in a balanced circuit. The noise pulses are applied to both leads - it is important that the leads are twisted together, to ensure that any noise is picked up by both. Because the signal is 180 degrees out of phase and the noise is in phase, only the out of phase signal is allowed through the amp. Any in-phase signal (common mode) is rejected, cancelling the noise signal almost completely.

In professional audio work, balanced leads are used almost exclusively. These are always shielded as an additional protection against noise.

Hi-Fi Super Cables

We have all seen advertisements for audio interconnects costing obscene amounts of money, and some of them actually do seem to sound better than "ordinary" interconnects. There is no "magic" here, these are often no more than a "pseudo balanced" cable, where the shield is connected at one end only, and the signal is carried by a pair of wires within the shield.

This is hardly worth all the money the hi-fi shops ask, since you can make them yourself, with good quality cable and connectors available from any electronics dealer.

As for so-called "directional" cable, this is utter rubbish. The only thing that is directional is the choice of which end the shield should be earthed at - send or receive. For cables having the shield connected at only one end, the answer is usually the sending end (e.g. the preamp, when connected to a power amp). It is worth pointing out that shielded cables should *always* have the shield connected at both ends, or noise reduction is imparied.

How can a cable carrying an AC signal be directional? There are some proponents of the oxygen free copper concept who will claim that if there is oxygen in the copper, it will be as copper oxide, and that copper oxide is a semiconductor, semiconductors rectify, and will therefore introduce distortion. Prove it to

me!

I defy anyone to produce concrete proof in any form that a cable is capable of introducing distortion - at any level. Even if we assume that there is some validity in the copper-oxide rectifier theory, all semiconductors have their forward conduction voltage (e.g. 0.65V for silicon) - I don't know what it is for copper oxide, but even if it were as little as 100mV (highly unlikely!), this would require that there was a 100mV or more difference between adjacent conductors for rectification to occur. Since the loss along a 1m length of signal interconnect cable will be a very small fraction of this, I (and many others) do not consider that this is in any way possible.

So, if there is no validity at all in spending $200 for an interconnect cable, why do people say how great they sound? Easy. If you had just spent that much and could hear no difference, would you be game to admit it to anyone? No, you will be tempted to try to convince yourself that you *must* be able to hear *some* difference, otherwise you just wasted $190, since a $10 cable would work just as well.

As a matter of interest, you might also want to have a look at my editorial page, which has some challenging things to say about $3000 mains leads (and no, that is not a misprint!).

Conclusions

It is quite possibly obvious that I do not believe any of the hype about cables. My own system uses perfectly ordinary cable throughout, and I have no desire to change this in any way whatsoever.

I am utterly unconvinced by any claim that a cable can make my hi-fi sound any different - never mind better, just different. I have never been able to measure distortion in a cable, and I know of no-one who has.

Certainly, some "super" speaker cables (because of high inductance or capacitance) can make a power amp unstable or even oscillate, but this is invariably a bad thing, so I don't want any of that stuff at any price.

One final point - gold-plated connectors. They do not conduct any better than any other type (worse than some), and they do not introduce (or remove) a "sound". Gold is used because it does not oxidise, so the connections don't have to be jiggled about every so often to remove crackles or other mechanically induced noises - no more and no less than this. (Although I have seen a claim that solder joints to gold can simply separate for want of anything better to do at the time. I have yet to see this proven, but it is possible.)

1.0 - Introduction

Microphones are often poorly understood, and this article seeks to provide some basic details about the various types, how they work, and the interfacing of the microphone with a suitable preamplifier. While it would be tempting to explain mic techniques, proper usage, etc., these are not topics that will be covered. There are several reasons, but the main one is that there are so many possibilities that it is impossible to cover them all.

Instead, the focus will be on the microphone basics - how each type works, along with its advantages and disadvantages. The following brief summary is a warm-up for the real thing - and even though it looks like a lot to cover, there are (and will remain) several omissions. For example, carbon microphones will not be covered because they are no longer used in new equipment, and 'esoteric' microphones (such as the so-called shotgun mic) will not be explained in any detail.

With microphones, the terms Directional, Cardioid, Omni-directional (or just omni), Hyper (or Super) Cardoid, etc. refer to the polar response, but these terms are sometimes loosely applied. The directivity of all microphones is frequency dependent, and becomes spherical (omni-directional) as the frequency decreases. There are exceptions, and these will be looked at as we progress.

The microphone, abbreviated to 'mic' or 'mike' is an essential part of the process of getting our music from the performers to our listening rooms. Mics are also used for sound reinforcement, ensuring we can hear everything at a concert (and also often ensuring that we can hear very little for hours afterwards). Correct microphone selection and placement during recording minimises the amount of equalisation that is needed, because the sound is already the way the producer intends. The choice is enormous, as the brief summary below indicates.

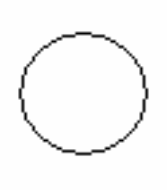
2.0 - Basic Microphone Characteristics

Although the number of different microphones looks daunting, they are all based on common parameters ... these are directional patterns and transducer types, and almost every microphone made is covered by the two listings below.

2.1 - Directional Patterns

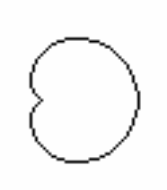
The directional characteristics of microphones are defined in the capsule (or capsules, in the case of dual capsule mics). Contrary to what some may claim, any type of microphone can be configured to have any of the listed configuration patterns. The directional characteristics are frequency dependent, and refer to the free field response - placing a microphone very close to any surface changes its directional characteristics, and they become unpredictable because of the almost infinite number of possibilities. Directional microphones are also called 'pressure gradient' mics, because their directional characteristics are created by means of varying pressure to the front and rear of the diaphragm (the pressure gradient).

Omni-directional ...



Pick up sound (more or less) equally from any direction. Omni-directional refers to the frequency response being essentially flat, regardless of the direction of the arriving sound waves. Omni mics often give fewer feedback problems compared to most cardioids, but this is highly dependent on correct usage. Omni mics have minimal proximity effect, and are (generally) better suited to instruments. These mics are not commonly used for live production because of limited understanding.

Cardioid ...



The most common directional pattern. These usually have a proximity affect that colours and enhances the bass end of vocals at close range. Different cardioid mics may suit male and female singers. Singers should own their microphones and be skilled in the techniques of using them, in the same way that musicians own their instruments. Cardioid mics are often misused for instruments, typically used in very close proximity to drum skins (among other misuses). Naturally, if this gives you a specific sound that you want, then it is no longer misuse.

Hyper-Cardioid ...

This is an exaggerated version of the cardioid mic, so it is more directional. A side-effect is that a small lobe is created at the rear of the microphone, so these mics must never be 'aimed' so that the rear lobe points towards a floor monitor (for example). Sometimes a distinction is made between 'super' and 'hyper' cardioid microphones, but other descriptions will consider them to be equivalent.

Figure-8 ...

The figure-8 mic picks up sound equally well from the front and back, but rejects sound coming from the sides (as well as top, bottom, etc.). The pattern can be looked at as an extreme form of hyper-cardioid, where the front and rear lobes are equal in amplitude and frequency response. Many dual element microphones combine an omni and figure 8 capsule to allow switchable directivity.

2.2 - Transducer Types

At the heart of every microphone is a transducer - simply a mechanism that converts one form of energy to another. The source (input) energy is sound, and the output is electricity. An electrical waveform is produced, which matches the acoustic input with as little modification as possible. All directional microphones must (by definition) alter the received sound to some extent. It is not possible to modify the directional characteristics without also altering the nature of the sound that is picked up. This is not necessarily 'bad', just different.

Likewise, many cartridge / capsule types (the actual transducer) have their own sound, whether real or imagined. This often influences the choice of microphone type for different tasks - for example, there are mics that are favoured for bass (kick) drums that may be deemed unsuited for anything else. This is not necessarily true, as experimentation can often demonstrate.

Condenser ...
More correctly called capacitor mics, these are generally considered to be the ultimate. They have exceptional detail, and can usually tolerate very high sound levels. Distortion is very low, because the diaphragm movement is so small (comparable to that of the human ear drum). Capacitor mics most commonly use a high DC voltage to polarise the 'plates' of the capacitor sensor, although some use the change in capacitance to modulate a radio frequency oscillator. The frequency modulated 'carrier' is then fed to a detector stage to be converted back to audio. Capacitor mics (of all types) require power - this may be supplied via the P48 (48V phantom feed) from a mixing desk, or may be an external power supply. Probably the most famous of all capacitor mics was the Neumann U47.

Dynamic ...
The dynamic mic uses a mechanism that is very similar to speakers. The majority are robust and can accept extreme sound levels, ideally suited for live productions. Most are cardioid, although omni-directional and hyper-cardioid types are also available. Dynamic mics are the most common of all types used in live work, and they are often used for studio recording as well. One of the best known is the venerable Shure SM58.

Electret ...
Also called 'Electret Condenser' or 'Electret Capacitor' microphones use a permanently 'charged' plastic membrane so that a high voltage polarising signal is not needed (as is

the case with true capacitor mics). Most are omni-directional, although cardioid inserts are also made. Like capacitor mics, an impedance conversion stage is essential because of the extremely high intrinsic impedance. While electrets can be used for stage work, they may distort at high sound pressure level (SPL). Many vocalists are capable of driving electret mics well into distortion. Temperature and humidity (such as from the breath of vocalists) can adversely affect them. Professional electret microphones are excellent for recording.

Ribbon ...
These are common in recording studios, but less so in live work because they are comparatively fragile. A very thin (usually aluminium) ribbon is suspended in an intense magnetic field, and generates a small current when it is moved by sound. Ribbon mics have extremely low impedance, typically (much) less than 1 Ohm. A transformer is used to raise the impedance (and output voltage) to a usable level. Although Ribbon mics have an inherent Figure-8 pattern, they are also available with cardioid or hyper-cardioid patterns. 'Planar ribbon' mics are a variation of the theme. These use a thin membrane with a planar (flat) coil deposited on the membrane.

Carbon ...
These microphones used to be very common - every old style telephone had one. The carbon mic has one major advantage over every other type - it has gain! Because the microphone element is made up of carbon granules, speech activating the diaphragm will compress and release the granules, changing the resistance significantly. Since power is needed by these mics, this is provided by the telephone line. The microphone gain is such that no additional amplification is needed to allow a normal phone call - even over a considerable distance. In the early days of telephony, this was essential to the operation of the 'phone network - so much so that if it were not for the carbon microphone, the telephone would never have been even useful (let alone gain acceptance) in those early days. Cheap and reliable amplification has made them redundant now.

As a short side-note, it is worthwhile mentioning that the telephone system uses a nominal 48V supply (see phantom feed, below). The influence of telephony on electronics as we know it is huge - so much so that the development of the phone system drove many of the inventions that we now take for granted. Have a look at the vast contribution of Bell Laboratories (which used to be an integral part of AT&T). Bell labs invented the transistor - the very cornerstone of every electronic product we use.

2.3 - Specifications

The output level of microphones should be rated in millivolts per Pascal (mV /Pa), although there are many variations. Other conventions used include dBm at 0.1 Pa (this will always be a negative number). All new microphones should be rated in mV / µPa, but the older standards persist in some countries.

1 Pascal = 10 micro-Bar = 94dB SPL
0.1 Pascal = 1 micro-Bar = 74dB SPL
1 dyne/cm2 = 0.1 Pascal = 1 µbar

There are also noise ratings (these vary widely, both in output noise and the way it is specified), output impedance, recommended load impedance, polar response, frequency response, etc. Frequency response claims are meaningless without a graph showing the actual response, and for directional mics this should also indicate the distance of the mic from the sound source. Cheap microphones are particularly bad in this respect, and it is not uncommon to see the frequency response stated as (for example) 50 - 20,000Hz. Because no limits are quoted (such as ±3dB) this is pointless - any microphone will react to that frequency range, but may be -20dB at the frequency extremes, with wide variations in between.

A proper graph showing the response at all frequencies will quickly show the actual response, although it is uncommon for any manufacturer to state the distance between mic and sound source, or the method used to take the measurement.

A polar response graph will also show the directivity at a number of different frequencies. As frequency decreases, the directional pattern commonly approaches omni-directional, although some mics maintain excellent directivity even at very low frequencies (the secret is in the rear chamber).

3.0 - Sub-Types of Microphones

There are some microphones that appear to be completely different from those described above. Not the case, as the essential characteristics and transducer types don't change, but more / different hardware or electronics are added to give additional functionality.

RF (Transmitting) Mics ...

These are available in many variations and professional types can be very expensive. A conventional microphone transducer having one of the directional characteristics listed

above is connected to a small radio frequency (RF) transmitter so the mic can be used without the need for cables. The transmitter for professional radio mics requires excellent frequency stability, and receivers are highly specialised to ensure no 'drop-outs' and maintain a good signal to noise ratio (SNR) at all times.

These mics require specialist knowledge and experience to use them correctly. Many have automatic limiting and compression that has to be managed carefully, because compression limits the dynamic expression of good singers, causing them to sound comparatively flat and lifeless.

PZM™ ...
The Pressure Zone Microphone™ (also known as a boundary mic) is a special application of the electret mic. A miniature electret sensor is mounted a small distance (typically less than 1mm) from (and facing towards) a flat plate. They are often used on the floor or walls, tables (for conferencing and the like), but can also be attached to large flat discs or plates. They have exceptional performance, and can effectively reduce reverberation if used carefully.

There are several variations on the basic technique, allowing for a single stereo mic unit, a cheap 'knock-off' made by Radio Shack (Tandy in Australia) called a boundary mic, but lacking the characteristics of a true PZM, and a few others.

Dummy Head ...
The dummy head mic technique yields extraordinary performance, but the recording can only give the full effect when listened to through headphones. Electret mic capsules are either embedded in a true dummy head (wig-carriers can be used ... meet Yorick below), or miniature capsules are worn in the ears of the sound recordist. When played back through headphones, the original sound field is essentially restored, and the listener hears the sound as if s/he were there.

The requirement for headphones has limited the appeal of the technique.

Shotgun ...
Shotgun mics are worthy of a complete article to themselves. Usually fairly long, they have an extreme directional pattern, and typically only pick up sound from the general vicinity directly in front of the mic. There are several ways to make shotgun microphones - techniques include a long 'barrel' with slots designed to create an interference pattern that rejects sound from the side, and multi-element designs with phase and amplitude balance between elements. An old method was to use multiple thin tubes of differing lengths, arranged so that the longest tube is in the centre, with smaller tubes

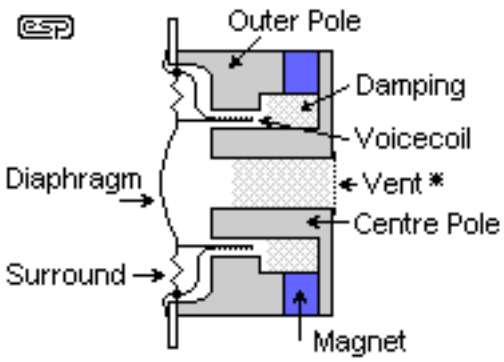
surrounding it.

Some shotgun mics use a combination of methods, as well as careful attention to the mic capsule's rear chamber. These mics are useful for location sound recording (for movies or TV), nature recordings, and anywhere else where very high discrimination is needed.

4.0 - Element Construction

The following is intended to give you an idea of the basic techniques used to make various microphone elements. These are the basic building blocks, and while some (such as dynamic mics) can be used with no additional circuitry, most others require some additional components to be useful.

Because the dynamic mic is one of the most prolific (or so it would appear to the uninitiated), it will be covered first.

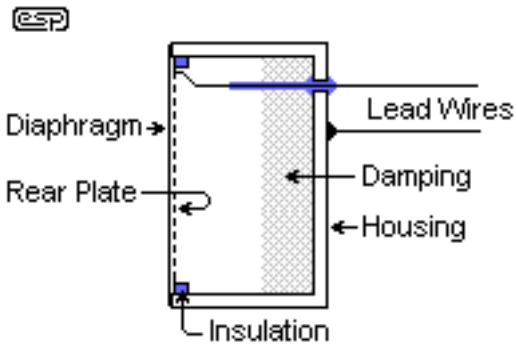


The general arrangement of a dynamic mic is shown to the left. A diaphragm is coupled to a voicecoil that is suspended in a strong magnetic field. As the diaphragm (and thence the coil) moves in sympathy with the arriving soundwaves, an electric current is generated. In a perfect microphone, the electrical current will be an exact replica of the acoustic signal, but in reality this is never the case.

The element (also known as a capsule) shown has a vented pole-piece (indicated with a *), and this is typically done to create the required directional characteristic. For an omni-directional dynamic microphone, the back would be sealed.

As you can see, this is very similar to the construction of a small speaker, and indeed, a speaker will work as a microphone (and a dynamic mic can also make noise). Naturally, the speaker and mic are each optimised for their intended application, and neither works particularly well when its role is reversed. 99% of intercom systems use the speaker as a microphone.

Typical dynamic microphones have an impedance of around 150 - 300 ohms, although some are higher or lower than that. While it may seem tempting to match the impedance of the microphone and preamplifier, this is ill advised, as it will reduce the signal level by 6dB, and thus reduce the signal to noise ratio.



A capacitor microphone is much simpler mechanically, but the material quality is critical for good performance. Because the capacitance is so small, the insulation resistance must be very high, as must the impedance of the following stage. It is not uncommon to find in excess of 100 Megohms input impedance for the impedance conversion stage.

While the capsule shown has damping material, this may not always be the case. The distance between the diaphragm and the rear of the housing can be made small enough so that no ill effects occur within the audio range.

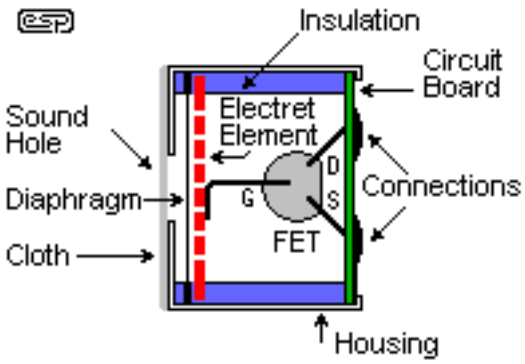
The backplate must be polarised so the microphone will work. While this may be as low as 48V, this may not be insufficient to allow a worthwhile signal level. Voltages up to 200V will be found in some examples. This places great constraints on the insulation, and means that such mics can be adversely affected by moisture.

In some cases, the microphone capsule may have two diaphragms, each spaced as close as possible to the backplate. This will create a microphone with a figure-8 directional pattern. The one shown is omni-directional - this may come as a surprise because sound coming from the rear of the mic is shielded from the diaphragm by the mic itself, but this only applies at very high frequencies. Many Neumann mics use a dual diaphragm capsule, and switch one diaphragm to change the directional characteristic from cardioid to omni-directional.

The diaphragm of capacitor mics must be conductive, and it is common to use metallised plastic film (Mylar is popular). The metallisation film must be protected from moisture, so may be on the inside of the capsule. In almost all cases, the insert will have a tiny bleed hole to allow the air pressure inside the housing to match that of the outside atmosphere. If this were not provided, the diaphragm to backplate spacing would vary with atmospheric pressure.

Electrically, a capacitor mic can be represented by a signal source in series with a capacitance equal to that of the capsule itself. As noted above, this will be very low. A typical capacitor microphone (such as the Neumann U47) has a capacitance of around 80pF (See References.)

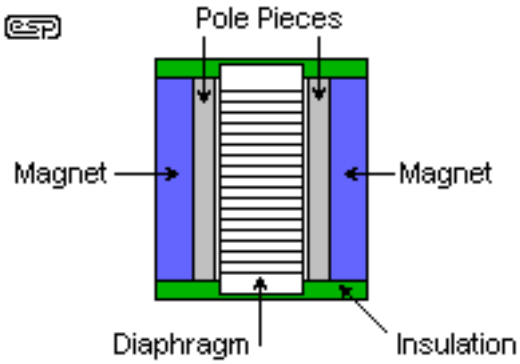
Historically, these mics have been known as 'condenser' mics for many years. 'Condenser' is the old term for a capacitor.



Electret microphones work using the same general principles as a capacitor mic. Instead of using a DC polarising voltage, the backplate is an electret material (this is a so-called 'back electret'). This material is a plastic that is subjected to an intense electrical field during processing. This causes the plastic material to retain a charge (more or less) permanently. The electret surface must be metallised to make it conductive. Some electret mics use the diaphragm as the electret element (and use a conventional backplate), and while this works very well, they do not have an indefinite life.

The FET shown is almost always included in the capsule itself. This is the impedance converter, and in most cases there is no resistor from the gate to common (ground, mic housing). This is one reason that electret mics can react badly to a sudden loud sound, and may lose sensitivity for a few seconds. The FET gate circuit relies on surface leakage alone to bias the FET correctly.

While I stated earlier that dynamic mics seem to be the most common, they are soundly (pun intended) beaten by electret microphones. All modern telephones use electret mics, including mobiles (AKA cell phones), answering machines, computer headsets, and virtually every piece of electronic equipment that needs to hear voice commands, noise, etc. The electret has been the most successful mic capsule ever developed - over 100 million are produced every year !



The ribbon mic has a special place in the heart of many a sound engineer. They have an inherent figure-8 pattern, although this is often modified to produce more 'conventional' patterns. Because the impedance of the ribbon is so low, all such microphones use a transformer to raise the impedance and output voltage to more usable levels. The transformer is almost always in the same housing as the microphone element itself.

Ribbon mics are often though to be fragile, and many of them are. There are others that are very robust indeed. Because ribbon mics use a relatively large diaphragm (much larger than most other mics), they can be very sensitive to air movement - even at subsonic frequencies.

However, high SPL does not usually bother a ribbon mic in the least. Provided the ribbon remains in the gap, almost nothing will cause a ribbon mic to distort - apart from the aforementioned air movement which *must* be avoided. Even apparently gentle air movement can distort the ribbon, which then must be replaced. 'Planar' ribbons are used by some manufacturers - a planar ribbon is not a ribbon in the true sense of the term, but uses a metallised coil printed on a thin plastic carrier. These are very rugged according to the literature.

Because of relatively low output level (even after the transformer), you need a very quiet preamp for ribbons. They have very low self noise, so preamp noise can easily exceed the microphone noise.

5.0 - Powering Schemes

For those microphones that require power, the most common option is phantom feed (P48). This uses a nominal 48V DC applied to both signal leads via a 6.81k resistor. A good example of a P48 powered microphone is described in Project 93, and Project 96 describes a 48V power supply and P48 distribution scheme. For the sake of completeness, Figure 5 shows the general arrangement of a 48V phantom feed system. Although the feed resistors are shown as 6.81k, 6.8k resistors can be used instead. It is recommended that they be matched to within 0.1% so common mode rejection is not compromised.

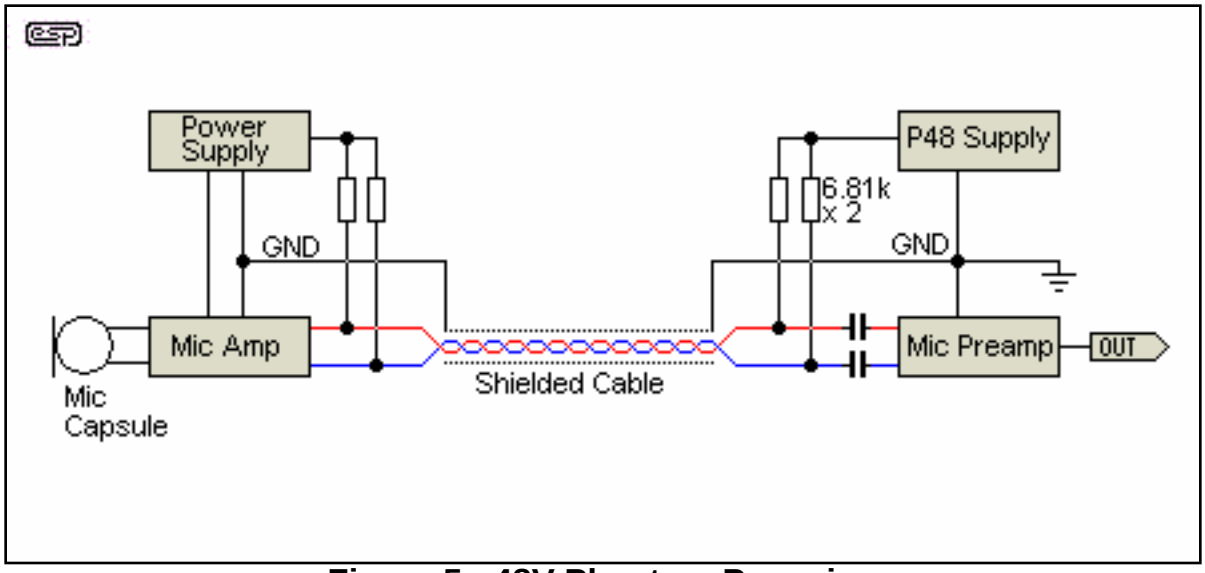


Figure 5 - 48V Phantom Powering

Although the phantom feed supply voltage has been standardised at 48V, there are many supplies that do not comply, with some operating at 30V or even less. While mics designed for P48 power might work with these low supplies, they may not. In general, phantom feed power supply *must* be able to supply 48V. The accepted voltage range for P48 is between 38V and 52V. A 'new' sub-standard has arisen, called P24 (20V - 26V), but this is (IMHO) a seriously retrograde step, creating potentially disastrous incompatibilities between competing standards.

Some time in the late 1960s, Neumann (of microphone fame) converted its valve (tube) capacitor microphones to solid-state. They decided upon a remote powering system that they called Phantom Power, and this was a trade mark of Neumann. Although other manufacturers originally avoided the trade mark (using terms such as 'simplex' instead), with time the term Phantom Power has become generic. DIN standard 45596 describes the powering of any device that uses the P48 phantom powering scheme.

Because phantom power is a common mode signal (it appears equally on both mic leads), plugging a balanced dynamic mic into a 'live' P48 powered mixer channel will not harm the microphone. The mic may make strange and/or loud and/or rude noises if the internal insulation is degraded (by age, saliva, beer, rum+coke, etc., etc.). In general, it is better to switch off the P48 supply unless it is needed.

Phantom powering is not the only way that power is supplied to microphones. Another standard is called T12 - as well as transverse feed, A-B powering, parallel powering, and occasionally by its full name ... 12V Tonader (it originated in Germany). It is not commonly found outside the film industry, and is totally incompatible with P48 powering. Adaptors can be fabricated, but require a transformer.

The T12 system uses 180 ohm feed resistors and a 12V supply, but the DC is not sent as a common mode signal like phantom feed. Referring to an XLR mic connector, the positive DC is applied on pin 2, negative on pin 3, and earth (ground) on pin 1. *However*, there is also a reverse version, with positive on pin 3 and negative on pin2. T12 powering will probably damage dynamic mics that are inadvertently connected while the T12 power is on.

Capacitor microphones using valves (tubes) will almost always require a special outboard power supply, and multi-pin connectors are common. Because of the current needed by the valve heater, the 2 - 4mA available from P48 is completely unsuitable. These power supplies will be specific to the microphone - as far as I know, there is/was no standard adopted by manufacturers, so each will be different.

6.0 - General Usage Guidelines

For live applications, the number of 'open' microphones (i.e. connected and picking up sound) should be kept to minimum. Unnecessary use of a large number of open mics creates excessive comb filter distortion. This reduces intelligibility and increases feedback problems. There are many recommendations that you may find - you may be advised to minimise the number of different microphones, for example. Exceptions are (directional overhead) for percussion and (dynamic high velocity) for bass drums. Placing any mic too close to an instrument, sound source or surface affects its response. This effect may be good or bad, depending on what you are trying to achieve.

There are many sites on the Net that give some general idea of what microphone to use where, but these are mainly a matter of opinion. Everyone who uses mics has different ideas on optimum placement and type. Some are reasonable, a few good, and a lot that are (IMO) just plain wrong. One thing that is almost never mentioned is that where you place a microphone may change its characteristics.

If a mic is placed very close to a surface (be it a wall, floor, drum skin or singer's face) it will no longer have the directional characteristics you purchased it with. Likewise, holding a mic in such a way that your hand cups the back of the mic ball will change directionality radically and unpredictably.

Something that is not well understood is just how much signal you can get from a microphone. A typical dynamic mic is easily capable of 0.5V RMS (500mV) when held close and singing (or in my case yelling) loudly. This may seem extreme, but look at the specification for the SM58 as an example. 1.85mV at 1 Pascal (94dB SPL), so 185mV

results at 114dB SPL - anyone can yell that loud at close range. You will get 500mV at just under 123dB SPL. While this may seem pretty extreme, many vocalists can achieve such levels at close range - good mic technique includes 'pulling back' from the mic when singing loudly, and getting in close for soft passages. This is a vocalist's natural compressor, but many singers don't have any mic technique at all (there seems to be an increasing number that don't have any singing technique either, but that's a different matter).

At these levels, you can completely forget using electret mics, as they will just distort badly. Because sensitivity is much higher than a typical dynamic mic, the mic may attempt to produce perhaps 3-5V RMS at the same SPL (123dB), and this is not possible with standard electret capsules. This is especially the case if it is powered by a 1.5V battery! Such mics are very common (and very useless for most applications).

7.0 - Conclusion

This article has only scratched the surface, but is a good starting place. Although there are a great many variations, the details above cover the majority of microphones in general use.

As an experiment, I was recently forced (i.e. it was something I'd been planning to do for well over a year) to build Yorick (as in "Alas poor Yorick, I knew him well" - Shakespeare). Yorick is a dummy head microphone, and details are available in Project 112 so you can build your own version. Tests are very encouraging, with an amazing ability to locate the sound source.

Yorick - My Dummy Head Microphone System

Please note that any resemblance between 'Yorick' and a certain well-known entertainer (who seems rather fond of cosmetic surgery) is completely coincidental .

Although you can purchase a Neumann dummy head mic already made, I suspect the price will be a fairly strong deterrent. There are other methods of achieving much the same result, but there is something rather nice about having a 'real' head rather than a plastic or MDF disc with mics on each side (the hair is optional of course). Each capsule uses a P93 mic amplifier board. In my case, I already had a suitable preamp that is multi-purpose, but the P93 mic amp is the easiest way to build the unit.

Introduction

A vexing question, regularly asked and rarely answered properly - Why Do Tweeters Blow When Amplifiers Distort? The answers are actually quite simple, but the common misconception is that the distortion creates harmonics, and the additional harmonic content destroys the tweeter.

Not really - woofers and midrange drivers can also blow from a distorted amp, and this is unlikely to have anything to do with harmonics. Certainly, there are additional harmonics generated, and they will be at relatively high levels, but rarely high enough to cause more than relatively minor stress to the tweeters (in particular).

It is also worth looking at the article Amplifier Clipping, as this provides some additional

information that is not covered below. Although it usually does not affect tweeters, the effects on low frequency drivers can be very harmful.

Because of the nature of music and the over-use of compression, it is not only tweeters that are at risk. Woofers can also be damaged, due simply to excessive continuous power.

Power Distribution

A great part of the mystery is uncovered when we look at two aspects of music - the average versus peak power, and the energy distribution of typical music material.

It is commonly accepted (and quite valid) that music has a peak to average ratio of about 10-20dB. This means that if the signal is being amplified by a typical 100W amplifier, the amp's power rating limits the absolute maximum power to 100W (give or take a little). Since this is the peak, the average must be somewhat lower, and we will assume 10dB for the sake of convenience. Average power is therefore 10W or less at the onset of clipping.

This is not dynamic range per se, but it is most certainly a part of the overall dynamic range of the music signal. The term 'dynamic range' usually refers to the very quietest up to the very loudest passages in a given piece of music. In some cases, there is no variation whatsoever - it starts loud, is loud in the middle, and (just to be different) finishes ... loud. The peak to average level may also be compressed, but it is difficult to reduce it to less than 10dB without it becoming flat and lifeless. If done incorrectly, it can simply become a jumbled mess with no intelligibility whatsoever (and no, I'm not going to take this to its logical conclusion and denounce various styles that may be classified as music to only a select few)

Most speakers are rated for a continuous power and an instantaneous power - the voice coil and to a lesser degree the suspension can withstand short bursts at much higher powers without damage. This does ***not*** imply that such power will be reproduced cleanly, and it will almost certainly be with a large increase in distortion. The peak power rating defines the maximum *transient* power the loudspeaker can handle without suffering electrical or mechanical (stress induced) damage.

Nearly all tweeters are rated to 'system power', and this will usually be quoted relative to a specific crossover frequency. An hypothetical tweeter may be rated at 100W system power when crossed over at 3,000Hz. The power that it can withstand is not 100W! Not

at any frequency or for any duration.

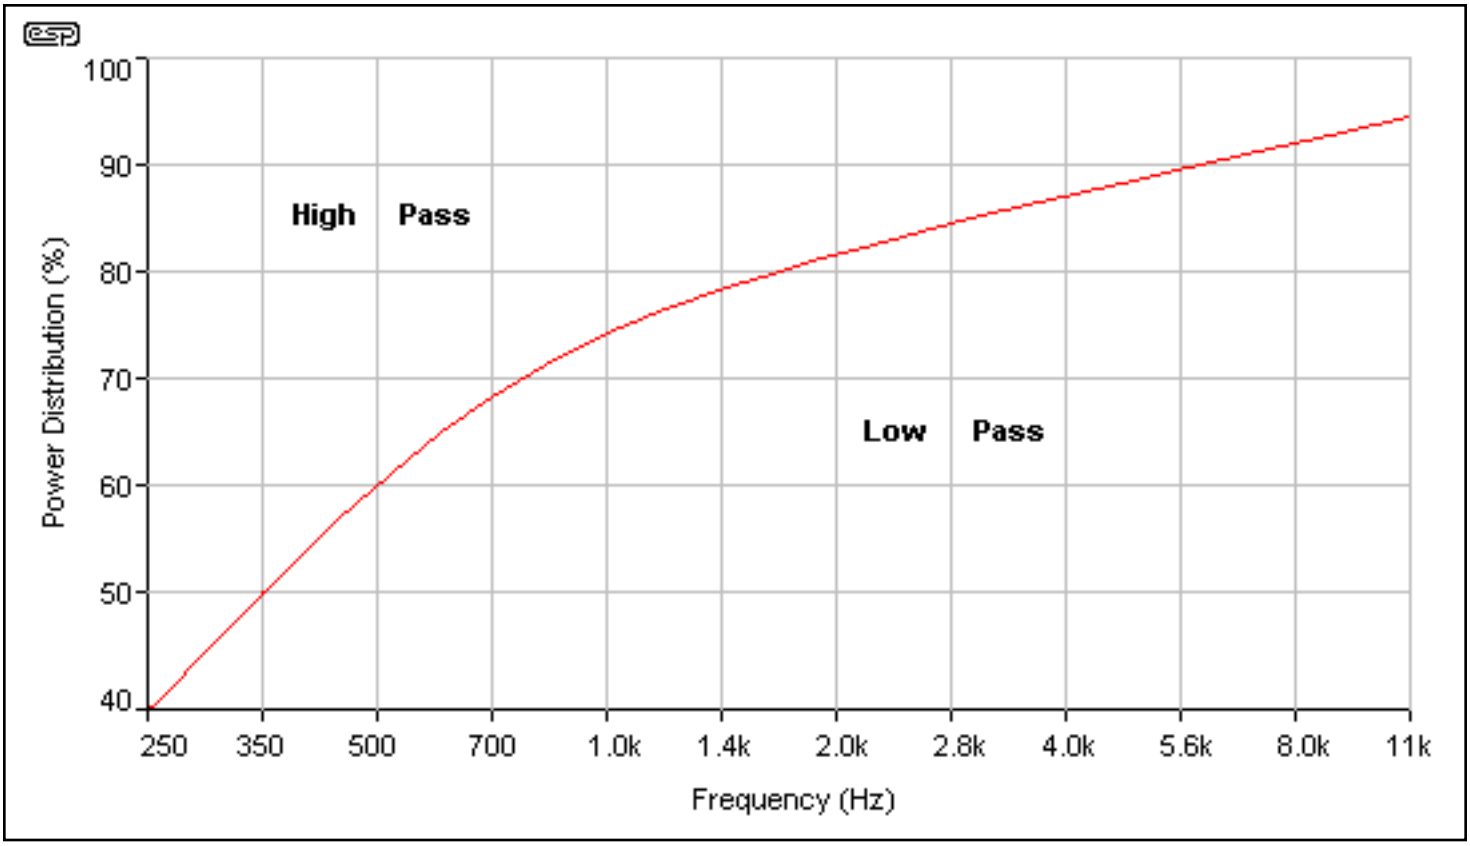

Figure 1 - Power Distribution Chart

The above power distribution table is approximate (as must be the case), and applies for 'typical' music - whatever that may be. If we look at the case for a crossover frequency of 3kHz, we can see that 85% of the power is in the low frequency spectrum, and only 15% in the high frequencies above 3kHz. It is not difficult to deduce from this that the peak power to the tweeter will be in the order of 15W at full power from the amplifier, with the average at about 1.5W

This is the way the system was designed to be used, and as long as the power amp does not clip, all is well (well, almost - read on).

Overdrive Conditions

When an amplifier is overdriven, the sound becomes distorted. This manifests itself in many ways, but the two we are interested in are the generation of harmonics, and the reduction of dynamic range - both the true dynamic range and the peak to average ratio. Let's assume that the amp is overdriven by a mere 3dB, so the average level is now 20W, and the peaks are clipping. With many systems (or listeners), this will be virtually inaudible. Careful listening will uncover the fact that there is distortion present, and there

is a definite reduction of intelligibility.

The speakers - both tweeters *and* woofers, are now being asked to absorb twice the power that would be normally obtainable, and the power is more constant - the signal is compressed by the power amp. Add to this the additional harmonics generated by the clipping waveform, and the tweeter may actually be getting up to 3 times the continuous power that was available before clipping. Peak power remains the same, since it is limited by the amplifier's power supply voltage.

Now, let's overdrive the amp by 10dB. The amp is delivering in excess of 100W, since it is reproducing square waves much of the time. The woofer will be subjected to perhaps a continuous 100W of power, and around 15W continuous will be available to the poor tweeter. Of this, probably less than 1% will be converted into sound (1% represents an efficiency of about 92dB/W/m). Ferrofluid helps, but virtually no hi-fi tweeter can withstand that sort of continuous power for any duration.

The tweeter was never designed for that! Just look at a 10W wirewound resistor for example. It is big and chunky, and made from a ceramic material that is designed to handle *a lot* of heat. Run one at 10W to find out just how much heat you will get. There is very little airflow around the tweeter voice coil, and the heat has nowhere to go. The result is that the voice coil will quickly overheat, and the adhesive that bonds the coil to its former, the former itself, and even the enamel insulation on the coil will be damaged. The result (naturally) is a dead tweeter.

As for the woofer - unless it is designed to take 100W or more continuous sinewave power, it will also overheat and eventually die. It takes a lot longer, because there is airflow around the voice coil, and the coil is bigger and has greater thermal inertia, but die it must if the abuse is maintained.

Example Power Waveforms

The following diagrams illustrate the above. Due to a complete inability on my part to create a power waveform that conformed to the examples I used before, the scale is somewhat different. In this case, the peak to average ratio is 30dB. Figure 2 shows the power over an arbitrary amount of time - it may be seconds or minutes - the result is much the same.

Note that this is not the signal waveform that you might see on an oscilloscope. This is a power vs. time waveform, and is not meant to represent anything specific - it is merely

an example.

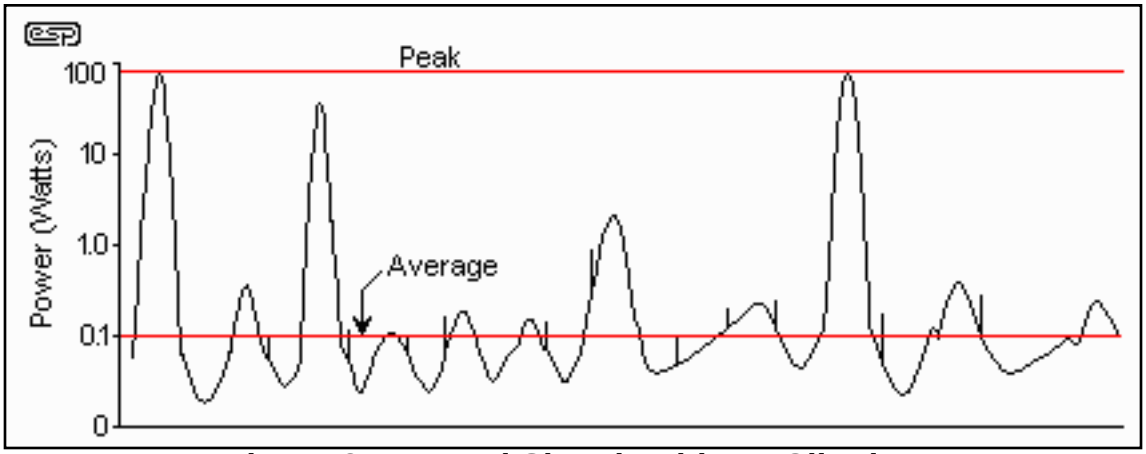

Figure 2 - Normal Signal, Without Clipping

This shows how the peak and average power are very different. Average power is 100mW, and the peak power is just under 100W, representing a 30dB ratio (approx). This can be quite typical of classical music, although there are obviously many other styles that can achieve similar ratios. It must be said that lovers of classical music are the least likely to clip their amplifiers except for short periods.

Any music with a smaller peak to average ratio simply makes the following examples happen sooner, with a smaller increase in overall volume control setting.

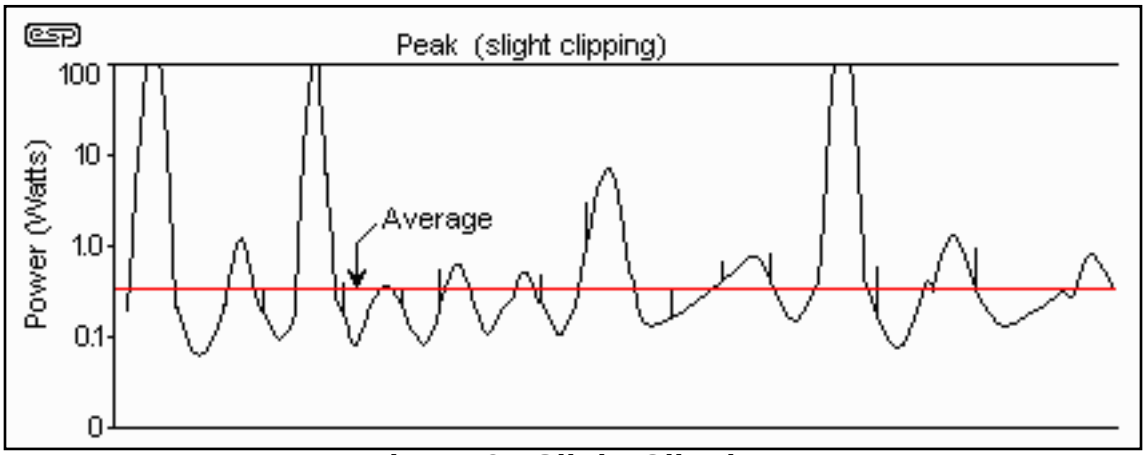

Figure 3 - Slight Clipping

Should the volume be advanced by 5dB, the peaks cannot exceed the power supply voltage, so they are clipped. This will be virtually inaudible with some music styles, but the average power is now about 300mW - an increase of almost 5dB over the previous case.

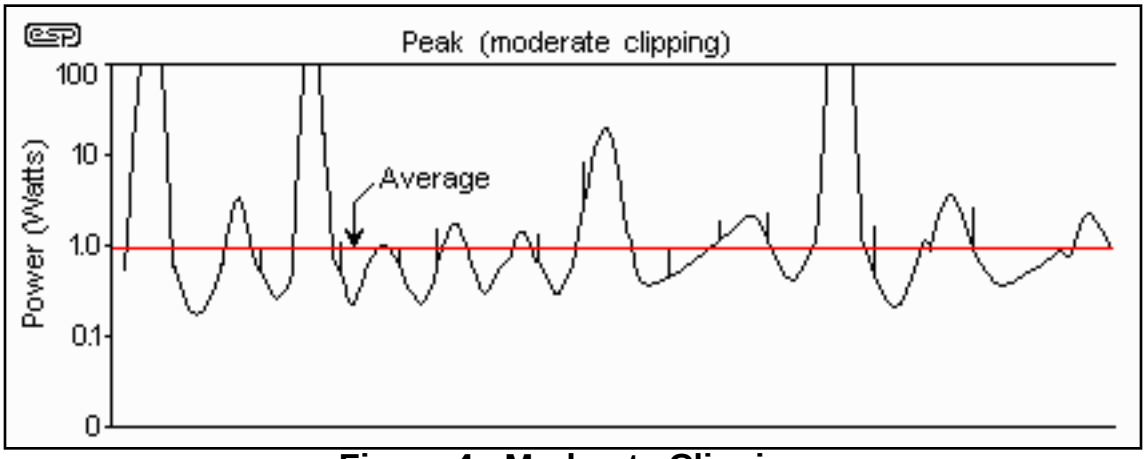

Figure 4 - Moderate Clipping

Should the volume be advanced by 10dB from the original, the peaks are clipped even more. This will be audible with most music, but is not at all uncommon. Parties are probably the worst offenders, although I have heard many high power (10kW or more) PA systems driven to at least this level of distortion. Average power is now 1 Watt, an increase of 10dB from the first example. The tweeter will probably be able to withstand this quite easily, but will no longer be linear (not that it matters any more, since there is so much amplifier distortion).

Bear in mind that most "ordinary" (non-audiophile) people will not be aware that there is anything wrong at this point! Liberal quantities of alcohol enriched fluids will ensure that ears remain unresponsive to the assault. Given the number of times I have heard about peoples' speakers "blowing up" during (or after - allegedly) a party, we can safely conclude that the requirement for more noise is far greater than any need for quality.

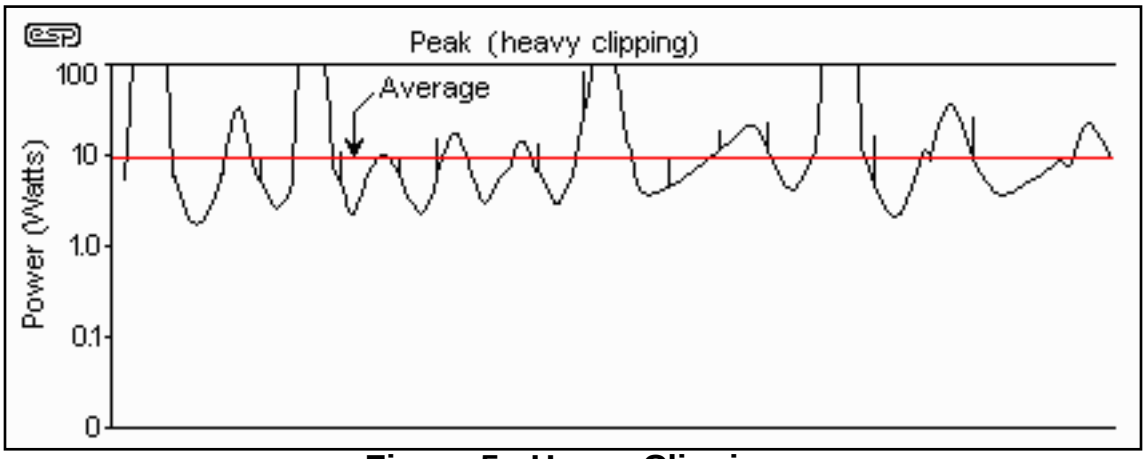

Figure 5 - Heavy Clipping

This is the bad guy! The average power is shown at 10W, but in reality is slightly higher because of the heavily clipped waveform. Few tweeters will last long with sustained power at this level - they are simply not designed for it. Midrange speakers and woofers will probably be pushed beyond their limits. Remember too, that not only is the "in band"

signal increased, but so is the out of band signal. The tweeter must now handle 10 times the normal power dissipation at all frequencies below the crossover frequency. This alone can cause damage, without the heating effects of such a high sustained power level.

Is the last example extreme? Not at all - I have actually understated the reality. When any system is driven so hard that the distortion is obvious to even untrained ears, it is reproducing close to square waves much of the time. A 100W amplifier driven to full power with a square wave will produce 200W, and when driven into heavy clipping with a music signal can easily achieve well over 100W average continuous power.

Conclusion ? ---- Exit tweeters (and/or midrange drivers and/or woofers).

Excessive Compression

All the above is valid when an amp clips, but what about speaker drivers that blow for no apparent reason, and with no clipping at all? Well, the people who create the final mix for CD (and those who actually transfer the final mastered tracks to CD format) have been using compressors for a long time - almost as long as music has been transferred to mass media in fact. What is different now, is that many of them seem to use their compressors with increasing vigour. The result is music that is compressed so heavily that the 10dB peak to average ratio we used in earlier examples no longer applies. Each individual track is compressed, the final mix is compressed, and it may be compressed yet again before it is transferred to CD. For reasons that I cannot fathom, it seems that every new CD that is released has to be 'hotter' (louder) than the last. Guess what people - there is a limit, *and we have reached it !*

Towards this end (and to make matters worse), you will find some CDs that are pre-clipped, with the peaks of the occasional loud signal neatly cut off at the top and bottom. With a peak to average ratio of perhaps 6dB in the worst cases, we need to examine the effects on the loudspeaker drivers.

Using the same 100W amp as above, it was already established that the average power would be around 10W at the onset of clipping. Although this is not a trivial amount of heat, most speakers will be able to dissipate it without too much difficulty. As the peak to average ratio is reduced by compression, the effect is exactly the same as clipping the amp, except we don't get the harsh distortion.

With a 6dB peak to average ratio, the poor loudspeaker now has to cope with an

average power of 50W as the peaks reach clipping level. Unless you are dealing with serious professional drivers that are designed for continuous high power, 50W becomes a lot of heat to dispose of. Should you be using a 200W amp, that increases to 100W - continuous! If you think 100W is trivial, try holding a 100W resistor that is dissipating its rated power. Actually, don't! You *will* burn yourself quite badly. Remember that over 99% of all power that goes into a domestic loudspeaker is dissipated as heat, with less than 1% being converted into sound.

As you can imagine, it is entirely possible to destroy drivers without ever letting the amp clip. Speaker systems rated for 200-500W almost always refer to peak power, and the average (or continuous) power rating is in reality as little as 10% of that claimed. This is perfectly alright for most people in a domestic environment, where very high SPL isn't needed. If you like to listen really loud, then you will almost certainly have problems with drivers failing. Perhaps the loudspeaker manufacturers haven't quite got the message that a great deal of music is compressed much harder than they anticipated.

The above applies to tweeters, midrange drivers and woofers equally - all can be damaged by excessive sustained power. Regardless of claims, there are actually very few loudspeakers that can withstand 100W of continuous average power for any length of time. To be able to do so requires large diameter voicecoils (preferably with aluminium formers to aid heat removal), vented pole-pieces, finned magnet assemblies and somewhere for the heat to go - preferably not just into the cabinet where it can't escape. This is not a trivial exercise, and professional drivers that can withstand that sort of abuse are very expensive indeed.

Finally, the CD (and other digital formats) allow the recording engineer/ producer to have as much bass as they want, plus some more for good measure. This can extend to very low frequencies - below audibility in fact. Tuned (vented) loudspeaker enclosures (usually) provide better bass extension than sealed types, but if there is any material recorded (and amplified) that is below the box tuning frequency, this will cause massive woofer cone excursion because the rear of the cone is unloaded below the vent tuning frequency. You won't hear the deep bass, but the cones will move very energetically indeed, and can easily reach physical excursion limits. Loudspeaker damage is guaranteed if this is done at high power levels, and can include buckled and/or detached voicecoils, broken lead-in wires and torn suspensions.

- What They Really Need to Know

Introduction

Hi-Fi - Where did it originate?

Its origin comes from the basic need to communicate. The methods of communication have become less sophisticated (i.e. more blatant) in recent years, and this same claim has probably been made by every generation for hundreds of years. There are only a few of the more subtle methods left, and music is most assuredly one of them. Naturally, the better the reproduction, the greater the enjoyment, although it must be said that a degree of education is needed to separate the good, the bad, and the indifferent. The downright ugly will not be discussed here.

As we scurry along with our lives, along the way we become excited by elements that we have not paid much attention to, largely because we are distracted by the fact that one's wife is pregnant, the bank approved the huge mortgage, pressures of work, etc. As these pressures

ease, we become more interested in the subtle aspects of music reproduction, where before it may simply have been used as something to dance to, or as background noise.

(At this stage I'm hoping my spelling is above average as I'm polishing off a Scotch & coke, and yes it is *very* dangerous to drink coke on its own!).

> This article is a contribution from Val, and is subjected to my standard editing policy only - i.e. a small change here, some extra text there, and the occasional editorial comment, as shown here in reduced font and indented. The views held are those of the author, and do not necessarily represent or contradict the opinions of Rod Elliott (ESP).

> For overseas readers who may be unaccustomed to it, the (Ed.) means editor, just in case you were wondering. No? Never mind :-) (Ed.)

About Hi-Fi

Hi-Fi has evolved into a fine art as technology has improved the quality of every aspect of audio. As is usual there are the two steps forward one step back, which occurs in many areas of technology.

For example, when we first made the transition from vinyl records to CDs, there was something very wrong with the CD sound. This was partly due to the fact that test measurements were designed to pick flaws on the existing (vinyl) system. The flaws that were overlooked cause serious distortions, therefore reducing the confidence, enjoyment and interest of the general population.

Currently we are heading into a golden era for digital sound due to higher resolutions of the digital converters and more attention is being paid to the often neglected analogue stage. I have for quite some time been improving CD players for a moderate cost and achieving a good performance for price ratio. Some owners that I know have spent AU$1,200 on machines that originally cost AU$1,000 by importing clock upgrades and souped up analogue sections. A case of too much money and not enough brains, or a lot of over engineering, maybe both.

I have had better results using quality opamps and very low ESR (Equivalent Series Resistance) capacitors for between AU$180 and AU$320, including minor repairs 60% of the time. To simplify things, the analogue stage is trying to cope with digesting a 44.1kHz square wave residual as per the original specification, and over 340 khz with single bit converters. With SACD this will be over 2 megahertz. Small amounts of this type of signal destroy the performance of the opamps and as machines gradually deteriorate (sometimes as early as 18 months.) the supply lines become infected by odd order noise. Having experimented with over 50 types of opamps, I have developed a bias for a select few. (Not necessarily the fastest

ones as they tend to oscillate, but only until you attach test equipment or remove the lid :-)

I have just returned from installing a Yamaha AV receiver and a couple of Hifi VCRs at a friendly customer's place. He greatly appreciated my prompt attention to earn some money while providing him the ability to enjoy his DVD collection, refrain from exercising and to keep him company for a short while.

Having known Rudolph for some time, we have become good friends and have a trusting relationship. That is, I suggest items and he buys what I recommend.

We came upon this relationship due to the fact that I pointed out that he was responsible not in choosing his own equipment, but choosing someone with the confidence to do it for him.

He may easily have ended on the hifi (HELL) heap, as did many of my customers, except for the fact that I got him early. Many people in an approach to obtain a great deal, take on a huge burden on deciding what are the important criteria when purchasing equipment they know little about. At this stage I know that the three most important things in a stereo system are ...

1. the recorded material,
2. the speakers,
3. the room they are performing in.

It has taken me 12 years to realise this and helps me to find people who also know what they are about in audio. Hopefully it will only take me a few essays to explain this simplification.

People who do mixes for bands pick this up, as do most women but we poor audiophiles are side-tracked by brands such as Krell, Gryphon, and their gold plated friends (plated so as not to expose the crap underneath, perhaps). A woman won't sit for very long if the atmosphere is poor, nor will a person with little or no understanding of acoustics. If something is irritating them they just leave.

That's right folks, let your wife or girlfriend listen to her favourite music through your stereo and if she stays for longer than 15 minutes you're on a winner, you either got lucky or have an engineering degree in acoustics, electronics and have been fortunate to make quick decisions based on your hearing.

Equalisation

EQ - there you go, I have just sinned according to many a purist. I have fitted many graphic equalisers in homes, cars, and PA systems and every time, yes ***every time*** there is an improvement. This also means I know how to use the tool correctly.

I agree with my customers, silver cables do make a difference and so do pointy feet, Teflon, temperature, humidity and many other factors but the holy trinity (recorded material, speakers, room) still account for 90% of it. Sometimes more but never less!

Oh, by the way my audiophile customers who loathed the thought of EQ'ing their system now have them permanently connected, and occasionally use the bypass switch to hear what they had before (YUK). As was said on many an occasion; "Its amazing how well our brain compensates for these atrocious transistor radios".

I have great respect for transistor radios, as they are not pretentious. On the other hand, very expensive equipment such as the Wilson "doggies" safeguard themselves by instructing the owner to place the speakers and themselves as far from the room boundaries as possible. Why bother, just wear headphones if your environment has such an adverse effect on the speaker. But if the speaker has any flaws you're still stuffed!

We need to do reviews on people who know how to set up our systems properly, and not just review the equipment itself.

If you're not sure whether something sounds good or bad then don't buy it, no matter what the rest of your peer group may say.

Hearing (and Seeing) Things

Recently one of my clients said the too often quoted phrase " I'm hearing things I have never heard before!". Upon which one of my associates who was under the floorboards running cables to another room commented "It was all there before, but it's just like looking at an ugly woman ... the longer I look the more uncomfortable I feel". You may need an example of "discomfort" in this context ...

From time to time I drop into my local mega stores to buy the traditional wedding toasters and such. Upon poking around and looking at the racks of ill matched and poorly displayed equipment I am approached by some unsuspecting new sales person.

Salesman	Hi! May I help you ? (Yes, please call the manager, supervisor and/or owner)
Me	This rear projection TV is poorly adjusted, will you bring the remote for it please so I can see how well it can perform?
S	Yes, just one moment (off he goes and gets it) There you go.
Me	Now can you dim the lights in this section by 70% please?
S	I don't know, just hold on.

A few minutes or so later ...

S Sorry sir, the manager says that for insurance reasons the level of light may not be adjusted.

Me Can you demonstrate this set in an appropriate environment so the contrast and brightness can be reduced from maximum? (I sense his growing frustration).

S Hold on a moment!

As he goes off, I proceed to adjust all of the TVs, reducing from maximum setting all the ones that have the greatest margin of profit. The ones they don't push or don't have in stock have the contrast set very low and look washed out. Some time later ...

Manager Please ask for assistance if you require help as we pay to have them set up.

Then I proceeded to explain that I have noticed less customers in the TV section since they have been "set up" and that if all the sets had a good picture people would be less likely to walk off.

The manager pulled me up on my next visit and asked me why there were more people in the section since I had a play with the tellies. "There are two reasons" I said, "Firstly, people feel more comfortable because they don't suffer fatigue from the poorly adjusted sets, and secondly, I adjusted the boominess out of a badly installed subwoofer located nearby."

What a way to get some free blank videotapes. I am saddened by the lack of basic knowledge of how to set up audio & video systems. Even the so-called specialist dealers (especially when they get in a bind) call on subcontractors to help them out.

> The reader may have noticed that the nearby subwoofer and the TV settings are seemingly unrelated - but we use all of our senses all of the time, and will equate bad sound with a bad picture (although the reverse is not always true). Tests have been done with an identical film clip, but different soundtrack quality. The viewers were asked to rate the picture quality *only*, and to disregard the audio. Overwhelmingly, the test group said that the clip with the highest sound quality had the best picture - but the *picture never changed!* I would cite the reference for this, if only I could recall where I saw it. (Ed.)

What They Really Need to Know

No sales person will find out anything useful unless s/he asks the right questions. This is regrettably rare.

The first question should be - *What is your room like, and how long will you live there?*

If you intend to stay in the one place, floor standers may be in order, if you move around small satellites & a subwoofer will be more flexible for placement reasons. The furnishings and the structure of the room determine the tonal character of the speaker.

What type of music do you listen to, and do you actually sit and face the speakers?

If you face the speakers while listening you may be able to determine a sense of width and depth between performers and instruments). This is called the sound stage.

"Imaging" is how well defined the performers and instruments are within the sound stage. Without going into great detail get a copy of "The ultimate demonstration disc" Chesky Records UD95. You will hear things you didn't understand before.

Do you have loud parties?

If ever you have to turn the knob past the 12 o'clock position on an amplifier STOP! Get another amp with more power and maybe more efficient and powerful speakers. (Except if you are using Rod Elliott's Better Volume Pot (Project 01). For this, 3 o'clock is its limit).

> There are some possible reasons that the above may not apply. If the source is low output, or the material was recorded at low level, it is sometimes necessary to increase the volume further than indicated. If you hear sounds of distress from the speakers, *then* you have a real problem with either the amp, speakers or both. Sometimes, if the sound is too loud, you may not even hear the distress. Place your fingers in your ears to reduce the level - you will be surprised at the result. Clipping distortion from 20kW PA systems is immediately audible when you reduce the level to something your poor ears can actually cope with (Ed.)

And lastly - *What is the budget?*

This is where the juggling begins!

If these questions are not asked you will be pointed in the "we have just the one for you" direction.

"This one is on special, a bargain" (we have just done a cash deal with the supplier who may shortly have a fire sale).

1.0 Introduction

In Part 1 of this topic some of the general principles were covered. It explained that many of the concepts applied to 'High-End' systems are at odds with one's listening pleasure, and included some reasons for this.

We tend to think that a hi-fi system should be accurate, but what exactly *is* accuracy, how do we assess it, and what happens if the system is not 'accurate' for one reason or another?

The purpose of this article is to attempt to cover the reasons that accuracy is not always

desirable or achievable, and to allow the reader to make an informed judgement of a system and its abilities. This is a somewhat daunting task, and one that may raise the ire of many, since it appears that I am suggesting that an accurate system is not useful.

It's not that an accurate system is not desirable - it is desirable in the extreme, IMHO. The problem is not so much with the system we listen to, but the source material itself. The room also plays a very important part in the equation, as the average listening room has a great many anomalies at varying frequency ranges, and can make an excellent system sound very ordinary indeed if it is unsuited to the purpose of listening to music.

I do not intend to cover room treatment in any detail - there are many articles already that do just that, and it is a non-trivial exercise at best. As an example though, I am sure we have all seen photographs on the Net and in magazines of superlative looking systems in a stark room, having no carpet and a nice tiled floor, minimal furnishings, and lots and lots of glass windows. While this may well suit the purposes of the photographer, a system in such a room will almost always be a complete sonic disaster.

Likewise, having heard a piece of music on the radio (for example), you go and buy the CD, only to get it home and discover that it is over equalised, compressed to within an inch of its life, and has excessive and boomy bass. I have several such recordings, and my system is *too* accurate, revealing every flaw with punishing accuracy. Under these conditions, an accurate system is not ideal - in fact it is a disaster! Music you might otherwise be able to enjoy is ruined, and a typical "high-end" audio system is completely inappropriate for a great many recordings. For example, it should not be necessary to switch off the subwoofer to play some CDs.

2.0 Accuracy

Accuracy in a general context could mean that the system will play the source material with no changes to the frequency response, harmonic structure, relative phase of the signals, or anything else. While this may seem to be the ideal situation, it is never achieved in a practical application. Non-linear distortion will be added, and this changes the harmonic structure of the signal. Very small amounts of non-linear distortion are added by most amplifiers and preamps, much greater amounts by all speakers. While the levels will rarely be objectionable with well designed equipment, that the signal undergoes some distortion is an absolute - there is no such thing as a zero distortion amplifier or transducer.

Certainly, the distortion levels may be able to be reduced to below the noise floor of the

listening room, but it is still there - whether you hear it or not is the only thing that is important. The concept of 'masking' - where one signal is deemed inaudible because of a higher level signal nearby does not always work as well as many designers may hope. A perfect example is MP3, where all 'masked' signals are removed as part of the compression algorithm, and 'near CD quality' MP3 recordings lack any sense of imaging or 'space' because we use the 'inaudible' signals as a cue for image placement. Since they have been removed, we lose that ability.

Frequency response will always be modified to some extent. Again, whether these changes are audible is the only question that is important - you (as the listener) may actually *want* to modify the frequency response, either to compensate for recording quality, room effects or even hearing loss. Should you suffer from a loss of high frequencies, then the ability to compensate (at least to some degree) will enhance your enjoyment, although it is probable that others will find the sound overly "bright".

Phase shifts occur in all aspects of electronics to some degree, and are particularly easily measured with crossover networks. Fortunately, our sensitivity to static phase shifts is rather low, and we can tolerate huge phase shifts with no noticeable change in sound quality. Relative phase is another matter, and any piece of electronics or transducer array that changes the phase of signals dynamically (almost always deliberately) will cause very audible effects. Rotating speakers (e.g. electronic organ Leslie cabinets), or phase shifting networks (e.g. phaser pedals for guitar effects) have a profound effect, but these are rarely found in hi-fi systems. Loudspeaker drivers inadvertently wired out of phase cause static cancellations of some frequencies, and this is almost always audible.

Phase shift is one of the least understood of the distortion mechanisms, but it is important to understand that the phase of any signal is changed radically by distance, even if it started out as perfect. Sound travels at 345m/s in dry air at sea level at around 22°C, but this changes with altitude, temperature and humidity. This works out to be .354mm/us, or 35.4mm/100us. Given that a typical listening distance may be 2 metres, that represents a time delay of 5650us, or 5.65ms. The chart below shows the relative phase shift of a perfectly phase coherent signal, at distances of 1 and 2 metres.

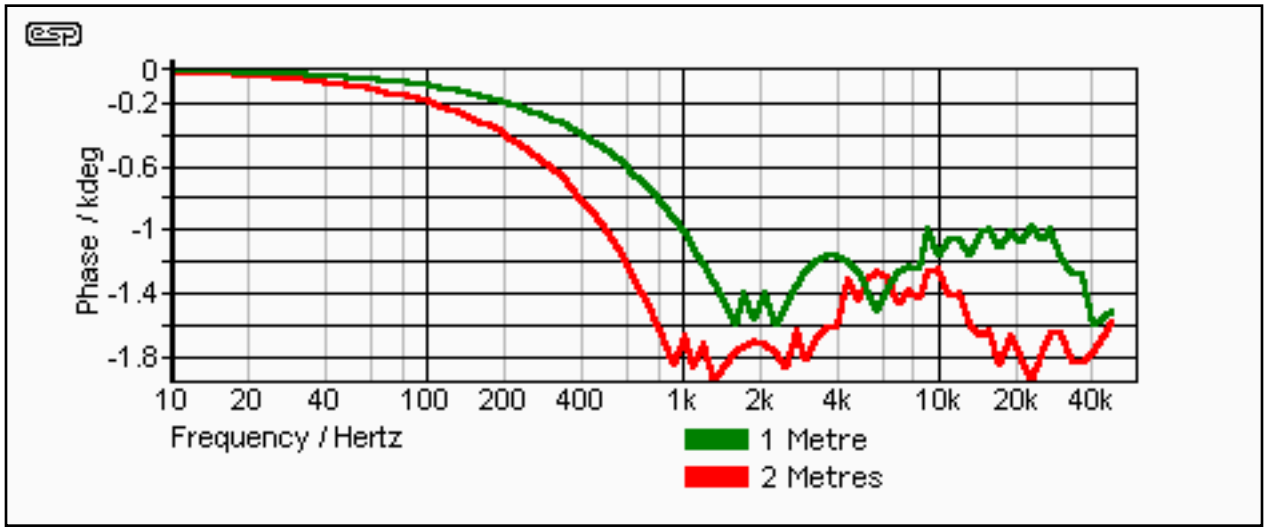

Figure 1 - Phase Shift at 1 & 2 Metres Listening Distance

At a maximum of 2,000°, this is hardly 'phase coherent' (note that the chart is in k degrees), but it happens with every speaker (including the human kind) in every room, under all circumstances. This is not distortion, but simple reality, to which our hearing is fully accustomed. The phase shift is the result of the time delay suffered by the signal as it travels through the air, and is completely normal. Hearing is not affected by this (radical) change for the simple reason that it occurs all the time, with every sound source. It also renders the claims that some speakers can reproduce a perfect squarewave rather suspect, as shown below ...

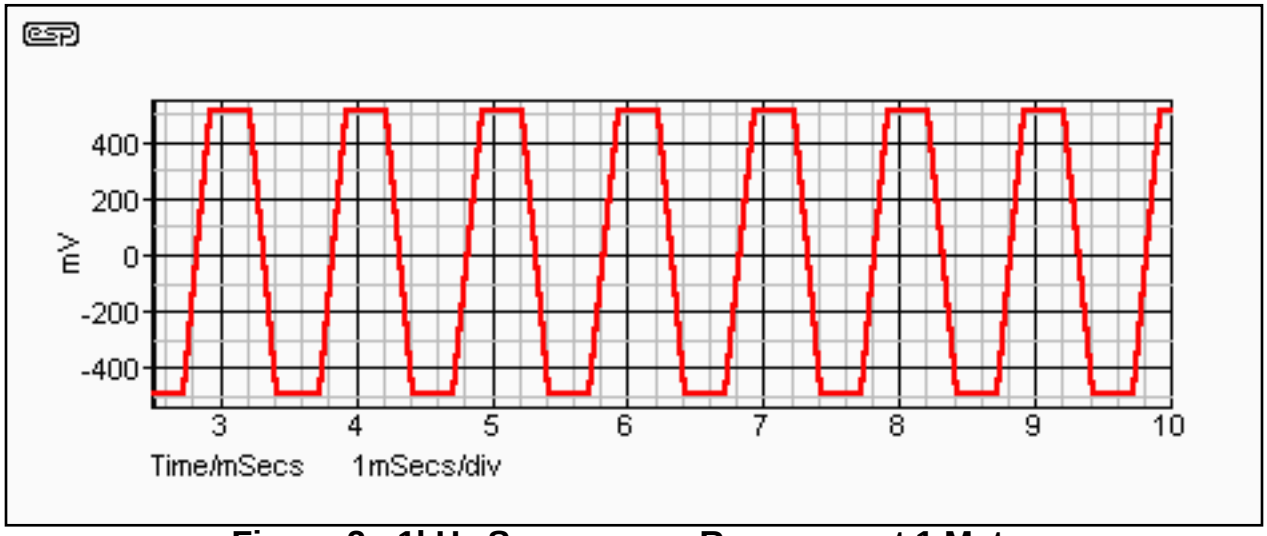

Figure 2 - 1kHz Squarewave Response at 1 Metre

Not what I would call a perfect squarewave, and naturally the shape varies with distance and frequency. The room will also have a profound effect on the waveform, and from tests I have done, I know that perfectly ordinary (non time-aligned) loudspeakers can also reproduce a squarewave - provided one is sufficiently patient to find the 'correct' microphone placement. As a matter of interest, it is almost impossible for *any* loudspeaker to introduce a phase shift of this magnitude, regardless of crossover

topology or baffle layout. As I have pointed out on several occasions, phase shift in and of itself is usually considered to be inaudible, but the effects of combining signal sources with different phase shift characteristics can be very audible indeed.

The greatest distortion is one of time itself - the re-creation of a piece of music without the musicians being present is obviously a "distortion". 100 years ago, if you wanted to listen to music, then the musicians would be right there with you, and there was no distortion - you heard exactly what you heard at your seating position. Others would hear things differently, because they would hear the same music from a different location, thus changing the sound. It is no longer necessary to have the musicians present, but for the purposes of any discussion, this distortion is usually ignored. It shouldn't be, because this is the one thing that people strive for - to make their system sound like the original performance. The fact is that this is impossible, because the original performance was recorded under conditions that cannot be duplicated in a home system, in a normal room, and with all the changes that have been made during the recording process itself. Indeed, even when present at a concert, you will hear the sound differently from different locations - which is right, which is wrong? Obviously, no position where all instruments are heard clearly is wrong, but they are different regardless.

2.1 When, And Only When You Need It

If your or my system is accurate yet cannot reproduce the music in a manner that is enjoyable, what is the point? One could scour the record shops in a quest for CDs that are well recorded and properly mixed (i.e. without excessive compression or use of effects), but if the CDs you can find have music that you don't particularly like, again, what is the point?

If you happen to enjoy "pop", contemporary or alternative music, then you absolutely need some method for correcting the often appalling mix quality, since a great many of such recordings are deliberately mixed to sound "good" on exceptionally average systems (such as factory installed car sound and department store "hi-fi"). If you like classical or string quartets, choral or organ music, you are not necessarily safe there either, since it is very common for "post processing" to be performed by the mastering engineer.

The fact of the matter is that the *only* way you will hear exactly what was intended by the recording engineers is to hear it in the studio where the recording was mixed, using the same speakers at the same level - that this is impractical in the extreme should be fairly obvious. No system and home environment will match the acoustics of the studio or the

monitor speakers used. Even if you got lucky with a "fairly good" match, it would only be applicable for a single studio at the same level that was used for mixing.

Equalisation is considered a rude word by most in the high-end (or audiophile) community, yet an equaliser, or even tone controls, can rescue an otherwise unlistenable recording. Exactly when and why tone controls got such a bad name is unclear, but my next preamp will most certainly use them. It is probable that they will be used only on a very few CDs, but at least my investment in the music is retained if I can actually listen to it.

What is really at issue here is that "accuracy" has become the catch-cry of some of the high end of the audio fraternity, and while it is absolutely essential that a system is capable of a flat response and full dynamics (accuracy), this is a very open-ended situation because the quality of recordings is so variable. It would be nice if orchestral recordings (for example) were labelled "No EQ" or "No Post-processing" so that we would know that the response had not been tampered with beforehand, but this is not the case (at least for any I have seen).

There are Audiophile recordings available, but if you can't find any with the artists of your choice or the material of your desire, then they are of no use to you. In some cases, while the recording quality may be excellent, the musicianship may be left wanting. This is a no-win situation, and will remain so until tone controls take their rightful place in systems once again.

It goes without saying that tone controls are not the real answer (even though I just seem to have said they were), but if they can be used to rescue a recording (or several), then they are worth inclusion. Ultimately, hi-fi is about music and enjoyment, and if someone *really* enjoys listening to everything with the bass turned way up, then the facility should be available. Musical enjoyment is a very personal thing, and for a great many people the audiophile world has shut them out because such systems do not have the features they desire.

No-one has the right to impose their standards on everyone else, yet by insisting that systems have a flat frequency response that cannot be adjusted (not even balance controls are used in many systems) you are allowing recording engineers to impose their preferred sound onto you - if you don't like it, there is nothing you can do about it, apart from return the CD and demand your money back (not a bad thing to do, by the way, but you may deprive yourself of a lot of music you'd otherwise enjoy).

I have commented elsewhere on these pages that RIAA phono equalisation does not

have to be super accurate, since no-one has any way of knowing what additional EQ was applied to the cutting lathe at the time of mastering. That the playback EQ should be accurate to within a dB or so is a sensible approach, and deficiencies can easily be made good by the use of tone controls - again assuming that they are available.

What of systems where the user can adjust each frequency band in a multi-way active system? By the normal high-end standards, we should be appalled by such an idea, but it makes sense. Given that music is such a personal thing, why should anyone have to listen to the system as it was designed and built?

There is no reason that people should not be able to tailor the sound to their preference if it increases their enjoyment of the music of their choice. It will rarely be accurate, but what difference should that make? If you don't like it the way the user has set everything up, that is your problem, not theirs. As long as the listeners (owners) are happy with what they can achieve, to get the sound they like, then that is all that matters. You can go home and listen to your system set up the way *you* like - naturally, I consider the ability to get a flat frequency response (as well as good transient response, low distortion, etc.) as essential in all of this, but whether it will be used like that is another matter altogether.

2.2 Linearity Vs. Accuracy

Accuracy in the sense that I use it here is primarily about frequency response, with phase and transient response following closely behind. Linearity is usually taken to mean freedom from non-linear effects, and specifically harmonic and intermodulation distortions. As noted above, these are always present to some degree, and usually vary with amplitude (loudness) and frequency. Most at risk are extremely low and high frequencies - low frequencies because they demand large amounts of movement in the transducer, and high frequencies because of limitations within many tweeters.

Quoting THD (Total Harmonic Distortion + noise) is a pointless exercise if the waveform of the distortion component is not disclosed (which it generally is not). Two amplifiers having *apparently* identical amounts of distortion can sound very different indeed, and this has led to THD measurements being declared 'useless'. Provided you know what kind of distortion is present, it is generally easy to make a prediction as to whether it will sound "good" or "bad". Solid state amplifiers with 1% crossover (or notch) distortion sound unquestionably bad, while a valve amp with 1% 2nd harmonic distortion will sound good (especially by comparison).

Linearity is important, since even relatively small amounts of THD can create much larger amounts of IMD (Intermodulation Distortion), where each frequency being reproduced beats or mixes with other frequencies to create new frequencies that were not present in the recording. This happens with electronics, but is usually much more pronounced with transducers, and for this reason (amongst others), it is common to use separate transducers for different bands of frequencies. The simplest is a woofer and a tweeter, with a crossover network that divides the signal and sends the low frequencies to the woofer, and high frequencies to the tweeter.

Transducer non-linearity usually exceeds that of electronics by a great deal, but tends to be 'softer' and less audible. Not so however when the linear excursion limits of a speaker are exceeded - the distortion produced can then be very audible and highly objectionable. For systems that are used at low levels this is not so much of a problem, but to obtain good linearity at even reasonably high levels requires that drivers be limited to a maximum of about 1 decade (a little over 3 octaves). To manage the whole audible frequency range, the signal may be split as follows ...

Low Bass	Mid Bass	Upper Mid	Treble
20 - 160Hz	160-1280Hz	1280-10kHz	10kHz-20kHz

Unfortunately, for a number of reasons, this is not a practical separation of the signal. Because of the difficulties with bass (in particular) a more common split may be as follows ...

Low Bass	Mid Bass	Upper Mid	Treble
20 - 80Hz	80-500Hz	500-3kHz	3kHz-20kHz

This too has problems - there is a crossover frequency at 500Hz that may cause problems for the natural reproduction of voices (a very critical requirement for any system). This is not insurmountable though, and the second variation is fairly common (with some minor changes depending on philosophy, driver specifics, etc.).

2.3 Distortion

Distortion actually covers every aspect of the system. Technically, if the volume is changed, you introduce distortion (amplitude distortion), since you are not listening at the same level that was used when the music was recorded or mastered. In turn, this

changes the response of your hearing, with the bass and treble seeming to be less pronounced as volume (SPL) is reduced (and vice versa). The change in amplitude is not considered as distortion, but it should be, since the relative loudness of the high and low frequencies is changed relative to the original.

The term "distortion" is usually taken to mean non-linear (harmonic or intermodulation) distortion, but the true meaning is *any* change that makes the reproduction different from the original. Since THD and IMD have already been covered, I shall only look at other changes to the system that change the way the sound is heard, versus the way it was recorded.

From this perspective, it is quite obvious that all hi-fi systems introduce distortion (of the original performance). The ability to manipulate tone controls, graphic or parametric equalisers, or crossover network frequencies and/or levels may be used to *reduce* the distortion introduced by the simple act of changing the listening level.

Years ago, it was common for systems to have a "loudness" control, often incorporated with the volume pot. That these almost never worked correctly is a given, since no attempt was ever made to provide any method of calibrating the "effect" to the SPL in the listening room. Needless to say loudness controls went away, but with them, in most high-end systems, so too did tone controls and even the balance control. While the loss of the loudness switch went almost un-noticed, the other losses should be missed, since they are useful.

It is far more convenient to be able to change a balance control or tone controls, than to have to move furniture about or listen at a specific volume all the time. Consequently, it could be said that most systems are "distorted" most of the time, since what you hear is not the same as what was recorded.

3.0 Conclusion

The dream of a system that is 'dead flat' (in frequency response) is not necessarily a good idea, since it is likely that it will be far less accurate than expected for a great many recordings. While technical excellence is always a good thing, it is unwise to place that above all else, and even less wise to assume that ever greater levels of excellence will lead to ever greater enjoyment.

What of the average person (non-audiophile) who wants a really good system? There is precious little available catering to that market at present, and the choices are limited to

the department store offerings (often with speaker boxes that look like something from outer space - and sound like it too!), or they can go and argue with the sales-thing at a high-end audio outlet, who will try to convince them that they don't want (or need) tone controls, balance controls, X-Bass or any of that "rubbish". Well, guess what? They *do* want them - all of them (well, most anyway). Will they use them with a good system? Probably not - initially they will all be used (usually radically), but after a while they will adjust and learn to listen to all of the music, and not just the bass. If it turns out that they do listen with the bass right up, then again, that is their right - it is their system, after all.

The purpose of a sound system in your home is for one thing only - to listen to music (and movie soundtracks, of course). Whether your system is optimal from a purist's perspective is immaterial. If *you* enjoy the sound, then you have a system that is perfect from your perspective. If others enjoy it too, then so much the better. The idea is for you to put together a system for yourself and (perhaps) your family - not other people. Should others in your household prefer a different sound, then there are two choices ... either you have two or more systems for different sounds, or use a system that can be tailored to suit each listener, or modified at will to suit classical music one session, rock the next, or tweaked further to suit the DVD currently playing.

The bottom line is that any sound system's ultimate purpose is for the enjoyment of music - not to follow the latest trend, or as a test vehicle for the latest magic stone, newest speaker leads or pure silver interconnects, but to enjoy music. Period.

Once you are in the position of listening for flaws in the system, you are no longer listening to the music - certainly you *hear* the sounds, but if you are so interested in the reproduction you can no longer concentrate on the music itself. You may use test instruments to analyse the response, phase alignment, spectral decay and distortion of your system, but if, after all of that, it still sounds good - who cares?

What of SET (Single Ended Triode) amplifiers and other systems that introduce often quite high levels of distortion? If this is what the listener likes to hear, then that is his prerogative, but it means that *all* music will be subjected to the same distortion. This may sound very nice with some recordings but revolting with others - again, limiting one's choice rather drastically. However, if this is what the owner wants, then fine. Such owners should resist the temptation to insist that others follow their path to 'nirvana' - most people don't want and don't need distortion.

Introduction

The term 'amplifier' has become generic, and is often thought (at least by some) to mean a power amplifier for driving loudspeakers. This is not the case (well, it *is*, but it is not the *only* case), and this article will attempt to explain some of the basics of amplification - what it means and how it is achieved. This article is not intended for the designer (although designers are more than welcome to read it if they wish), and is not meant to cover all possibilities. It is a primer, and gives fairly basic explanations (although some will no doubt dispute this) of each of the major points.

I will explain the basic amplifying elements, namely valves (vacuum tubes), bipolar transistors and FETs, all of which work towards the same end, but do it differently. This article is based on the principles of audio amplification - radio frequency (RF) amplifiers are designed differently because of the special requirements when working with high frequencies.

Not to be left out, the opamp is also featured, because although it is not a single "component" in the strict sense, it is now accepted as a building block in its own right.

This article is not intended for the complete novice (although they, too, are more than welcome), but for the intermediate electronics or audio enthusiast, who will have the most to gain from the explanations given.

Basic Terminology

Before we continue, I must explain some of the terms that are used. Without knowledge of these, you will be unable to follow the discussion that follows.

Electrical Units

Name	Measurement of	A.K.A.	Symbol
Volt	electrical "pressure"	voltage	V
Ampere	the flow of electrons	current	A, I
Watt	power		W, P
Ohm	resistance to current flow		Ω,R
Ohm	impedance, reactance		Ω,X
Farad	capacitance		F, C
Henry	inductance		H, L

Hertz	frequency		Hz

Note: A.K.A. means "Also Known As". Although the Greek letter omega is the symbol for Ohms, I shall use the word Ohm or the letter "R" to denote Ohms. Any resistance of greater than 1,000 Ohms will be shown as (for example) 1k5, meaning 1,500 Ohms, or 1M for 1,000,000 Ohms. The second symbol shown in the table is that commonly used in a formula.

When it comes to Volts and Amperes (Amps), we have alternating current and direct current (AC and DC respectively). The power from a wall outlet is AC, as is the output from a CD or tape machine. The mains from the wall outlet is at a high voltage and is capable of high current, and is used to power the amplifying circuits. The signal from your audio source is at a low voltage and can supply only a small current, and must be amplified so that it can drive a loudspeaker.

Impedance

A derived unit of resistance, capacitance and inductance in combination is called impedance, although it is not a requirement that all three be included. Impedance is also measured in Ohms, but is a very complex figure, and often fails completely to give you any useful information. The impedance of a speaker is a case in point. Although the brochure may state that a speaker has an impedance of 8 Ohms, in reality it will vary depending on frequency, the type of enclosure, and even nearby walls or furnishings.

Units

In all areas of electronics, there are smaller and larger amounts of many things that would be very inconvenient to have to write in full. For example, a capacitor might have a value of 0.000001F or a resistor a value of 150,000 Ohms. Because of this, there are conventional units that are applied to make our lives easier (well, once we are used to using them, anyway). It is much easier to say 1uF or 150k (the same as above, but using standard units). These units are described below.

Conventional Metric Units

Symbol	Name	Multiplication
p	pico	1×10^{-12}
n	nano	1×10^{-9}

μ	micro	1×10^{-6}
m	milli	1×10^{-3}
k	kilo	1×10^{3}
M	Mega	1×10^{6}
G	Giga	1×10^{9}
T	Tera	1×10^{12}

Although commonly written as the letter "u", the symbol for micro is actually the Greek letter mu as shown. Because this would require the continuing use of a small graphic, I shall use the letter "u".

In audio, Giga and Tera are not commonly found (not at all so far - except for specifying the input impedance of some opamps!). There are also others (such as femto - 1×10^{-15}) that are extremely rare and were not included. Of the standard electrical units, only the Farad is so large that the defacto standard is the microFarad (uF). Most of the others are reasonably sensible in their basic form.

Amplification Basics

The term "amplify" basically means to make stronger. The strength of a signal (in terms of voltage) is referred to as amplitude, but there is no equivalent for current (curritude?, nah, sounds silly). This in itself is confusing, because although "amplitude" refers to voltage, it contains the word "amp", as in ampere. Maybe we should introduce "voltitude" - No? Just live with it.

To understand how any amplifier works, you need to understand the two major types of amplification, and a third "derived" type:

- Voltage Amplifier - an amp that boosts the voltage of an input signal
- Current Amplifier - an amp that boosts the current of a signal
- Power Amplifier - the combination of the above two amplifiers

In the case of a voltage amplifier, a small input voltage will be increased, so that for example a 10mV (0.01V) input signal might be amplified so that the output is 1 Volt. This

represents a "gain" of 100 - the output voltage is 100 times as great as the input voltage. This is called the voltage gain of the amplifier.

In the case of a current amplifier, an input current of 10mA (0.01A) might be amplified to give an output of 1A. Again, this is a gain of 100, and is the current gain of the amplifier.

If we now combine the two amplifiers, then calculate the input power and the output power, we will measure the power gain:

$P = V \times I$ (where I = current, note that the symbol changes in a formula)

The input and output power can now be calculated:

$P_{in} = 0.01 \times 0.01$ (0.01V and 0.01A, or 10mV and 10mA)

$P_{in} = 100uW$

$P_{out} = 1 \times 1$ (1V and 1A)

$P_{out} = 1W$

The power gain is therefore 10,000, which is the voltage gain multiplied by the current gain. Somewhat surprisingly perhaps, we are not interested in power gain with audio amplifiers. There are good reasons for this, as shall be explained in the remainder of this page. Having said this, in reality all amplifiers are power amplifiers, since a voltage cannot exist without power unless the impedance is infinite. This is never achieved, so some power is always present, but it is convenient to classify amplifiers as above, and no harm is done by the small error of terminology.

Input Impedance

Amplifiers will be quoted as having a specific input impedance. This only tells us the sort of load it will place on preceding equipment, such as a preamplifier. It is neither practical nor useful to match the impedance of a preamp to a power amp, or a power amp to a speaker. This will be discussed in more detail later in this article.

The load is that resistance or impedance placed on the output of an amplifier. In the case of a power amplifier, the load is most commonly a loudspeaker. Any load will require that the source (the preceding amplifier) is capable of providing it with sufficient voltage and current to be able to perform its task. In the case of a speaker, the power

amplifier must be capable of providing a voltage and current sufficient to cause the speaker cone(s) to move. This movement is converted to sound by the speaker.

Even though an amplifier might be able to make the voltage great enough to drive a speaker cone, it will be unable to do so if it cannot provide enough current. This has nothing to do with its output impedance. An amplifier can have a very low output impedance, but only be capable of a small current (an operational amplifier, or opamp is a case in point). This is a very important point, and needs to be fully understood before you will be able to fully appreciate the complexity of the amplification process.

Output Impedance

The output impedance of an amplifier is a measure of the impedance or resistance "looking" back into the amplifier. It has nothing to do with the actual loading that may be placed at the output.

For example, an amplifier has an output impedance of 10 Ohms. This is verified by placing a load of 10 Ohms across the output, and the voltage can be seen to decrease by 1/2. However, unless this amplifier is capable of substantial output current, we might have to make this measurement at a very low output voltage indeed, or the amplifier will be unable to drive the load.

Another amplifier might have an output impedance of 100 Ohms, but be capable of driving 10A into the load. Impedance and current are completely separate, and must not be seen to be in any way equivalent. Both of these possibilities will be demonstrated later in this article.

Feedback

Feedback is a term that creates more and bloodier battles between audio enthusiasts than almost any other. Without it, we would not have the levels of performance we enjoy today, and many amplifier types would be unlistenable without it.

Feedback in its broadest sense means that a certain amount of the output signal is "fed back" into the input. An amplifier - or an element of an amplifying device - is presented with the input signal, and compares it to a "small scale replica" of the output signal. If there is any difference, the amp corrects this, and ideally ensures that the output is an exact replica of the input, but with a greater amplitude. Feedback may be as a voltage or current, and has a similar effect in either case.

In many designs, one part of the complete amplifier circuit (usually the input stage) acts as an error amplifier, and supplies exactly the right amount of signal to the rest of the

amp to ensure that there is no difference between the input and output signals, other than amplitude. This is (of course) an ideal state, and is never achieved in practice. There will always be some difference, however slight.

Signal Inversion
When used as voltage amplifiers, all the standard active devices invert the signal. This means that if a positive signal goes in, it emerges as a larger - but now negative - signal. This does not actually matter for the most part, but it is convenient (and conventional) to try to make amplifiers non-inverting. To achieve this, two stages must be used (or a transformer) to make the phase of the amplified signal the same as the input signal.

The exact mechanism as to how and why this happens will be explained as we go along.

Design Phase
The design phase of an amplifier is not remarkably different, regardless of the type of components used in the design itself. There is a sequence that will be used most of the time to finalise the design, and this will (or should) follow a pattern.

- **Power Output vs. Impedance**
  The power output is determined by the load impedance and the available voltage and current of the amplifier. An amplifier that is capable of a maximum of 2A output current will be unable to provide more, just because you want it to. Such an amp will be limited to 32W peak (or 16W RMS) into 8 ohms, regardless of the supply voltage. Likewise, and amp with a supply voltage of +/-16V will be unable to provide more than 16W RMS into 8 ohms, regardless of the available current. Having more current available will allow the amp to provide (for example) 32W into 4 ohms (4A peak current) or 64W into 2 ohms (8A peak current), but will give no more power into 8 ohms than the supply voltage will allow.

- **Driver Current**
  Especially in the case of bipolar transistors, the driver stage must be able to supply enough current to the output transistors - with MOSFETs, the driver must be able to charge and discharge the gate-source capacitance quickly enough to allow you to get the needed power at the highest frequencies of interest. With valves, the driver needs to be able to supply enough current to supply the bias resistors only, since the valve grid draws little or no current (except for the special case of Class-AB2).

  For the sake of simplicity, if bipolar output transistors have a gain of 20 at the maximum current into the load, the drivers must be able to supply enough base

current to allow this. If the maximum current is 4A, then the drivers must be able to supply 200mA of base current to the output devices.

- **Prior Stages**
  The stages that come before the drivers must be able to supply sufficient current for the load imposed. The Class-A driver of a bipolar or MOSFET amp must be able to supply enough current to satisfy the base current needs of bipolar drivers, or the gate capacitance of MOSFETs.

  Again, using the bipolar example from above, the maximum base current for the output transistors was 200mA. If the drivers have a minimum specified gain of 50, then their base current will be ...

  200 / 50 = 4mA.

  Since the Class-A driver must operate in Class-A (what a surprise), it will need to operate with a current of 1.5 to 5 times the expected maximum driver current, to ensure that it never turns off. The same applies with a MOSFET amp that will expect (for example) a maximum gate capacitance charge (or discharge) current of 4mA at the highest amplitudes and frequencies.

  This is not normally an issue with valve amps, as the early stages of the amp are not loaded with any significant impedance. No further determinations are needed (other than the normal loading effects of valve stages in general).

- **Input Stages**
  The input stages of all transistor amps must be able to supply the base current of the Class-A driver. This time, a margin of between 2 and 5 times the expected maximum base current is needed. If the Class-A driver needs to supply a quiescent current of (say) 8mA, the maximum current will be 12mA (quiescent + driver base current. Assuming a gain of 50 (again), this means that the input stage has to be able to supply 12 / 50 = 240uA, so it must operate at a minimum current of 240uA * 2 = 480uA to preserve linearity.

- **Input Current**
  The input current of the first stage determines the input impedance of the amplifier. Using the above figures, with a collector current of 480uA, the base current will be 4.8uA for input devices with a gain of 100. If maximum power is developed with an input voltage of 1V, then the impedance is 208k (R = V/I).

  Since the stage must be biased, we apply the same rules as before - a margin of between 2 and 5, so the maximum value of the bias resistors should be 208 / 2 = 104k. A lower value is preferred, and I suggest that a factor of 5 is more

appropriate, giving 208 / 5 = 42k (47k can be used without a problem).

These are only guidelines (of course), and there are many cases where currents are greater (or smaller) than suggested. The end result is in the sound of the amp, and the textbook approach is not always going to give the expected result.

Types Of Amplifier Devices

For the purposes of this article, there are three different types of amplifying devices, and each will be discussed in turn. Each has its strengths and weaknesses, but all have one common failing - they are not perfect.

A perfect amplifier or other device (known generally as "ideal") will perform its task within certain set limits, without adding or subtracting anything from the original signal. No ideal amplifying device exists, and as a result, no ideal amplifier exists, since all must be built with real-life (non-ideal) devices.

The amplifying devices currently available are:

- Vacuum Tube (Valve)
- Bipolar Junction Transistor (BJT)
- Field Effect Transistor (FET)

There are also some derivatives of the above, such as Insulated Gate Bipolar Transistors (IGBT), and Metal Oxide Semiconductor Field Effect Transistors (MOSFET). Of these, the MOSFET is a popular choice among many designers due to some desirable characteristics, and these will be covered in their own section.

All of these devices are reliant on other non-amplifying ("support") components, commonly known as passive components. The passive devices are resistors, capacitors and inductors, and without these, we would be unable to build amplifiers at all.

All the devices we use for amplification have a variable current output, and it is only the way that they are used that allows us to create a voltage amplifier. Valves and FETs are voltage controlled devices, meaning that the output current is determined by a voltage, and no current is drawn from the signal source (in theory). Bipolar transistors are current controlled, so the output current is determined by the input current. This means that no voltage is required from the signal source, only current. Again, this is in theory, and it is not realisable in practice.

Only by using the support components can we convert the current output of any of these amplifying devices into a voltage. The most commonly used for this purpose is a resistor.

Common Limiting Ratings

All active devices have certain parameters in common (although they will have different naming conventions depending on the device). Essentially these are ...

- **Maximum Voltage** - The maximum voltage that may be applied between the main terminals of the device. This varies from perhaps as low as 25V (sometimes even less) for small signal transistors and FETS, and up to 1,200V or more for some valves and high voltage transistors. MOSFET voltages are typically up to about 600 to 800V for switching devices for use in power supplies.
- **Maximum Current** - The maximum current that the device may pass safely. Ranges from a few mA up to many amps. This will never be while the device also has the maximum voltage across it, as this would result in power dissipation far in excess of ...
- **Maximum Power Dissipation** - The maximum power that the device may dissipate (in mW or W), under any condition of voltage and current. (Called plate dissipation for valves).
- **Heater Voltage/Current** - (Valves). The operating voltage and / or current for the filament (directly heated cathodes) or heater (for indirectly heated cathodes). This should always be within 10% of the quoted value, or cathode life will be severely shortened.
- **Maximum Junction Temperature** - (Semiconductors) The maximum temperature that the semiconductor die will tolerate without failing. At this temperature, most semiconductors will be unable to perform any work, as this would raise the temperature above the maximum permissible.
- **Temperature Derating** - (Semiconductors). Above a specified temperature, the allowable power rating of semiconductor devices must be reduced to remain below the maximum allowable junction temperature. The power is normally derated above 25 degrees C.
- **Thermal Resistance** - (Semiconductors). The thermal resistance between

junction and case (high power) or junction and air (low power). Measured in Degrees C/W, This allows a suitable heatsink to be determined.

This is by no means all of the ratings, there are many more, and vary from device to device. Some MOSFETs for example will have Peak Current ratings, which will be many times the continuous rating, but only for very limited time. Bipolar transistors have a Safe Operating Area (SOA) graph, which indicates that in some circumstances you must not operate the device anywhere near it's maximum power dissipation, or it will fail due to a phenomenon called second breakdown (described later).

With most semiconductors, in many cases it will not be possible to operate them at anywhere near the maximum power dissipation, because thermal resistance is such that the heat simply cannot be removed from the junction and into the heatsink fast enough. In these cases, it might be necessary to use multiple devices to achieve the performance that can (theoretically) be obtained from a single component. This is very common in audio amplifiers.

Essential Electronics Formulae

There are some things that you just can't get away from, and maths is one of them. (Sorry.) I will only include the essentials here, but will describe any others that are needed as we go. I am not about to give a lesson in algebra, but the best reason for ever doing the subject is to learn how to transpose electronics formulae ! Transposition is up to you (unless I am forced to do it for a calculation here or there).

Ohm's Law

The first of these is Ohm's Law, which states that a voltage of 1V across a resistance of 1 Ohm will cause a current of 1 Amp to flow. The formula is

R = V / I (where R = resistance in Ohms, V = Voltage in Volts, and I = current in Amps)

Like all such formulae, this can be transposed (oops, I said I wasn't going to do this, didn't I),

V = R * I (* means multiplied by), and

I = V / R

Reactance

Then there is the impedance (reactance) of a capacitor, which varies inversely with frequency (as frequency is increased, the reactance falls and vice versa).

$$X_c = 1 / (2 * \pi * f * C)$$

where Xc is capacitive reactance in Ohms, π (pi) is 3.14159, f is frequency in Hz, and C is capacitance in Farads.

Inductive reactance, being the reactance of an inductor. This is proportional to frequency.

$$X_l = 2 * \pi * f * L$$

where X_l is inductive reactance in Ohms, and L is inductance in Henrys (others as above).

Frequency

There are many different calculations for this, depending on the combination of components. The -3dB frequency for resistance and capacitance (the most common in amplifier design) is determined by

$f_o = 1 / (2 * \pi * R * C)$ where f_o is the -3dB frequency

When resistance and inductance are combined, the formula is

$$f_o = R / (2 * \pi * L)$$

Power

Power is a measure of work, which can be either physical work (moving a speaker cone) or (much more commonly in audio), thermal work - heat. Power in any form where voltage, current and resistance are present can be calculated by a number of means:

$$P = V * I$$
$$P = V^2 / R$$
$$P = I^2 * R$$

where P is power in watts, V is voltage in Volts, and I is current in Amps.

Decibels (dB)

It has been known for a very long time that human ears cannot resolve very small differences in sound pressure. Originally, it was determined that the smallest variation that is audible is 1dB - 1 decibel, or 1/10 of 1 Bel. It seems fairly commonly accepted that the actual limit is about 0.5dB, but it is not uncommon to hear that some people can (or genuinely believe they can) resolve much smaller variations. I shall not be distracted by this!

$$dB = 20 * \log (V1 / V2)$$
$$dB = 20 * \log (I1 / I2)$$
$$dB = 10 * \log (P1 / P2)$$

As can be seen, dB calculations for voltage and current use 20 times the log (base 10) of the larger unit divided by the smaller unit. With power, a multiplication of 10 is used. Either way, a drop of 3dB represents half the power and vice versa.

There are many others, but these will be sufficient for now. I do not intend this to be a complete electronics course, so I will give you that which is needed to understand the remainder of the article - for the rest, there are lots of excellent books on electronics, and these will have every formula you ever wanted.

Introduction

Amplifier efficiency is a topic that seems to be poorly understood, judging from the comments and questions I have had from readers, so I thought that I would put something together to explain away some of the mystery. As I progressed, it became obvious that I was going to have a lot more work to do than originally intended, since many of the basic concepts will also require explanation.

Efficiency in itself is not hard - power out versus power in. No electronic device can ever be 100% efficient, and all lost power in an amplifier is converted to heat. It makes some sense to try to make an amp as efficient as possible, but if this causes an unacceptable degradation of

the sound quality, then it matters not how many efficiency stars it has, no-one will want to listen to it.

At the other end of the scale, there are Class-A amplifiers, some of which are so inefficient that it almost defies belief. This waste of power does not necessarily translate into better sound, although reading some material would lead you to think that the lower the efficiency, the better it must sound. This is (of course) not true.

This article describes a single channel amplifier, using Class-A and Class-B. No allowance has been made for reactive loads (as occur in loudspeakers), which can increase power dissipation dramatically.

Amplifier Power Losses

So, where do the power losses come into play? We will need to look at a basic amplifier design first, so that the mechanism can be seen clearly. I shall start with a Class-B stage, as these are the most common (although very few are truly Class-B, most are actually Class-AB - but more on this later). For all calculations, a sinewave is the signal source, and for those who might be ready to claim that music is much more complex, music - and indeed any waveform - is derived entirely from sinewaves of differing frequencies and amplitudes.

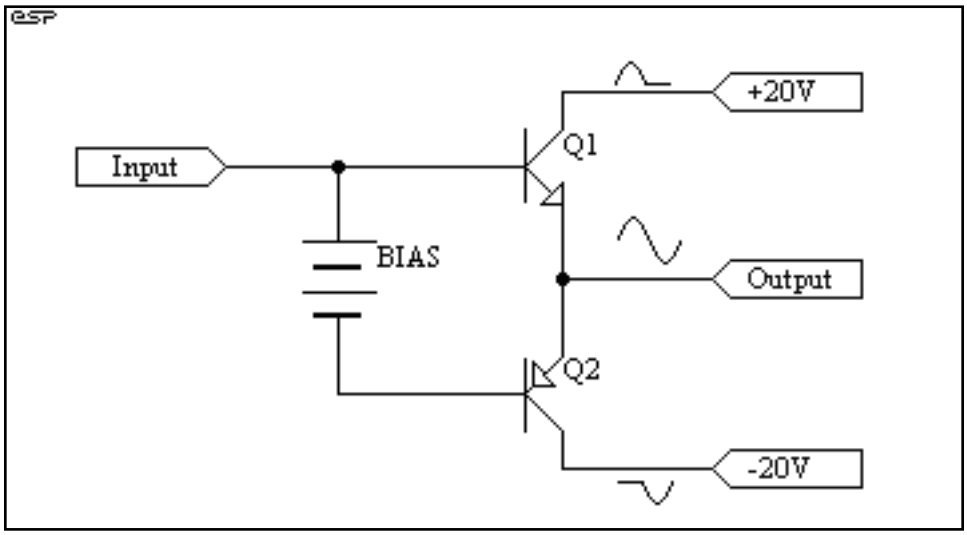

Figure 1 - An Ideal Amplifier

Class-B

We will start with the assumption that the transistors in Figure 1 are "ideal", in that there is no base current needed (they have infinite gain), and no voltage at all is lost when fully conducting. The bias voltage is adjusted so that the transistors are exactly on the verge of conduction, but no quiescent current flows. Given that the supply voltage is +/-20V, this allows

a peak swing into an ideal 8 Ohm resistive load of 20 Volts, which is an RMS voltage of 14.14 V. The peak current is 20/8, or 2.5 Amps, and this equates to 1.768 Amps RMS. The power to the load is 25 Watts.

$$P = V * I \quad \text{.... or}$$
$$P = V^2 / R \quad \text{.... or}$$
$$P = I^2 * R$$

Where P = power in Watts, V = voltage, I = current, and R = resistance. Voltage and current are RMS. Note that the term "RMS Power" is erroneous - power is the result of RMS voltage and RMS current applied to a load, and is measured in Watts. Any other "rating" (such as PMPO) is completely worthless for comparison.

The DC current waveform is shown on the diagram, and it can be seen that for each half cycle, one supply or the other supplies the current to the load. This can safely be ignored, as RMS (with a sinewave signal) implies that the waveform is symmetrical, and therefore the added individual DC currents make a "whole" RMS current.

The RMS input current (see note, below) must therefore equal the RMS output current, and we can now calculate the input power using the first equation above. The DC applied is 20V, so the input power is 20 * 1.768A, or 35.36W. The 10.36W difference is dissipated as heat in the output devices (5.18W each), and is removed using a heatsink. We do not need to take the entire supply voltage (40V) into account, since only half of it is used at any point in time.

Efficiency may now be calculated as

$$Eff = P_{out} / P_{in} * 100 = 25 / 35.36 * 100 = 70.7\%$$

This is the theoretical maximum efficiency of a Class-B push-pull amplifier, assuming no losses. Since in real life (as opposed to advertising brochures) there are always losses, this figure can only be approached - no amplifier will equal or exceed the maximum theoretical efficiency. Of course there are many amplifiers that use multiple power supplies, modulated DC, and many other electronic tricks, but at the end, when operating at full power they are all limited to this figure. Class-D (switchmode or "pulse-width-modulated") amplifiers can exceed this figure, but they are a completely different animal, and will not be discussed in this article.

Note: It is worth pointing out that using RMS current for the input power calculation is convenient, but not strictly correct. It can be shown that the average value is more accurate, and for a sinewave (the waveform of choice for all power tests) this is equivalent to 0.636 (rather than 0.707) of the peak input current. The difference is actually not at all great, especially since the amplifier should spend virtually none of its time at maximum output power

(since the likelihood of clipping is very great indeed). It is in the interests of accuracy that I let you know that ...

Average current (using the same example as above) is 2.5A (peak) * 0.636 = 1.59A, so maximum efficiency is

$$\mathbf{Eff = P_{out} / P_{in} * 100 = 25 / 31.8 * 100 = 78.6\%}$$

The "textbook" figure says 78.53%, so the above is close enough for our purposes. This still assumes that there are no losses in the devices (never the case in practice), and again is only applicable at full power. In reality, efficiency will be less, and about 70% at full power is normal for typical Class-AB amplifiers when all factors are taken into consideration.

> My thanks to Robert Milby for pointing out that average current is correct for the purposes of calculation. He also sent a spreadsheet that can be used to work this out very accurately - please contact ESP for a copy if desired.

All the above figures are quoted at maximum power, and a Class-B amp will still maintain a passable efficiency at lower powers, since the ratio of input power to output power is maintained - at least to some degree (see below). The input to output power ratio is actually quite complex. As power is reduced, efficiency is also reduced, and output device dissipation increases until a critical point is reached, after which it again falls with falling output power. The table below shows the relationship, and this must be considered when designing an amplifier, so that the safe operating power levels of the devices are not exceeded. This is based on ideal devices, so there will be about a 5% to 10% overall reduction of efficiency in real world amplifiers. In order to take the overall losses into account, I have used the RMS input current for these calculations - although not strictly accurate, this more closely approximates the actual (as opposed to theoretical minimum) losses incurred in practical designs.

Class-B Power Dissipation Versus Output

Vout (Peak)	**V**out (RMS)	**I**out	**P**out	**P**in	**Dissipation (W)**
20	14.14	1.77	25.00	35.36	10.36
18	12.73	1.59	20.25	31.82	11.57
16	11.31	1.41	16.00	28.28	12.28
14	9.90	1.24	12.25	24.75	12.50
12	8.49	1.06	9.00	21.21	12.21

10	7.07	0.88	6.25	17.68	11.43
8	5.66	0.71	4.00	14.14	10.14
6	4.24	0.53	2.25	10.61	8.36
4	2.83	0.35	1.00	7.07	6.07
2	1.41	0.18	0.25	3.54	3.29
1	0.71	0.09	0.06	1.77	1.71

Table 1

At 1/2 power (12.5W in this case), the dissipation is at a maximum, and the dissipated power exactly equals the output power, giving an efficiency of 50%. It is also apparent that at lower powers efficiency falls even more, but output stage dissipation also falls, so heating would not seem to be such a problem. However, since we are working with music in the real world, we need to consider the dynamic range (or, to be more precise, the peak to average ratio) of a typical signal. This is between 10dB and 20dB, so average power will be somewhere between 2.5 and 8 Watts. This implies from the table that the amplifier will be working fairly consistently at an average dissipation of 8 to 12 Watts at maximum power output before clipping.

This is not often taken into consideration, and many amplifiers have insufficient heatsink capacity to operate at anywhere near full power for prolonged periods. Thankfully, most music is listened to at fairly moderate levels most of the time, so the problem is rarely as bad as it looks. Sinewave testing is a most arduous test of an amplifier, quite contrary to the beliefs of some, who claim that it is too simple, and cannot give any reliable indication of the amp's performance on complex music. It is rare music indeed that will stress an amp like this, as there is a constant variation of power, allowing the heatsink time to dissipate the heat generated during loud passages.

Class-A

If the bias voltage of the amp in Figure 1 is increased to ensure that the transistor's quiescent current is about equal to the peak speaker current, then we have a Class-A amplifier. The efficiency of this amp can also be easily calculated by the same method. Since a Class-A amp conducts at all times, the DC current must be at least equal to the peak output current. A 20V peak signal will still create a 2.5A peak current in the load, so the DC quiescent current must be equal to (or greater than) this figure. The output to the load will still be 25W, but the DC input power is now 100W (2.5A * 40V). Since all of the supply voltage is in use all of the time, we must perform calculations based on this. Efficiency now (from equation 4) is

Eff = 25 / 100 * 100 = 25%

This is again the best that can be expected, and there are many Class-A topologies that are considerably worse than this. Without going into extreme detail, efficiency of Class-A stages can range from about 12.5% up to about 22% (allowing an additional amount of current to ensure that the transistors never reach a point where no current flows). The "modulated current source" (as used the the original Linsley Hood amp), can reach efficiencies up to about 30 to 35%, and although I have claimed that this is not "true" Class-A this is not strictly true, since output devices conduct for the entire waveform cycle, and such amps are capable of extremely good results. With a Class-A amp, the efficiency falls with reduced power, until at zero output power, efficiency is 0%. At an output power of 1W, efficiency is 1%, and so on (with the voltages and currents as described).

Power Supply Losses

But wait, there's more! The power supply is expected to convert it's input sinewave (at 50 or 60Hz) into a nice smooth DC that the amplifier can use. This also has losses, since the laws of physics are omnipresent. Since we used +/-20V as the power for the amp, we shall work with the same voltage output from the power supply, and will assume "typical" components.

A 14.14V RMS sinewave will provide 20V when rectified using "ideal" diodes. In real life, there will be a voltage drop of about 1V (or more, depending on current) across each diode, and also losses in the transformer, which can be expected to have an internal resistance of about 1.0 Ohm (typical of a 120VA transformer). The situation here is complicated by the fact that diode conduction is for only as very short period, so the current waveform is difficult to measure accurately. We can still use basic theory to work out what happens, and Figure 2 shows a typical supply circuit and waveforms. We will assume that the capacitance is so great that output ripple (although shown) can be considered negligible (bad news for the diodes though, since the peak curent will be very high).

As a matter of interest, the only meter that will give a passably accurate reading of the current is a moving coil (average responding) type. True RMS meters will get it (sometimes horribly) wrong. The best is to use an oscilloscope, and calculate the true average from the waveform shape and amplitude.

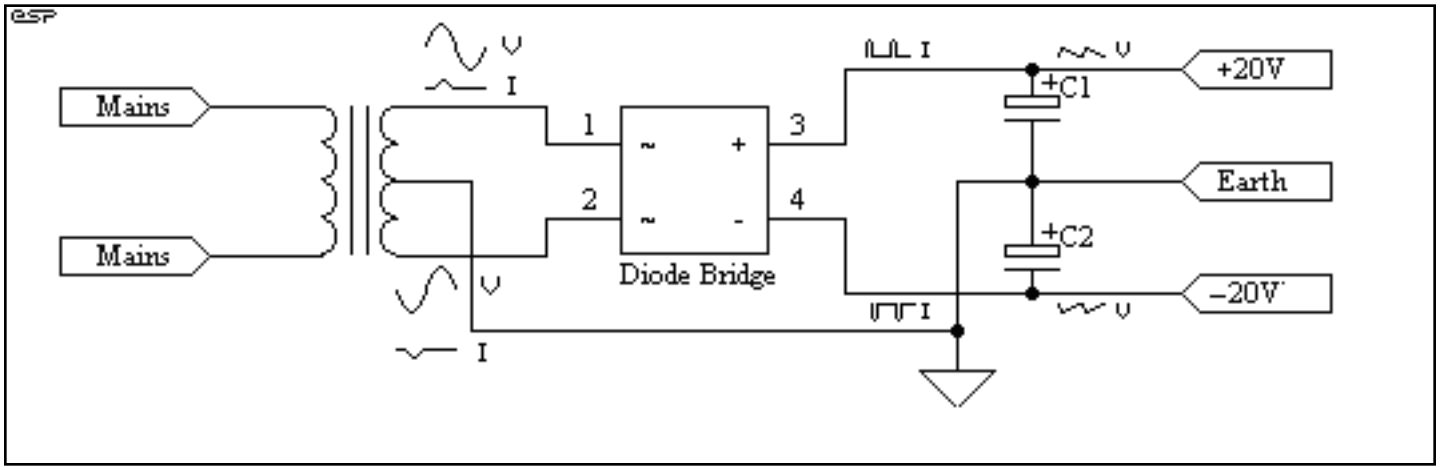

Figure 2 - Typical Power Supply

With the input of 14.14V AC, we will have a DC output of 20V (less the diode voltage drops), since the capacitors charge to the peak value of the RMS voltage. If the peak output current (on each supply rail) is 2.5A as demonstrated above, then the input power must be at least equal to the output power plus any losses. Even this configuration is open to some degree of interpretation. Is the circuit of Figure 2 a full-wave centre-tap, or a bridge. I consider it to be a dual full wave centre tap, but I could easily be wrong!.

In reality, the AC transformer current can only be accurately determined using complex analysis, but the table below is useful for passably accurate results. There are several other variations (such as choke input filters), but these are not commonly used due to the excessive cost and weight penalty, and are not shown.

Rectifier Type	Filter Type	RMS Transformer Secondary Current
Full Wave Centre Tap	Capacitor Input	1.2 x DC
Full Wave Bridge	Capacitor Input	1.8 x DC

Table 2 (1)

Assuming a Class-B amp first, 20V peak output (14.14V RMS) at an AC current of 1.768A. I have indicated that the DC current must be equal to the AC load current, so using the above table we can determine the transformer secondary current using a full wave centre tap configuration as shown above

Transformer secondary current = **DC current * 1.2 = 1.768A * 1.2 =**

2.12A
Transformer secondary voltage = **28.28 + 2 x 1V diode voltage + 2.12V** (transformer loss)
= **28.28 + 2 + 2.12 = 33V** (approx)

Since we have a transformer secondary voltage of 33, we can calculate the power rating of the transformer as

P = V * I = 33 * 2.12 = 70VA

This seems like an extraordinary amount of power needed for a simple 25W amp, and in reality it is not needed. A smaller transformer can be used, and although it will not be capable of providing enough current to charge the capacitors on each cycle, (causing the supply to droop), the maximum power will only be needed for relatively short periods. We also have to accept that there will be resistive losses in the transformer, and the resistive and junction voltage losses in the rectifier bridge.

The power lost by the transformer winding resistance and diodes is (typically)

(2V + 2.12V) * 2.12A = 8.73W

which again is dissipated as heat. These losses will decrease as amplifier power is reduced, but at full power from a little 25W amplifier we have lost about 19W in heat from the amp and its power supply. Needless to say, this is much worse with a Class-A amplifier, as shown below (using much the same calculations as before, but at the higher current).

Transformers also have "iron loss". This is power that is needed to maintain the magnetic flux in the transformer core, and is always present. As the load is increased, the magnetising current becomes less significant, and at full power, the resistive losses in the windings are usually far greater than the iron loss. It is the magnetising current that causes a transformer to get warm even with no connection to the secondary winding. Typically, small transformers have greater iron and copper losses than large transformers per volt-amp of output (i.e. they are less efficient).

Class-A amplifiers will operate at the full DC load all the time. This means that at least 2.5A DC is needed on a continuous basis, requiring a 3A rating for the transformer secondary. Since some extra voltage might be needed to allow for (say) a capacitance multiplier filter, we will give an extra 3V RMS each side. This means that the AC voltage needs to be 38V centre tapped, at a continuous rating of 3A. Using the same formula as above, this gives

VA = V * A = 38 * 3 = 114 VA

This would suggest that a 120VA transformer is needed. The losses are now much higher, too, and are continuous where before they were transient. With the 38V centre tapped transformer, we can expect about 25V DC before the filter - assuming one is used. We still have the diode and transformer losses which will actually stay about the same, since the bigger transformer will have less resistive loss, but the diodes will have more. To get the 20V supplies, we must drop about 5 Volts in the filter, so

`P = 5V * 2.5A = 12.5W` (each supply, +ve and -ve)

This has just added 25W filter dissipation and 10W rectifier and transformer loss (a total of 35W) to the already low efficiency of a Class-A amplifier. Total amplifier input power is 135W, to get 25W of audio. This will be greatly increased if you were to use a regulator, since the input voltage must be high enough to allow for power line droop (typically up to 10%). I shall leave this as a reader exercise to work this out :-)

Further Reading

From the above, you can now see where the power goes to. There are losses everywhere, and it is essential that the amplifier builder has a reasonable knowledge of losses and dissipation requirements for an amplifier before starting construction.

For further reading, see Amp Design and Heatsink Design, both of which will assist in the final determination of the supply and heatsinking requirements for your next project.

1.0 Introduction

Having finished your masterpiece, it is with some distress that you find that it doesn't work. Such failures range from instantaneous meltdown upon power-up (remember the safety resistors I always suggest? Now you know why!), through to strange noises, intermittent behaviour, etc., etc.

It is not possible to write an article that covers every possibility, but hopefully the material presented here will get you underway with as little pain as possible.

One of the points I have made in a number of places on my site is that if the project does not work, you have almost certainly made a mistake. While I will usually do what I can to help you to get the project working, there is only so much I can do, and it is your responsibility (*not* mine) to find out what you did wrong.

Since basic troubleshooting techniques are not widely known - or so it seems, I get a great many requests for help, and have to try to diagnose what went wrong from the description I am given. It almost goes without saying that many of the descriptions leave me wondering what I *am* being asked. This is not to blame the person asking, but shows

that even terminology can be very misleading. There is a *huge* difference between "hum" and "buzz", but if you don't realise that, then I have to either figure out the most likely (correct) term from the description, or ask.

This information should be read in conjunction with the Amplifier Design and How Amps Work articles, and you *will* need a copy of the amplifier's circuit diagram (schematic) as reference. I have been very general in this description, since there are a great many amplifier designs both on my site and elsewhere, and if the descriptions were specific to only one design, you may have great difficulty when working on something different.

To be excellent at fault finding, you need to understand how the circuit works - this allows you to make informed decisions, to know what to look for (and where), and to recognise instantly if a voltage reading is right or wrong. I never said that this was simple!

I have made one major assumption in this article - the forward voltage drop of a diode (or a transistor junction) is nominally 650mV (0.65V), but it can vary by a considerable margin. In most descriptions that follow, I will assume 650mV, but expect to see anywhere between 0.55V to 0.75V, depending on type, current, etc.

2.0 Common Problems

There are quite a few common issues that you will be faced with from time to time. If one channel of a stereo project works and the other does not, this makes fault finding a lot easier, since you have a reference that you can use. This applies to voltage readings, resistance measurements, etc., and also eliminates some of the more common errors - for example leaving the zero volt return line off when the amp is wired into circuit. (If you do that, neither channel will work.)

Having said that, with any of the PCB projects on The Audio Pages, if it does not work, then you have made a mistake. There are some occasions where new components are faulty or incorrectly marked, but other than fake power transistors these are very rare. You do need to be aware that new components can be faulty, but in general, suspect your own work first.

The following basic guides indicate some of the most common project failures ...

2.1 Bad Solder Joints

When completed, a solder joint should be clean, shiny, and show a perfect adhesion to both the component lead and the PCB. If there is any sign of the solder being "frosty",

sitting on the PCB as a "blob", or not flowing up the component lead in a nice smooth arc, then the solder joint is incorrectly made. It may appear to work, but the contact is/may be pressure based, rather than alloy based as it should be (solder forms an "alloy", or molecular metal bond between the solder, component lead and PCB). For an excellent tutorial on basic techniques (and what *not* to do), see www.epemag.wimborne.co.uk/solderfaq.htm. There are a great many such sites on the web, and a web search for "soldering techniques" will find you a broad cross section for reference.

The most important thing about making an excellent (as opposed to disgusting or barely ok) solder joint is cleanliness! The component leads, PCB and soldering tip must be completely free from any contamination - burnt flux, melted plastic, oxides, old solder, etc. must be removed. Make sure that the component cannot move as the solder cools, and ensure that your soldering iron (or station) can supply the right amount of heat. To much heat will burn the flux (and even the solder itself!) and may damage the component. Too little heat makes a "cold" joint, where the solder just sits in blobs but does not make a metallic bond.

2.2 Incorrect Components

All components must be inserted in the correct place, as shown on the PCB overlay and/or other instructions. While this may seem obvious, it is the most common form of "component failure" - the component is not faulty per se, but if it is in the wrong place it will affect the operation of the circuit. This is made worse by the fact that many components use "strange" markings, and it is not always easy to figure out what the value is supposed to be.

With resistors, unless you know the colour code very well, it is a good idea to measure all colour coded resistors before insertion. This is especially true with 1% 4-band codes, as they can be very confusing - even for professionals! There is some information about basic components, markings, etc., in the articles section of this site (see Articles). This is not comprehensive, and cannot be - there are just too many different devices available to cover them all.

Always, *always*, make sure that you download the manufacturers data sheet for transistors, ICs etc. It is not uncommon that suppliers will substitute brand name parts with "equivalents" - these may (or may not) be as good as the original, but they may also have different pinouts. The only way to know for sure is to get the data sheet from the company who actually made the device you have - this applies mainly to semiconductors, but also may be of concern for relays, some electrolytic capacitors (especially power supply filter caps), and other components as well. For semiconductors, most will be fine, but expensive power output transistors are regularly

counterfeit! See Counterfeit Transistors for more information on this topic.

Occasionally, you will get a brand new, brand name component that is faulty. Irritating? Of course it is, but also inevitable. This is where you really do need to hone your fault finding skills, since it is clearly not the result of a mistake on your part. These faults can be difficult to find, and require a disciplined approach to troubleshooting to repair.

2.3 Oscillation

The zobel resistor in most amps is at the output, and is in series with a cap - typically 100nF, but this varies. If the resistor goes up in smoke and/or the amp gets hot *fast*, either the amp is oscillating, or you are trying to amplify too high a frequency.

Oscillation is caused by using the wrong value compensation cap (typically between 47 and 220pF), or (and more likely) having input wiring too close to speaker wiring. Input cables to power amps should always be shielded, and kept as far away as possible from DC power leads, mains transformers and wiring, speaker leads and connectors, etc. In some cases, it may be necessary to provide shielding between the input circuits and power amp.

During testing, the heatsink may not be earthed to the power supply common. In some cases, this can cause oscillation because the heatsink acts as an antenna - as does the input lead if it is not shielded. Always earth the heatsink - even for just a quick test.

Speaking of heatsinks, *never* operate any power amplifier without its heatsink. The devices can overheat very quickly, and are easily damaged by the excess temperatures. A small clamp may be used to attach a temporary heatsink if you are in that much of a hurry, but make sure that you monitor temperatures carefully.

2.3 Schematic/ PCB Errors

I am pleased to be able to say that there are few (if any) schematic errors on The Audio Pages. This is not always the case however, and there are many errors to be found in schematics on the Web (some circuits published won't work at all, or will stress all components way beyond their ratings), and even established and normally reliable magazines can (and do) make mistakes. Sometimes these mistakes will prevent a circuit from working at all, so be warned.

While there may be the occasional PCB error in some of the project PCBs, the error is clearly explained in the construction notes, and will usually only be minor - major mistakes require the artwork to be re-done (which is expensive), but no ESP circuit board requires any modification - track errors are fixed, regardless of the cost.

It goes without saying that if you do find a mistake in any of the ESP projects (PCB, schematic or construction details), then please let me know - this is the main reason that there are so few - people *do* let me know, and I appreciate the feedback. If you find a mistake in someone else's project however, I *don't* want to know - tell the author - not me.

3.0 Troubleshooting Tools

3.1 Multimeter - To be able to do even the most basic fault finding, you will need at the very least a multimeter, and preferably two. Most people prefer digital meters, but if you know how to use an analogue meter you may find things that a digital will miss.

You need to be able to measure ...

- Volts, both AC and DC, from a few millivolts to 100V (or more)
- Amps, DC only is sufficient, but preferably up to at least 2A
- Ohms, from less than 1 ohm up to 10 megohms
- Other functions (transistor tests, capacitance, frequency) are useful, but not essential

3.2 Signal Source - You also need a signal source. While a walkperson (for example) is useful, it is not a good source of proper test signals, and is therefore limited. There are several PC based audio oscillators available on the Web, and these are fine (if a little inconvenient). Ideally, an audio oscillator should be used, see the Projects Pages for details of test gear you can make quite cheaply.

3.3 Oscilloscope - For some tests, an oscilloscope is almost essential. While few hobbyists can justify the purchase of such an expensive piece of test gear, for many professionals the CRO (Cathode Ray Oscilloscope) or 'scope, is the first thing that is attached to anything that does not work. Again, there are many PC programs that allow you to use your computer as a basic oscilloscope. By nature, most soundcards are limited to 20kHz upper frequency, so such PC based tools will not find all problems.

> **Warning:** An oscilloscope cannot be used in the same way as a multimeter (unless a self contained hand-held unit is used), since one probe terminal is connected to the chassis, and thence to mains safety earth. Never, ever disconnect the safety earth from an oscilloscope - this is an invitation to disaster, death and/or destruction of something or someone, at some time. This is an

extremely dangerous practice.

3.4 Load - A "dummy load", usually a high powered resistor or bank of resistors, and ideally switchable to 4 or 8 ohms. This enables you to perform full power tests without the noise, and if a fault develops, the load just gets hot, but your speakers do not get fried. If desired, you can have a 47 ohm 10W resistor from each terminal of your load to an external speaker, so you can monitor the output signal.

A load resistor bank can also be immersed in oil (light engine oil is fine) or water if you have a lot of power to dissipate. Water is the best for removing heat, but may cause corrosion. Glycol (engine coolant) would probably be good too - I've not tried it, but I don't envisage any problems.

3.5 Power Supply - A bench power supply is immensely useful, but possibly even more useful is a variable voltage transformer ("Variac™"). This allows you to make any power supply variable, and the amplifier voltage can be slowly increased while monitoring the amplifier's output voltage (and supply current with your second multimeter). Another useful test tool for those who cannot justify the expense (again, Variacs are not cheap) is a "lamp lead" - a standard light bulb (100W is usually about right), carefully wired in series with a mains lead (and properly insulated!). An amp with a short circuit fault will cause the lamp to glow at full brightness, but a normal load will cause the lamp to flash brightly for a moment, the settle down to a steady dull glow.

One of the most essential power supply tools is a pair of 10 Watt resistors, between 10 and 22 ohms (or as suggested in the project article). These must be used in series with the supply leads before applying power, and limit the current to a (hopefully) safe value, especially when used in conjunction with a Variac or lamp lead.

Now that you have the fault finding tools, we can continue on to making some actual measurements.

4.0 Most Common Failures

This is the part where it all comes together. The first thing to do when you know an amp is faulty, is to determine the exact nature of the fault. Does it short out the supply (safety resistors get hot), or does the output swing to one rail or the other and refuse to leave? Perhaps it seems to be alright, but is badly distorted. Make sure that you identify the fault completely - there is no point chasing a fault that was incorrectly diagnosed!

4.1 Shorted Supplies

First, let's look at a "shorted" supply. This is most commonly caused by shorted output or driver transistor(s), but may also be the result of any of the following ...

- Incorrectly installed transistors - PNP instead of NPN (or vice versa), either as drivers or output devices
- Shorts between transistor case and heatsink, due to a punctured mica washer
- Open circuit bias servo circuit. The bias servo is the transistor and pot that generates the bias voltage needed to keep the transistors conducting at just the right level to avoid crossover ("notch") distortion. An incorrectly installed transistor, faulty (open circuit, wrong value, or improperly adjusted) pot, dry solder joint or broken track can all cause the output transistors to turn on fully when power is applied. In some designs, the bias "servo" is simply two or more diodes, and may also have a series resistor.
- Solder bridges between tracks or component pads.

The first thing to determine is if the short is "hard" or "soft". A hard short will show up as a very low resistance between the supply rails (less than 1 ohm), when measured with a multimeter with no power applied. Hard shorts always indicate either blown transistors, solder bridges or punctured mica washers. If you are lucky, it will be either of the second two, but don't get your hopes up. Hard shorts are unusual in an amp that has just been built and is being tested for the first time (using the safety resistors!).

A soft short is identified by the fact that a resistance measurement between the supply rails to each other, the output and earth (ground) does *not* show a very low resistance (less than (say) 650 ohms or so). Resistance readings of around 600-700 ohms are possible in one direction (this is actually a voltage, and is developed across diode junctions either on real diodes, or within the junctions of transistors). Resistance may be the same or much higher in the other direction - swap the meter leads for all such tests so you measure with both polarities. You almost certainly have a component (power transistor or driver) installed incorrectly if you get a soft short, but a faulty bias servo will create the same effect.

If you can vary the voltage, determine the voltage where the soft short comes into play. It is very rare for soft shorts to be present at extremely low voltages (less than +/-1 or 2 Volts), but if it is, then something is installed incorrectly.

See Component Tests (below). These techniques will isolate 99% of all soft short problems.

4.2 Output Stuck to Supply

When the output voltage "sticks" to one supply or the other, there are (as always) several possibilities. In order of likelihood, these are as follows ...

- Incorrectly installed components
- Solder bridges between tracks or component pads.
- Dry (or cold) solder joint(s)
- No earth return between amplifier and power supply
- Broken tracks
- Faulty transistor(s)

If one output or driver transistor is shorted, this does not cause rail sticking, it causes a soft short. Rail sticking can be the result of an open circuit transistor, possibly in conjunction with its opposite being shorted. These faults can be found with a multimeter (as described above). It is important to eliminate blown devices early, or you will spend a lot of time trying to find the problem in the wrong place. A common error is to leave off (or forget) the power supply earth return - this gives a similar effect to supply rail sticking, but it usually happens slowly (several hundred milliseconds to several minutes)

A stuck rail can be caused by any of the following faults closer to the input ...

- Open circuit feedback resistor (or track)
- Open circuit (or simply non conducting) class-a driver transistor
- Open circuit (or simply non conducting) current source/sink transistor
- Open circuit bootstrap resistor chain
- Solder bridges between tracks or component pads.
- Incorrectly installed transistors, diodes, LEDs, etc. (As always, and anywhere)
- Non-functional long tailed pair input circuit/ error amplifier.

Again, the hard part is finding the fault, and this is where the next section will be useful. The most common problem by far is still incorrect components, but when a visual check fails to find the problem, then you need to measure voltages.

4.3 Distortion

Distortion comes in many flavours, but may be roughly categorised as "gross" or "subtle". Both are in reality "gross", but from a testing perspective it is essential to separate the two somehow. I would consider gross distortion as being a state where only half of the signal is reproduced. From a listening perspective, this is way beyond mere gross - it is totally unlistenable! "Subtle" distortion is also unlistenable, but some people don't notice it (true).

Should only half the signal be reproduced (or a small amount of one polarity and the full amount of the other), then you almost certainly have an open circuit somewhere in the driver or output stage. It may be an open transistor (rare) but is more likely to be ...

- A bad solder joint, leaving part of the output stage inoperable
- Incorrectly installed components (as always)
- A fault in the Class-A driver circuit, such that there is insufficient current to drive one output or the other

This is where an oscilloscope is almost essential - faults of this nature are very hard to diagnose if you can't see the waveform. The above fault list will help you to solve most gross distortion problems relatively easily.

Subtle distortion is more insidious, as there are several possibilities. Again, very difficult to determine without an oscilloscope, but voltage measurements *will* isolate some of the more likely issues. The things to look for are ...

- Incorrectly set quiescent (idle or bias) current
- Faulty or shorted bias servo
- Solder bridges between tracks or component pads.
- Parasitic oscillation

The first three are easy enough to test, requiring only a multimeter. A few measurements will isolate the problem fairly quickly, and all should be well.

Parasitic oscillation is a lot harder, and usually needs an oscilloscope. I can say with confidence that the designs on the ESP website will be free from parasitic oscillation provided that all normal precautions against continuous oscillation are taken - earthed heatsink, shielded input leads (separated from output or DC wiring), and input connectors a sensible distance from output connectors (or shielded by an earthed metal cover).

Also, make sure that bypass capacitors are fitted as required, and keep DC supply lines as short as possible. Distortion tests will almost *always* require a load to show up. While a small amount of distortion may be visible with no load, most will reveal themselves either fully or partially with as little loading as 20 ohms or more at the speaker output.

4.4 Spontaneous Failure

The amplifier has been working for some time (from minutes to weeks) then fails. You

have eliminated nearly all of the potential construction faults, since the amplifier has shown that it does (or did) work. Unfortunately, this does not make your job any easier.

One of the most common problems in the case of spontaneous failure is counterfeit power transistors. See the article Counterfeit Transistors for more information on this topic. Other things to look for are ...

- Infant Mortality - the term usually used to describe components that fail a short time after a device is first used. Most common failures are semiconductors - specifically transistors or ICs, but other components may be affected as well (electrolytic capacitors - rare but it happens, diodes, zeners, etc.) Infant mortality failures are not as uncommon as you may hope for, but are still comparatively rare. This is completely normal (albeit very irritating).
- Dry solder joints - seemed Ok when first tested, but failed after use (not uncommon!)
- Excessive supply voltage, causing component stress
- Inadequate heatsinking, allowing components to overheat
- Incorrectly set bias current (too high), causing overheating
- Incorrectly mounted power transistors, with inadequate thermal contact to the heatsink
- Short circuited outputs, usually the result of inadequate (or no) insulation, or changing speaker leads around with the amp on and with a signal present - not recommended, even if an amp has short circuit protection

Since most cases of spontaneous failure result in shorted power transistors, these are usually easily found with a multimeter. The amp's fuse(s) may blow, but transistors (aka "3-legged fuses") are much faster than any conventional fuse :-(If a fuse blows, apply proper testing procedures (look for shorts, etc) rather than replace the fuse and hope that all will be well. This rarely happens, but additional damage (and to more components) is common.

For all projects on The Audio Pages, there are quite specific absolute maximum supply voltages, and minimum specified load impedances (which may vary with applied voltage). It is extremely important that this information is adhered to, or individual device ratings may be exceeded, resulting in premature failure. None of the project amps is designed to work with a 2 ohm load, and simply adding parallel output transistors (for example) just makes the driver transistor subject to failure, and having failed, it will nearly always result in output device failure as well.

It is worth noting that the principle failure mode for a BJT is short circuit. Open circuit devices will be found, but this occurs when another device shorts, and the internal bonding wires then fuse. The device then measures as open circuit, but the die (the silicon "chip" inside the transistor) has failed short circuit. External fuses are *not* intended to protect the transistors - they are there to prevent catastrophic failures (including fire) should an output device fail.

When one or more output devices fail, it is usually a good idea to replace all output and driver devices, even though they may seem to be alright. It is almost certain that they have been stressed, and may be more prone to failure at some later date. In some cases, an output stage fault can also damage the Class-A driver (and/or the current sink, if used). This rarely affects the input stage, which normally survives even the most destructive failure. Note that in some cases the fault current can be so high as to open-circuit the emitter resistors (usually not all, but one or two can fail). *Always* check these if an amp fails, preferably after you have removed the power transistors and drivers.

Unless the failure can be positively attributed to counterfeit transistors (which will fail at much lower power levels than the genuine device), try to determine exactly what went wrong *before* re-commissioning the amplifier. Check speaker leads, supply voltages and speaker impedance - something caused the amp to fail, and it is better fixed than allow it to happen again.

5.0 Voltage Measurements

Voltage measurements must be done with the greatest of care. A simple and cheap fault can easily turn into a complex expensive one with just the slip of a probe!

In keeping with the general nature of this article, I will not refer to any specific voltages, but will rather give an overview of what to look for. At this point, a good understanding of the basics of transistor operation is expected and necessary, otherwise you will not be able to understand what you are seeing on you meter or oscilloscope.

Always measure your supply voltages first !

Countless man-hours (person-hours?) have been wasted trying to locate "bizarre" faults, when all that has happened is that the supply voltage(s) are either not present or are incorrect. This is the very first voltage measurement you should make - always !

5.1 General Principles

In the most general of terms, with any bipolar transistor (FETs and MOSFETs are completely different!), there should be about 600-700mV measured between the emitter and base, and in linear circuits (such as conventional amplifiers) there will be some higher voltage of the same polarity between emitter and collector as that between base and emitter. For example, on a PNP transistor, with the red meter lead to the emitter, there will be around -650mV between emitter and base, and anything from (negative) a few volts to several tens of volts between emitter and collector.

An oscilloscope will show perhaps almost no AC voltage at all on the base, but a large AC signal on the collector - this is usually quite normal. The DC voltage readings will tell you if the transistor is correctly biased, and therefore able to do its job. A voltage of 650mV between emitter and base, but full supply voltage on the collector is not necessarily wrong - you must read the voltage with reference to the circuit diagram.

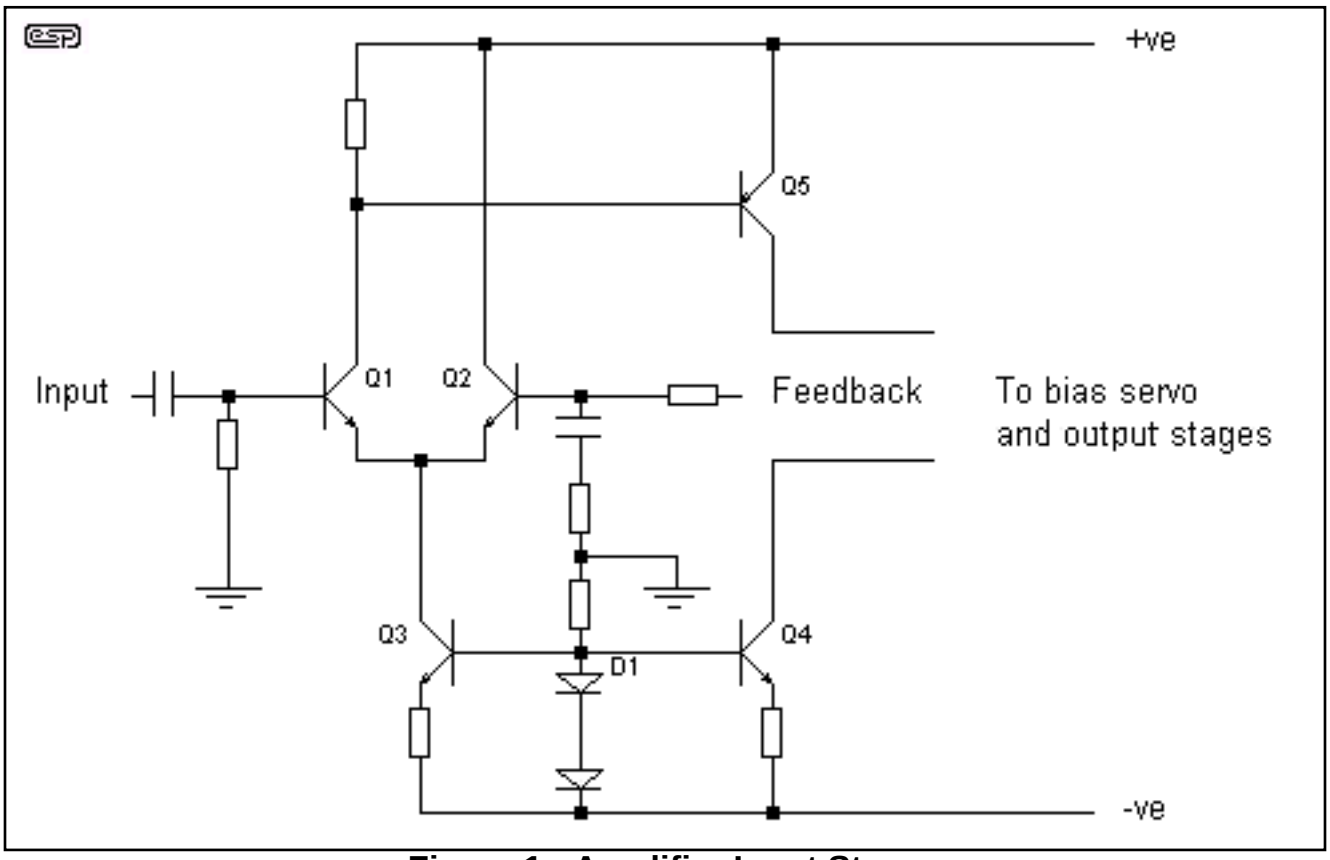

Figure 1 - Amplifier Input Stage

5.2 Example

Let's assume for a moment that you have a conventional NPN long-tailed pair for the input circuit (Q1 and 2, Fig 1). The emitters are tied together, with perhaps small resistance values in series with each emitter in some designs. The voltage at the bases will probably be a few millivolts negative, and the emitter to base voltage should be

around 650mV. The collectors will be at almost the full supply voltage in most circuits (there are exceptions though). If you were to see that the output was stuck to one of the supply rails, then that will upset the long-tailed pair, and all voltages will be wrong. This could mean that one of the long-tailed pair transistors is faulty, but maybe not!

This is where you need to play detective, to ascertain *why* the output is stuck to the supply rail (having eliminated all the previous fault types - incorrect components, bad solder joints, etc.). The next device to test is the class-a driver (Q5). Check the emitter-base voltage, and make sure that it is around 650mV. If that is correct, then the collector should be at close to zero volts, but it won't be. Instead, you may find that it is sitting at (or near) one supply rail voltage. Look at the circuit - the class-a driver is PNP (using the previous example) and the collector is at full positive supply, that means that the transistor is fully turned on ... why? Or is it?

The next step is to look at the current sources (Q3 and Q4). Between the emitter and base of each there should be 650mV or thereabouts, and the current through each is easily determined. Measure the voltage across each emitter resistor - it should be about ... 650mV (can you see why this would be so?). The current is equal to V/R so if the emitter resistor is (say) 100 ohms, then the current should be 0.65/100 = 6.5mA (close enough).

The collector of Q3 should be at around -700mV, and that of Q4 at around zero volts. If this is the case then the amp should be working. Assume that the collector of Q5 is almost the full supply voltage, and likewise that of Q4 - there are either of two possibilities - Q5 is shorted (or turned on fully), or it has no collector current. The job of Q5 is to pull the output high as it turns on, and let it swing low when it turns off, but if Q4 were supplying no current, then the output will swing high. The input stage will try to turn Q5 off, but will become unbalanced by the voltage at the feedback input. This will make the circuit inoperable until the fault is located - this is your mission, should you choose to accept it, of course ;-)

So, Q5 has full positive supply at its collector, give or take a volt or so (not important at this stage). The collector voltage at Q4 should be about the same, and the current should be about 6.5mA, but wait! If everything were working as it should, the amp would be functional, so there is something amiss - but we knew that already. What is the voltage at Q4's collector? Is the voltage across Q4's emitter resistor 0.65V as it should be?

If the collector voltage is near the negative supply rail, or the emitter voltage is a lot lower than 0.65V, then Q4 is open circuit at the collector - this is not a common failure

mode for a bipolar transistor, so it is likely that there is a bad solder joint at the collector of Q4 (or perhaps a hairline crack on the PCB). If the collector voltage were at close to positive supply, then the emitter resistor could be open - probably a bad solder joint, as resistors rarely go open without a lot of smoke and fuss. Check the value carefully - was a 100k resistor inserted by mistake?

5.3 Summary

The purpose of this exercise was to demonstrate the general processes of elimination that should be used to locate the type and nature of a fault, and then it can be easily corrected. It is not possible to cover every possibility here, even with the simple circuit shown, but by carefully measuring the voltages you will be able to track down the most likely cause, without having to rebuild the whole circuit!

The answer to the little riddle above ... There must be about 650mV across the emitter resistor of the current sink because there are two diodes in series. D1 balances out (or "cancels") the emitter-base voltages of both Q3 and Q4 - also 650mV. Whatever voltage exists across D2 (and we know it must be 650mV), must also appear across the emitter resistors. It really is that simple, but it may take a bit more experience before you see it clearly.

A useful thing to remember about transistors - if it gets hot, it is working (or trying to). Looking at Fig 1 again, if Q4 gets hot and Q5 is dead cold, then Q5 is the faulty device - not Q4 as you may think at first.

6.0 Component Testing

Transistors can be tested for basic functionality with a multimeter. If you use an analogue meter, be aware that when on the ohms range, the red probe is negative. Digital meters retain the "correct" polarity. A BJT (Bipolar Junction Transistor) can be thought of in terms of two diodes, as shown in Fig. 2. As with any diode, they should conduct in one direction, but not in the other. All BJTs may be tested this way, revealing open circuit, leaky or shorted junctions. The test tells you nothing about gain, voltage breakdown, or anything else, only that the device is *likely* to be functional.

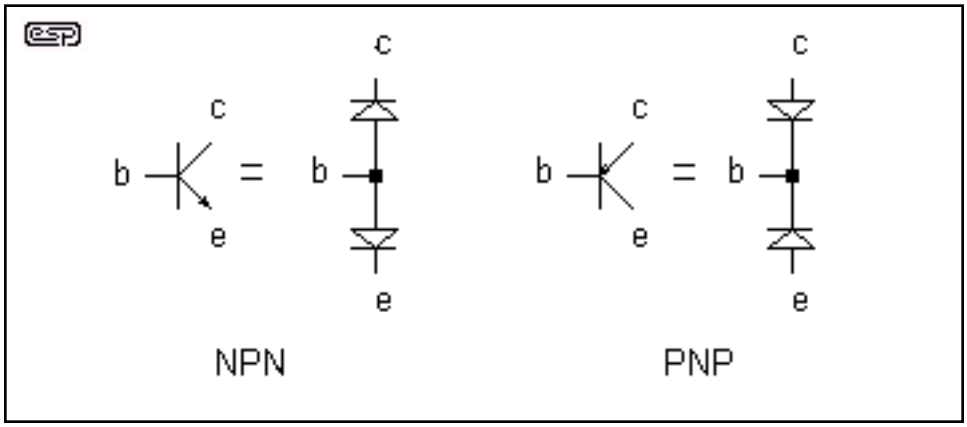

Figure 2 - Basic Transistor Test Model

6.1 Transistor Quick Check

Check in both directions with your multimeter between the base and emitter/collector of each power and driver transistor. An NPN transistor will show a "resistance" of 600-700mV (shown as ohms, but is actually voltage with 99% of digital meters) with the positive (red) lead of a digital meter connected to the base, and the black lead on emitter and collector. Reverse red and black and measure again - in some cases, one connection may still show 600-700mV because of a connected power or driver transistor - this is normal.

By using this method, the proper conduction of each diode can be checked - as with any diode, the forward voltage drop is around 650mV (which as explained above shows on most digital multimeters as 0.65k ohms), and the reverse bias condition should show infinity(keep your fingers away though). In-circuit tests can also be done like this, but the results may be misleading because of other devices in the circuit.

In case you were wondering (and you are by no means the first to do so), you cannot use two ordinary diodes wired as shown as a transistor. Transistor operation relies on the junction between the "diodes" (hence bipolar *junction* transistor).

6.2 Other Components

Resistors should read their correct value, but again, in-circuit tests can be misleading. All diodes should show proper conduction and blocking as the probes are switched from one end to another. This is not a useful test for LEDs or zener diodes, but at least you will know if it is open or short circuit.

Capacitors really need a capacitance meter (as well as an ESR [Equivalent Series Resistance] meter) to test properly, but you can still get a fair idea with a multimeter. Shorts are uncommon in film caps, but can occur, although in most projects this is highly unlikely. Electrolytics should show a low resistance at first, which will rise as the cap

charges. Reverse the leads and make sure that the cap discharges (expect to see silly resistance values at first), and charges up again. Low voltage reverse polarity will not harm electros.

Most other components (transformers, connectors, wiring) needs only to be checked for continuity, and that all wiring is connected to the proper place.

7.0 Opamp Circuits

There is not much that can go wrong with an opamp circuit. Most linear circuits (as used in preamps) have one thing in common - the two inputs should be at almost exactly the same voltage, and so should the output. The most common problem is oscillation - especially with very fast opamps. The ESP boards are designed so that bypass capacitors are as close as possible to the opamps, and there is also additional filtering using small electrolytics.

It is still possible to make an opamp circuit oscillate though, so sensible precautions should be taken - keep inputs and outputs shielded and apart, and always use a 100 ohm resistor in series with the output of any opamp that connects to a cable - regardless of length.

Other problems can occur, but normally they will be the result of bad solder joints (as always), or incorrectly installed components. All ESP boards will function first time, every time if assembled according to the instructions, but if yours doesn't, then there is a mistake in the component placement, or the opamp is faulty. Yes, opamps can be faulty from new - it doesn't happen very often, but it does happen.

As with power amps, leaving off (accidentally or otherwise) the power supply earth (zero volt) line is quite a common "fault". A +/- supply means that the earth (or ground) lead is required - it is *not* optional!

8.0 Earthing (Grounding)

This is the area where it all goes to pieces. Hum or buzz is the usual symptom, but unfortunately, there are no fixed rules that can be applied in all cases to cure the problem.

The distinction between a "hum" and a "buzz" is extremely important! If you describe a

noise as a hum, then the expectation of anyone knowledgable in the field will think "low frequency, no (or few) harmonics". This describes the noise made by an earth loop - a situation where two or more pieces of circuitry are joined by the mains safety earth lead and the shield of an interconnect (for example), forming a loop. This can inject a very low voltage (but sometimes surprisingly high current) into the loop, and the signal is picked up by the inputs. You hear hum - a single low frequency tone.

"Buzz" has a sharp edge to it - there is usually a low frequency component, but it has a hard sound that may even be audible in tweeters at times. Buzz is caused by any number of things - input leads close to mains wiring, power transformer or bridge rectifier (and associated wiring), bad or no earth connection, loops (they can cause buzz as well as hum), the list is almost endless.

Sporadic oscillation in an amp can also create a buzz or hum in some cases - follow the guidelines above to ensure that the amp is stable under all conditions - low level oscillation can usually only be detected with an oscilloscope, but you may be able to detect it using an RF "detector" probe - see the projects page for a suitable example.

With any of these problems, it is almost impossible to give a standard "fix". The solution is different in nearly every case, and sometimes the best result is obtained with an arrangement that should not work at all. My normal approach is to keep lots of separation of input cables from anything else, and for locating the optimum earth location, I use the following methods ...

- Make a "soft" earth connection with a 10 ohm resistor, usually from the amp's input to a convenient place on the chassis
- Get an alligator clip lead, connected to the amp's input earth point, and probe likely places for low noise - the star earth point for the filter caps, right next to the input connectors, etc., until the quietest place is found. Just hope that it doesn't end up being to some part of your anatomy or the cat :-)
- Make the "sweet spot" a solid connection, and do tests to determine if there is any possible way to improve matters.

This method *usually* works well, and if you really do find the optimum location, you will need another amplifier to be able to hear any noise. It should be possible to earth the end of the input lead to any of your other equipment without adding noise, but there is a point where it is fruitless to try to make it better.

If you have to put your ear right next to a speaker to hear anything, then from the listening position it is effectively completely silent. Further improvements will not yield

any audible benefit.

A common mistake (and an excellent source of undesirable noises) is to take the DC from the rectifier. DC must always be taken from the filter caps, and never from the rectifier. Those short leads will develop serious noises when the amp draws current, and may create a background "haze" that is audible as a background noise from the amp - but only when it is playing! This is very insidious, since the amp seems dead quiet with no signal. An oscilloscope and/or distortion meter is essential for locating problems of this type.

9.0 Removing Dead Components

Once you have determined that a component is dead (or is probably dead), you need to remove it from the PCB. *Never* attempt to just heat the leads and prise them from the board, and resist the temptation to use a solder sucker (or solder wick) to remove the solder prior to prising the component out. This will nearly always result in damaged PCB pads and tracks. It is far better to use a very slim cutter, and cut off the legs first. Cut as close to the PCB surface as you can (for both component-side and copper side mounted parts - be careful that the cutter does not damage the pad or track!), and then use a sucker or wick to extract remaining solder and the remnant of component lead.

While desoldering, a clean soldering tip is just as important as when soldering. A clean (and properly "tinned") tip requires less heat and time than a dirty one, and therefore lessens the chance of damage. In some cases, it may be necessary to apply a small amount of new solder to an existing joint to facilitate desoldering - it is important to keep temperatures as low as possible and make the desoldering activity as short as possible to prevent PCB damage.

None of this will guarantee that you will not damage the board, but such damage is a lot less likely. Should a pad be lifted while desoldering, do not rely on that pad when the replacement component is resoldered. Instead, fold the component lead down flat against the PCB, directly along the connected track (5mm or so is recommended). Carefully solder the lead and track to make a solid connection - the pad is now almost irrelevant, but the component is properly connected.

In the case where more than one track runs from a pad, make sure that the remaining section of track is intact - use a multimeter!

Hairline cracks

Cracked copper traces (hairline cracks) caused by PCB damage are quite common, and are very hard (sometimes almost impossible) to see. It is far easier to make a quick measurement whilst doing the repair than to try to find the fault later.

The most common reason for PCB failures (lifted pads and tracks, hairline cracks, etc.) is excessive heat and/or force. The copper is held onto the PCB laminate by an adhesive, and there are very few adhesives that can withstand soldering temperatures for any length of time. A damaged PCB can always be repaired using tinned copper wire soldered along the faulty section of track and to the component lead(s), but future repairs will be more difficult, and the result may be very untidy.

10.0 Testing

Once repairs are done, or at least thought to be done, the next step is to test the amp (or preamp, etc) to make sure that everything is now working properly. There is a natural tendency to want to hear it working immediately, but it is important that you resist the temptation, lest you be showered with fire, brimstone, and capacitor guts.

Make sure that you have everything needed to hand - multimeters, signal source, dummy load (for power amps), etc. In all cases, the first power-up should be done with a low voltage, current limited supply (if available), or use safety resistors in series with the supply leads. The idea is that since you have most likely replaced possibly expensive components, it is preferable that they don't blow up because there is a secondary fault that you did not find the first time.

Such secondary faults are very common, and their destructive capabilities should never be underestimated. By using limiting resistors and a Variac (or a 100W light globe wired in series with the mains cable) the energy available is greatly reduced, and the chances of (further) component damage are minimised.

For the remainder of this section, I have assumed a power amplifier, since they cause far more grief than anything else. Before testing, make sure that all power transistor hold-down screws are very firm - do not overtighten, but screws must exert sufficient pressure to ensure that a small amount of heatsink compound is forced out around all transistors.

10.1 Power Up

Initially, do not connect your dummy load. Use alligator clip leads from your multimeter, and connect to the supply rails (positive and negative). Any quiescent current setting pot

should be set for minimum current (see the original project article). If you use a Variac, advance the voltage slowly and observe the voltage. Check the safety resistors for heat - they should remain cool! Any heat (from anything) as the voltage is advanced is an indication that something is amiss. Should you find heat do not advance the voltage further. Measure the voltages before and after the safety resistors to determine the nature of the fault.

If you use the series light globe method, then initially, turn the power on for a brief period - the lamp should flash brightly, then settle to a dull glow. When turned off again, the voltage should decay relatively slowly (typically a few seconds) - if the lamp remains at full brightness and the voltage collapses quickly, then there is a fault. The safety resistors will probably be warm to hot.

If everything is ok, leave the amp on for a few minutes, and check *everything* for heat. Some components are expected to get warm, but *anything* that causes you to exclaim "RudeWord!" is an indicator that something is amiss. Refer back to the fault finding sections of this page, and locate the fault. Any remaining fault calls an immediate halt to the test process.

10.2 Voltage Checks

Having successfully reached this part, you should now verify that all voltages are normal. The voltage across each safety resistor should be only a few millivolts to up to a volt or so, depending on the amp design. The output voltage should be close to zero - as a rule of thumb, any offset in excess of 100mV or so is excessive, but be aware that some amplifiers may not be able to better this while the safety resistors are still installed (uncommon but possible).

If the output voltage is at zero volts, and the supply rails are close to normal voltage, there is a good chance that the amp will work. I don't suggest that you start shouting "Hurrah!" just yet though (sorry ;-)

10.3 First Power Check

Making sure that your dummy load is set to 8 ohms (or more), connect it to the output (do not disconnect the safety resistors!). Connect your signal source (output set to zero!), and then slowly advance the level while monitoring the voltage at the amplifier side. Advance the level until there is about 5V across each safety resistor. The voltages should be the same across each resistor. Voltage across one but not the other indicates an open circuit power stage. You may also use a speaker, with a series resistor of around 22 to 47 ohms. If the sound is heavily distorted, then there is something wrong. Advance the level a little more to determine if you are hearing crossover or "rectification"

distortion. If distortion lessens as the signal level increases, then it is crossover distortion, and you have nothing to worry about (the quiescent current is set to minimum, remember).

10.4 Final tests

Having verified basic functionality, at least to the best of your ability, just do a quick re-cap of the tests ...

- Supply voltage at amp terminals (with safety resistors) is within 1V of the voltage across the filter caps
- Nothing gets hot - including safety resistors (slightly warm only)
- Output voltage is within 100mV or so of zero volts (preferably less than 50mV)
- A basic power test shows that both sides of the amp draw current, and a reasonable signal is heard on a speaker.

You are now ready to test the amp at full power (but still use the Variac or light bulb lead for safety). Disconnect the safety resistors, and replace any fuses you removed with the correct value. You may leave the speaker connected with the series resistor - just in case. Turn on the power (or wind up the variac) - all voltages should come up to normal, but they may be a little low if you use the "lamp lead". Check carefully for anything that may be hot (or getting hot).

If all is well, adjust the quiescent current to about 1/2 the recommended value, inject a signal, and verify that the amp sounds clean. Do not try to get full power if you still have the lamp lead. Leave everything for at least 10 minutes, checking that bias (quiescent) current remains stable, and that no components are too hot. Note that some devices do run quite warm in many amps, but you should be able to hold all small/ medium transistors without being burnt.

When you are satisfied that everything is working properly, switch off, remove the Variac or lamp lead, and switch on. Double check the supply and output voltages, and apply a signal - if you still have the series resistor in series with your speaker, you can advance the input level until the sound becomes distorted (clipping).

Check all temperatures (again! I know this is tedious, but it is worth the effort). Set quiescent current to the recommended value, using the method suggested in the project article (this can vary considerably). Leave the amp to stabilise, monitoring temperatures - transistors, resistors, heatsink. After the temperature has settled (typically about 15 minutes), verify the quiescent current, and adjust as needed.

Note: If the heatsink temperature continues to increase (and so does quiescent current), you have a problem! Switch off immediately, and reduce the current setting. Do not apply power until the heatsink cools (a fan will make this a lot faster). The amplifier may have a thermal stability problem - verify that the bias transistor (if used) is mounted according to instructions. Thermal runaway (as this problem is known) is usually the result of insufficient thermal feedback. Consult the project designer for information on how to solve the problem.

Never use an amplifier while this problem persists - it will overheat and fail.

11.0 Preamplifier Tests

This is a very short section, since the range of tests on preamps is minimal - especially for opamp designs. As always, an oscilloscope is very useful, but not everyone has the luxury of ownership. As a result, other methods need to be found to enable you to track the signal through the preamp, until the point where it disappears is found. This narrows down the "search area", and makes it a lot easier to find the problem.

First, check that the opamp outputs are at (or near) zero volts, and that you have +/-15V (or whatever your supply voltage is supposed to be) at the supply pins. This is fairly obvious, but when you are desperate, it is often overlooked. Also, make sure that the 0V (GND) connection from the power supply is connected - this is a common error.

Then, apply a signal from a PC sound card, tuner or CD player, and use an old active PC speaker as an audio probe (it *must* be an active speaker, with its own internal amplifier). That way, you can check the signal level at the input, output of 1st opamp, etc. You need to find where the signal stops, and you can do that easily by just following the signal path, and monitoring the signal. Check for level, distortion, or anything else that may be amiss.

Remember that the PC-speaker input lead's shield must be connected to the ground (common) of the preamp, and the centre wire is used to probe the circuit under test. These speakers are low power, but I recommend that the level be adjusted so that you have a clean signal in the speaker. Never connect the PC-speaker input to the supply voltage(s), as you may damage the internal amplifier. A 1k resistor in series with the signal lead is a good idea.

In nearly all cases, there is a mistake somewhere, as all PCBs have been fully verified and definitely work if wired properly. Faulty opamps are possible, but very rare. Because

of the ground-plane in some designs, there are a lot of very closely spaced tracks, and solder bridges are easy to make.

This method can be used on almost any opamp based circuit, be it preamp, equaliser, or whatever - however it is limited to audio frequency circuits for obvious reasons.

12.0 Terminology

There are all sorts of strange noises that electronics can make through loudspeakers, and only a few are intentional. Clicks, pops, farts, hum, buzz, hiss, thumps - all have meaning, but the meanings are sometimes confused (such as "hum" and "buzz"). I can't (and won't) attempt to cover them all, but will go over some of the more important (and common) ones.

Hiss: The sound of an FM tuner that is not on a station, or the sound of air between your teeth. The "sss" sound in the letter ess. Those are all hiss - anything that does not sound like one of those is not hiss. Some hiss is inevitable - all components make noise - even cables, and the use of low noise components (especially opamps and resistors) will reduce, but never eliminate, hiss.

Hum: As described above - a smooth, 50/60Hz low frequency, with no harshness or high frequency energy at all.

Buzz: Any frequency, but usually 100 or 120Hz depending on your mains frequency. Buzz has a harsh tonality, and is typical of rectifier noise, TV frame synchronisation noise (run a signal lead behind the telly to hear that one), and general mains noise. Probably the hardest to fix.

Crackle: Sometimes crackles can be caused by a faulty component (transistor, opamp, etc.), and dry solder joints are also a good source of crackles, pops, farts, and other noises of similar ilk. Occasionally (especially in valve equipment), crackles may be caused by the valve itself, or a faulty capacitor. Usually easy enough to find, except crackles and pops (etc.) almost never occur when test equipment is nearby - can be very sneaky. Try lightly tapping the board and components with an insulated probe of some kind (a plastic screwdriver handle works well), as many such noises are vibration sensitive.

Distortion: Extremely variable. A couple of the more common types are ...

- Crossover (or "notch") distortion sounds similar to tearing paper, and is only present when there is a signal. It gets worse as the level is *reduced*. Severe crossover distortion will allow an amplifier to stop reproducing anything other than signal peaks at low volumes.
- There are many other forms of distortion as well - "rectification" distortion can occur if only half the signal is reproduced, and is typical of open circuit power transistors, faulty drivers or current sources. It is sometimes difficult to hear some forms of distortion (such as that caused by an amplifier oscillating).

An oscilloscope is essential for detecting oscillation induced distortion - there is no other way to see exactly what is happening to the signal.

Thump: A low frequency noise, often as power amps (in particular) are turned on or off. This is usually a design issue, and most thumps are not of concern - unless you use an amp that thumps to drive tweeters in a biamp or triamp setup! You will almost always need a speaker delay relay to get rid of thumps, since the only real alternative is to redesign the amp. Some opamp circuits also thump (or Crack!) as power is applied or removed. High speed opamps in the P09 electronic crossover is a prime example. Again, relays and a delay circuit are the best solution.

Chirps: Some power amps (notably some otherwise excellent power opamps) emit a "chirp" or bird-like noise as power is removed. Like thumps and cracks, this is a design issue that is very difficult to prevent. If it really annoys you, then a loudspeaker mute relay is the only real solution.

13.0 Conclusions

As stated right at the beginning, there are just too many possibilities to try to cover them all. Nonetheless, I hope that this article helps you to debug your project, and allows you to concentrate on listening to music. I doubt that there are many things more disheartening than a shelved project that you just could not get to work properly.

As I find out more of the problems that people face, I will add to this article, and will try to ensure that it is up to date with the latest and greatest faults. It is probable that the vast majority have been covered here, but there is always a new one, or one I didn't think of at the time of writing.

Should you go through the steps outlined for your particular problem, and still not find the solution, then let me know - I will help you solve it if I possibly can.

Note that this *only* applies to ESP projects - if you found a circuit or project elsewhere, then you must discuss it with the designer or publisher - **not** with me. I not only do not have the time to discuss other people's designs, but have a distinct lack of inclination to do so.

Of all the issues I have discussed here, the most common problem of all is failure to follow the instructions, and/or failure to place all components where they are supposed to be. I would estimate that well over 90% of all faults are caused by incorrect component placement - "I have checked and double checked" is a phrase I have seen in e-mails countless times, but the problem still turns out to be wrongly installed parts. This *must* tell you something ;-)

This is not to be taken as an insult to your intelligence by any means - everyone does it. When one of my prototypes fails to work as expected, there are two possibilities ...

- I made a mistake in the board layout
- I installed something incorrectly

So far, incorrect components have accounted for maybe 60% or more of original failures - in some cases because I goofed in the design phase, but mostly I just did what everyone else does - put something in the wrong place.

If it helps at all, just remember ... "*The person who makes no mistakes, makes nothing at all !*"

Introduction

The so-called "Trimode" system used by most car amps seems mysterious, as there is no speaker switching, and commonly only a simple stereo/ Mono switch. Even without the switch being operated, a speaker connected between the +ve (Red) terminal of one amp (typically the left channel) and the -ve (black) terminal of the other will still work with a typical stereo signal.

There is nothing magical about this, and the basic concept is used in almost every car amp known. What follows is a simplification, but describes the process and how it works.

Decription

A schematic of a trimode amp is shown below, in Figure 1. As you can see, there are two

completely normal power amplifiers, and a simple inverter circuit is used in front of the Right channel amp. The "trick" is that the output terminals for this inverted channel are reversed, so the +ve Red terminal is actually connected to ground (chassis), and the -ve Black terminal connects to the amp's output. For any normal stereo signal, this maintains the correct polarity of the system, and the speakers will not be out of phase.

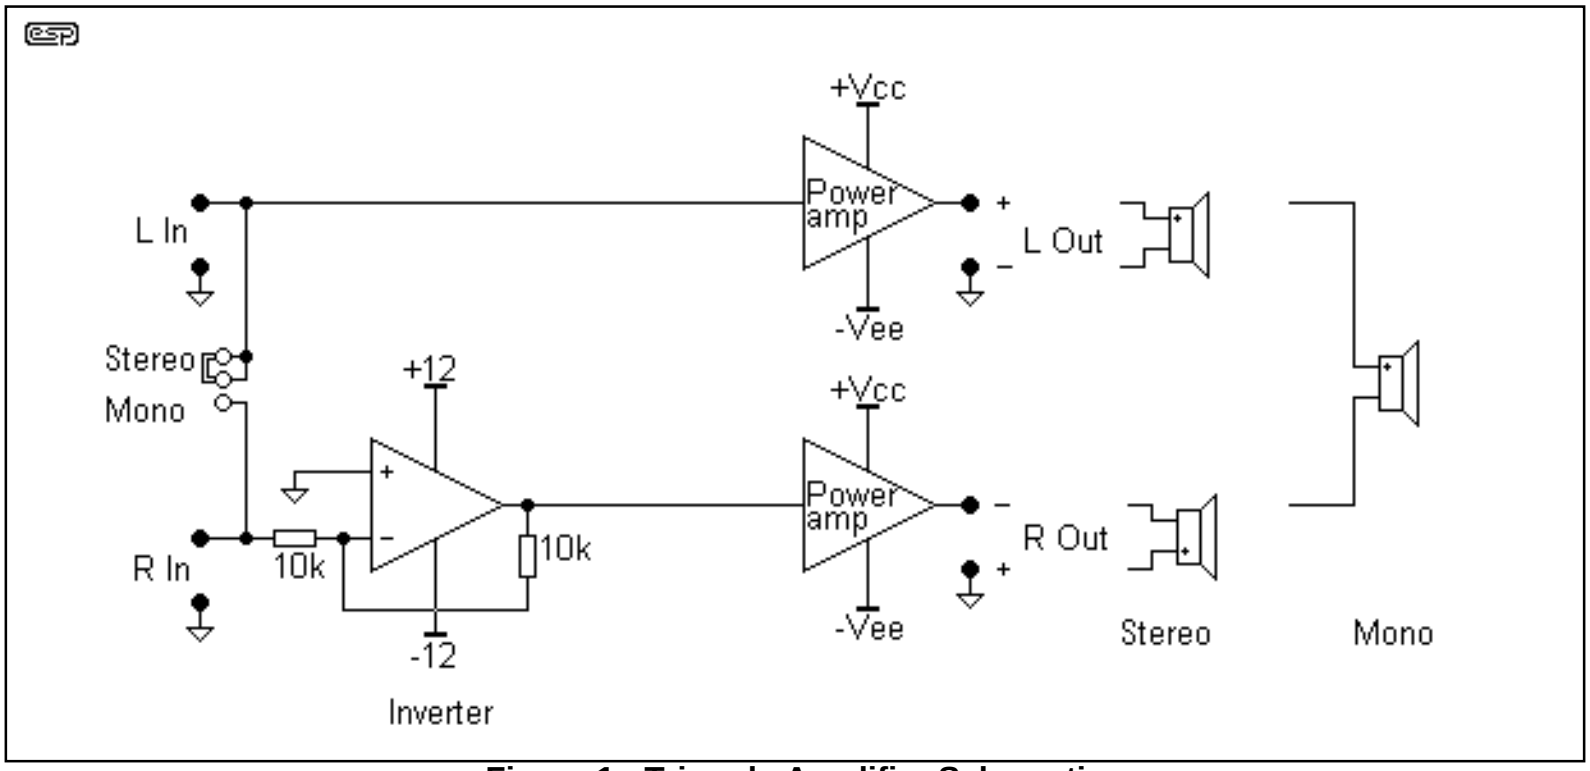

Figure 1 - Trimode Amplifier Schematic

The opamp is usually nothing special, and virtually any standard opamp (such as a TL071) can be used. If another opamp is used in the front end, then the device may be a dual opamp - I have deliberately not added pin numbers, since you will need to work out for yourself what you need here.

Since this is not intended as a design as such, if you want to use this method, you will have to work out the details for yourself. Do **not** send me e-mails asking for a complete design! There is enough detail here for anyone who is capable of wiring a simple circuit, and who understands the basics of amplifiers in general terms. The +/-12V for the opamp is commonly taken from the main switching supply, either using a separate small winding, or by using regulators off the main supply.

Again, you will have to work this out for yourself - I will not do it for you.

How Does it Work?

A bridge tied load (BTL) amplifier applies a normal signal to one terminal of the speaker, and an inverted signal to the other. If a single amp is capable of producing 20V RMS across the speaker, this equates to $P = V^2 / R$, so in this case, 20^2 / 4 = 100W.

When connected in BTL, the same speaker "sees" 20V at one terminal, and an inverted 20V signal on the other - a total of 40V RMS (I shall leave the proof of this to the reader :-) Using the same formula, 40^2 / 4 = 400W - **four** times the power. But ... each amp now sees only half the load impedance (think of an imaginary centre tap in the voice coil, connected to ground). The amplifier must be stable into 2 ohms, or this method will not work. Of course, you can use an 8 ohm speaker and still get 200W if the amplifier cannot drive 2 ohms safely.

Conclusion

The method described here is in almost universal use for car amplifiers, is simple and works well. Strangely enough, it is rarely used in (home) hi-fi amplifiers, possibly because it would be considered "unacceptable" by audiophiles (for whatever reason).

As stated above, please don't e-mail me for further information on the construction of high power car amps. There is a project article for a high powered switchmode converter, and that can be used with almost all amplifiers shown on these pages - however, none of the amps I have presented will drive 2 ohms safely, and they are not recommended for car audio use. Most car amps are very rugged, but are typically of "sub-hifi" performance, often having relatively high levels of crossover distortion (especially audible at low impedance and low volumes).

A power amplifier for car audio use may be offered at some later time, but at the present there is nothing available on these pages that I consider suitable. Several people have enquired about using LM3886 power op-amps, and although these will work, they really need to be connected in parallel. There is an excellent Application Note (AN-1192) on how best to do this available on the National Semiconductor site (the document is a PDF file - approx 529k in size). There is also a simplified method of achieving the same result as shown above, but bear in mind that input impedance will be low (and there are possible stability concerns as well).

The Audio Pages

Elliott Sound Products **A Beginners Guide to Audio Bulletin Boards**

Contributed by Geoff Moss
(de facto editor of the Audio Pages)

Articles Index

Main Index

A useful source of information for those starting out in audio electronics is the Audio Bulletin Board or Forum. There are a number of these on the Web where you can exchange views with and seek help from other people with similar interests and possibly greater experience. However, before venturing forth into a forum, it helps to know the customary procedures and protocol.

The following notes will give you a basic understanding of what to expect and how to behave when visiting these sites.

- When you register with a forum or submit a posting (message), use a silly name; it helps to preserve your anonymity and adds an air of gravitas to your postings.
- Ignore all spelling, punctuation and grammar; not only is it time-consuming to get these right, but somebody might actually understand what you are trying to say.
- Use as many abbreviations and acronyms as possible; if there isn't a standard abbreviation, make one up (but please don't define it when it is first used).
- When you start a new thread (topic), give it an ambiguous title; that way, more people will access your thread to see what it is about.
- When adding to an existing thread, try not to respond to the original question; it is

preferable to go off at a tangent and expound upon your latest obsession.

- Try to keep adding to postings in an existing thread, even if it means repeating that which has been said before; this will ensure that the thread has chance of becoming one of the longest on the Forum and will receive the appropriate accolade.
- Do not treat any comments on your postings as being constructive; respond vehemently, as if you have suffered a great personal affront.
- Never, *ever* admit you are wrong or apologise if you are proved to be wrong.
- Don't be hidebound by facts and accuracy; these are of little importance to the overall debate.
- The views of certain correspondents carry more weight than others; this is usually in direct proportion to the number and length of their postings (it has nothing whatsoever to do with their competence, knowledge or ability).
- Feel free to comment on the quality of an amplifier even if you have never built or heard it; your views and observations are still relevant.
- Simulations are a good basis for comparing the quality of different circuit topologies; you don't need to build or listen to anything to determine the relative merits.
- An amplifier should only be judged subjectively; objective measurements don't mean anything and are a complete waste of time.
- An amplifier should only be judged by objective measurement; you do not need to listen to it to determine its abilities.
- All amplifier designs originating from the USA are better than any 'foreign' alternatives.
- All amplifiers built in the USA are superior to any 'foreign' alternatives.
- MOSFETs are always better than BJTs (because Nelson Pass uses them); BJT designs are archaic and of historic interest only.
- Nelson Pass designed amps are always best; Nelson Pass is always right!
- Try to ensure that you always have the last word in any debate, even if you have

no more constructive comments to add.

Though I have referred to amplifiers in the above notes, the comments equally relate to all other items in the audio chain.

On a more serious note: I started out by suggesting that an Audio Bulletin Board or Forum is a 'useful' source of information for the beginner. This is not necessarily the case.

There is a lot of incorrect information being expounded in these fora (forums) by people who do not know what they are talking about (though I am sure that they genuinely believe what they are saying). All information obtained from these questionable sources should be treated with caution and thoroughly checked against an authoritative source before being used in a project. Either that, or restrict your reading and research to reliable sources such as the ESP Audio Pages.

No-one gets out of here alive ... (well, maybe not that bad, but I have to add my piece). From Rod ...

The above is intended as humour, and I hope that readers will see the funny side to Geoff's comments. When next you visit one of the various bulletin boards, read a little more closely than usual, and you will see that a great many respondents follow these instructions to the letter!

Humour aside, the topic has a serious side. Geoff added in an e-mail ...

> *"I had two serious intentions, one to warn the uninitiated against believing everything they read on the Web and the other to try to shame the correspondents into better behaviour (probably a waste of time as this is likely to prove impossible). It is a pity that all fora seem to degenerate to the same abysmal level. A good one could be both interesting and informative and of great benefit to the DIY community."*

There is a vast amount of "disinformation" offered by the chronic bulletin board addicts - in some cases this is simply because the respondent(s) don't know enough to know when not to say anything, and in other cases it is because they have their own (usually hidden) agenda. For example, one can find posts from "high end" cable dealers who will blithely say that anyone who can't tell the difference between "cords" has tin ears, but do they say anywhere in their posts that they make a living from reeling in the suckers? Noooooo.

The list of charlatans is endless and depressing, and the poor audiophiles lap it up as if it were nectar from the Gods.

Every so often I visit some of the 'boards, these days mainly to see what they are saying about my site and its contents. There was the great "flame out" of '99, and I think that came close to the record for the longest thread - all over mains leads! During the entire thread, barely a civil word was uttered, as the respondents became more and more determined to have it go their way. This (of course) never

happened, and eventually *everyone* gave up in disgust.

Heaven help anyone who disagrees with one of the self appointed BB experts, for surely will the wrath of the (anonymous) snake oil dealer descend upon s/he who dares to offer a word of dissent. If you even try to be sensible or factual, you are dead meat, mate, since everyone there knows that to detect by ear is divine, but to measure is heresy - punishable by death, defenestration and/or disembowelment (but not necessarily in that order) if they had their way.

Introduction

There are few audio designs today that do not use operational amplifiers (opamps). Over the years, the poor opamp has been much maligned, with mainly spurious claims about 'audibility', distortion, and other so-called defects.

Although some of the more basic opamps do have limitations which make them less than desirable in some cases, most of the new breed are unsurpassed for linearity, with total harmonic distortion figures as low as 0.00008%. Even the basic types still have their uses in control circuits and other non-demanding applications.

The operational amplifier was first used in the 1940's, as the basis of analogue computers. Since integrated circuits were unknown at the time (this was before the invention of the transistor), the earliest versions were made using valves. The basic concept is to have an amplifier with differential inputs, whose operation is controlled only by the external feedback components. By rearrangement of the feedback circuit, different "operations" could be performed. Typically, these early opamps could add and subtract, and these are essential functions to this day (even in audio). With the advent of the IC and mass production techniques, the opamp became very popular and remains so - with considerable justification.

This article will concentrate mainly on audio applications, but there are some configurations that are just so wonderful that I cannot resist the temptation to include them. For the most part, any of the configurations shown can use the simplest (and cheapest) opamp you can get (especially for testing), unless extremely wide bandwidth or low noise is a prime consideration. For any of the test circuits this is not an issue.

I also suggest that you build up the Opamp Design and Test Board (Project 41), which is ideal for the experimenter. Most of the circuits shown can be built using this test board, and will function perfectly, although there will be limitations as to bandwidth and noise because of the LM1458 dual opamps recommended for the project.

Essential Formulae

To understand this article, you need to know Ohm's law and it's derivatives. Ohm's law is fundamental to electronics, and with little more it is possible to derive most of the other resistance based formulae. Ohm's law states that a potential of 1 Volt through a resistance of 1 Ohm will cause a current of 1 Ampere to flow. This is expressed as:

R = V / I ... where R is resistance, V is voltage and I is current, or ...
I = V / R ... or ...
V = I * R

Later on, we will also use the formulae for inductive reactance and capacitive reactance, as well as calculating frequency response and some filter design. These will be presented as needed.

You will also see references to 'an instantaneous level of "x" volts AC'. At any point in time, an AC voltage has an instantaneous voltage - this is the voltage that is present at that moment, and for

analysis can be treated as DC. This is valid only when we consider this 'DC' level as a transient thing, since many of the circuits do not operate down to DC at all (many others do, but this is beside the point :-)

Basic Rules of Opamps

Many years ago I used to teach electronics, and I devised what I called the 'Basic Rules of Opamps' for the purposes of explanation. There are two Rules, and although real life is never like theory (I could fill the page with suitable examples, but shall refrain), they describe the operation of all opamp circuits very accurately:

1. An opamp will attempt to make both inputs exactly the same voltage (via the feedback path)
2. If it cannot do so, the output will assume the polarity of the most positive input

Needless to say, this requires some explanation. So let's look at Rule #1 ("No Poo....", oops, sorry, wrong Monty Python sketch).

An opamp will attempt to make both inputs exactly the same voltage
When an opamp is operated in its linear mode (which is most of the time for audio), the feedback circuit will cause a voltage to appear on the inverting input (-in) that is almost exactly equal to that present on the non-inverting input (+in). Any change of voltage on the +in terminal is reflected by a change in the output that causes more or less current to flow in the feedback circuit to maintain equilibrium.

If this is unclear to you, see the further explanations below - but remember the 1st Rule !

If Rule #1 cannot be satisfied, the output will assume the polarity of the most positive input
There are many circuits that use opamps in non-linear mode, and this can also happen if the output cannot swing its voltage fast enough. In these cases, should the +in terminal be the most positive, then the output will (or attempt to) swing positive. If the -in terminal is more positive, the output will swing negative.

There is almost no opamp circuit that you cannot understand once these Rules are firmly established in your thinking. Even circuits that use external transistors in strange ways will obey the Rules. An opamp that does not perform as above is being used outside of its normal operating parameters, and the results will be unpredictable and almost always unsatisfactory.

It is more often explained that an opamp reacts only to the difference between the two inputs, and not to their common voltage. The ability to ignore the common voltage is called the Common Mode Rejection Ratio (CMRR), and will be covered later in this article.

Some Essential Opamp Information

Before we cover the circuits themselves, we need to look at some of the parameters you will come across, how to apply power and bypass the supply rails and so on.

There are many parameters that you will see in data sheets, and these are covered in more detail a little later. There is no point doing it now, as the importance will be lost until you know more about the opamp itself.

Configurations

Opamps come in a variety of configurations, but the most common are:

Single - one opamp in an 8 pin DIL (Dual In Line) package
Dual - Two separate opamps, sharing only the power supply pins - commonly in an 8 pin DIL package
Quad - Four separate opamps, again sharing the power supply - most commonly in a 14 pin DIL package

Amazingly, nearly all opamps use the same pinouts, and these were established many years ago by the venerable uA741 for single opamps, and the likes of the LM1458 dual opamps set the stage for the others that followed. Many of the quads use the same pinouts as well, and this has enabled people to swap opamps for 'better' ones for a very long time.

However - Don't count on it! There are some variations, and although uncommon, they do exist. I shall not be concerned with any of the different devices - only the common pinout versions will be shown.

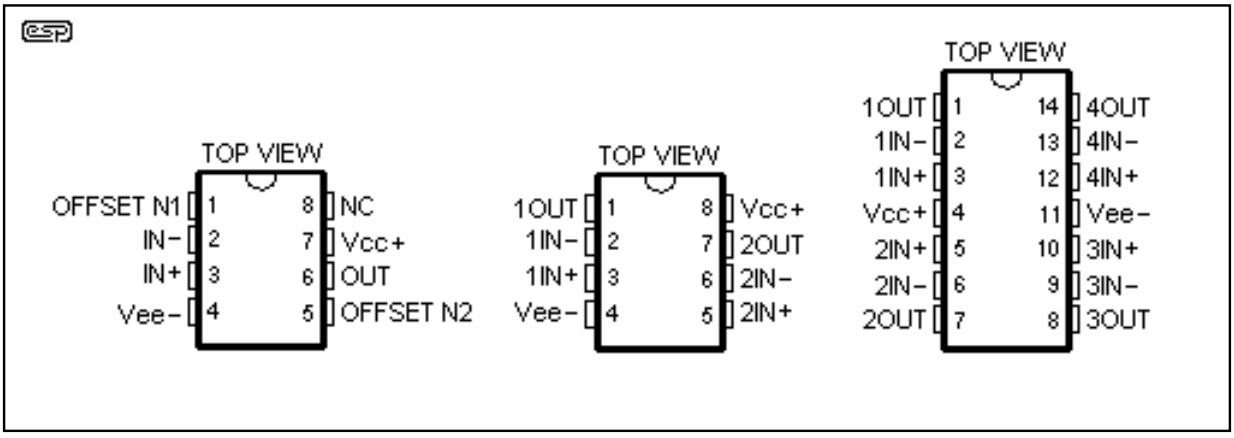

Figure 1 - Common Opamp Pinouts

Figure 1 shows the standard connections for single, dual and quad opamps, but be aware that the remaining pins on the common single devices can occasionally have uses other than those shown. Single opamps have additional connections available. These are most commonly:

- Offset Null - used to adjust the amplifier to ensure that the input transistors are perfectly balanced, so that with no input signal, there is zero volts output. This is important for DC amplifier circuits.
- Compensation - Some single opamps do not have inbuilt frequency compensation capacitors, and these are connected externally instead. This allows the designer more freedom, and the opamp's high frequency performance can be optimised for the design objective.

You may at times see these connections used in unconventional ways. This may be to obtain greater bandwidth than might normally be available, or perhaps just so the designer can show how clever s/he is. Either way, I shall not be delving into these aspects of the design process :-)

Applying Power

No (active) circuit works without power, so this has to be the first step. Most opamps will operate with a maximum of 36V between the supply terminals. As this is the absolute maximum, operation at a lower voltage is the general rule, and the most common is to use +/-12V to +/-15V to power the circuit. Some opamps are rated for higher voltages, and others for less, so consult the spec sheet from the manufacturer.

A dual supply is not required, but it does simplify the design, and is recommended for most applications. A dual supply has the advantage that all inputs and outputs are earth (ground) referenced. This can eliminate a great many capacitors from a complex design, and is the most common way to power most opamp circuits. Note that from a commercial perspective, elimination (or reduction) of capacitors is done for economic reasons rather than any great desire to simplify the signal path.

Since the pinouts are nearly always the same, Figure 1 will be applicable in most cases, but as I said earlier "Don't count on it!". When in doubt, get the specification sheet from the manufacturer. When not in doubt, get the specification sheet anyway.

Power Supply Rejection Ratio

The PSRR (Power Supply Rejection Ratio) of an opamp is a measure of the amount of power supply noise that finds its way into the output signal. Most specification sheets give the test conditions for this measurement, and this should be consulted if an unusual design is contemplated. Mostly it can be ignored.

Bypassing

Although most opamps have a very good PSRR, it is always recommended that the supply be bypassed with capacitors - especially with high speed opamps. Bypassing should always use capacitors with good high frequency performance, and ceramics are probably the best in this regard. It is common for designs to use electrolytic capacitors, themselves bypassed by low value (100nF) capacitors. This ensures that all noise sources are minimised, and helps to prevent

oscillation. When this occurs with a high speed (HS) opamp, it will commonly be in the MHz region, and is extremely hard to see on most oscilloscopes.

A sure sign is inexplicable distortion, that mysteriously disappears (or appears) when you touch the opamp, or a component in its immediate vicinity.

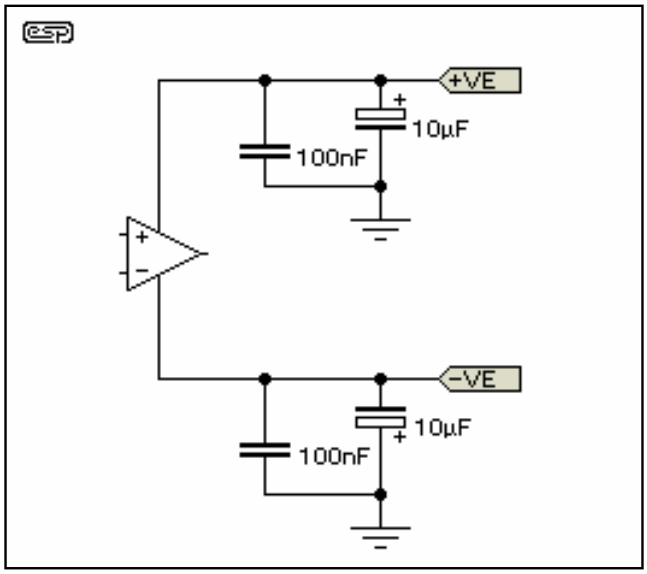

Figure 2 - Bypassing The Opamp Supplies

Even with HS opamps, electrolytic capacitors are not needed for each device, but the use of ceramic bypass caps between the supply pins of each device is highly recommended. Figure 2 shows the most common method of bypassing power supplies for opamp circuits, but there are others. In some cases, the supplies may not be bypassed to earth (ground), but just to each other. This is relatively uncommon.

Claims have been made that supply bypassing ruins the sound (rubbish), or that ceramic caps should never be used in audio, even for bypassing (more rubbish), and even that high value capacitors (> 1uF) slow down the sound (unmitigated drivel). These claims are made by frauds and charlatans, and should be completely ignored - they have no basis in fact whatsoever, and indeed, quite the reverse may be true in each case.

The Ideal Opamp

An ideal opamp has an infinitely high input impedance, and therefore needs no bias current. It is also capable of infinite gain without feedback, so there are no errors between the two inputs (i.e. Rules 1 & 2 will hold for all cases). The ideal opamp also has zero ohms output impedance, and is capable of supplying as much current as you will ever need. The ideal opamp does not exist :-(

Although it does not exist, the ideal opamp is the common model for nearly all opamp circuits, and few errors are encountered in practice as a result of designing for the ideal, and actually using a real (non-ideal) device. The tolerance of even the best resistors will ultimately limit the accuracy of

any opamp circuit at low frequencies (where gain is highest).

The primary practical limitations are:

- Input Impedance - Typically from one to several hundred Megohms. FET inputs are used for very high impedance inputs
- Gain - 100dB at up to a few hundred Hertz is common
- Common Mode Input Voltage - typically limited to the supply voltages, but may be up to 0.6V greater with some designs
- Bandwidth - opamps with a usable high frequency limit of 1MHz at unity gain are now common
- Output Current - most common opamps are limited to about 20mA of output current.

There are others, such as input offset voltage and current, but we shall not concern ourselves with these parameters just yet. Power opamps may be capable of up to 10A, but these are outside the scope of this section of the article.

The use of ideal opamps is assumed for much of the following, but all are designed to function properly with real world devices. In practice the difference between an ideal opamp and the real thing are so small as to be ignored, but with one major exception - bandwidth. This is the one area where most opamps show their limitations, but once properly understood, it is quite easy to maintain a more than adequate frequency response from even basic opamps.

The common mode input voltage can be important in some applications. Ideally, an opamp only reacts to the voltage difference between its inputs. Provided this does not change, in theory, the actual voltage between the two inputs and the common (zero volt line) may be anywhere within the specified range *with no change in the output voltage*. In other words, the inputs can assume any voltage between the negative and positive supplies, and there will be (almost) no change at the output.

With a real (as opposed to ideal) opamp, there will be some change, and this is specified as the common mode rejection ratio. An opamp with a CMRR of 100dB (not uncommon) will ensure that the change in output voltage is 100dB less than the change of input voltage (as applied to *both inputs simultaneously*. Any *difference* between the inputs is amplified normally. CMRR is affected by the open loop gain of the opamp, so is usually worse at high frequencies.

The Basic Opamp Circuits

The following collection shows the most common configurations for amplifiers. These are intended as linear amplifiers, in that they are essentially distortion free (within the capabilities of the opamp itself, of course).

As we progress, most of these original circuits will be seen over and over again, since they are the

very foundations of building an audio circuit using opamps.

In all cases, a dual power supply is assumed, and this is not shown on the circuits. This partly for clarity, since the additional circuitry makes the diagrams harder to understand, and partly because it is a convention not to show all the supply connections anyway. We all know they have to be there, so there is little point in showing the obvious over and over again. Likewise, bypass capacitors and other support components are not shown - only the basic opamp and its associated components.

You will also see reference to the "instantaneous value of the AC waveform". This is like a snapshot, and we simply freeze time while we analyse the operation of the circuit. At any point in an AC waveform, it can have only one value of voltage and current, *regardless* of the complexity of the signal source. A sinewave is no different from any other signal - provided its amplitude and frequency are within the capabilities of the opamp.

The Non-Inverting Amplifier

The most common of all configurations is the non-inverting amplifier. I will therefore use this as a starting point, because it is also the simplest to understand. Figure 3 shows a completely conventional non-inverting opamp voltage amplifier.

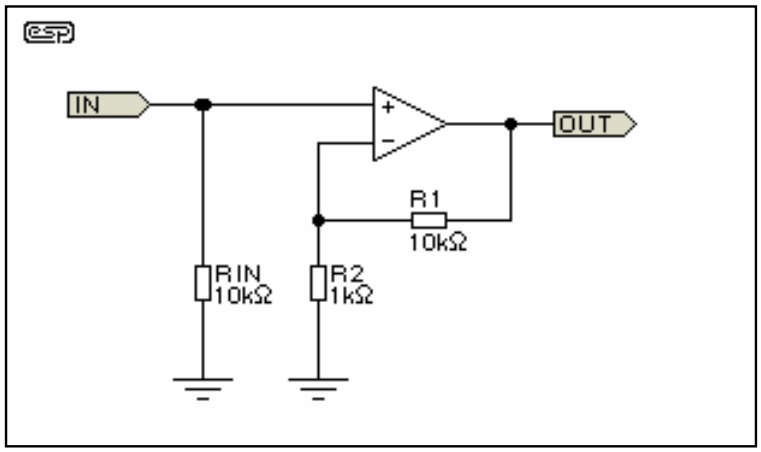

Figure 3 - Non-Inverting Opamp Amplifier

Rin is the input resistor, and is needed because an opamp needs a reference voltage at the input. In this case the reference voltage is the zero volt (earth) bus. Input impedance is equal to the value of Rin in parallel with the opamp input impedance. Generally the latter can be ignored because it is so high.

The gain (Av - Amplification, Voltage) is set by the ratio of R1 and R2, and is equal to:

$$Av = (R1 + R2) / R2$$

The gain of this stage cannot be less than unity, regardless of the resistor values used. As shown

in the diagram, the gain is 11 times, so a 100mV input will become a 1.1V output. To re-examine Rule #1, it is obvious that if 100mV (instantaneous AC or DC) appears at +in, the amplifier must have 1.1 volts at the output, since the voltage divider R1/R2 will ensure that 100mV also appears at -in. This is obtained from the simple voltage divider formula, which is strangely familiar ...

$$Vd = (R1 + R2) / R2$$

This will hold for any gain and any output within the capabilities of the power supply and the opamp's ability. A signal at 10MHz will not follow the rule, since the opamp will almost certainly be incapable of amplifying such a high frequency. An input voltage of 10V with a gain of 11 will also break the rule, since the opamp has only +/-15V supplies, and the output cannot exceed the supply voltage. Likewise, an 8 ohm load will break the rule, since the opamp cannot supply the current needed to drive such a load.

To see how the opamp behaves in these abnormal conditions, I suggest that the circuit be built, and run the tests if you have access to an oscilloscope. Examine the inputs as well as the output, since the inputs are by far the most interesting when the opamp is appearing to break the Rules.

Inverting Amplifier

Once, all amplifiers were inverting. A single valve or transistor stage (other than a cathode or emitter follower buffer stage) always inverts the signal, and this is how it must be (see Amplifier Basics - How Amps Work for more info).

With the advent of the opamp, all this changed, and the inverting amp is a very different beast from the simple discrete designs. The gain ratio is again set by a pair of resistors, but the +in terminal is earthed, either directly, or via a resistor. This configuration is also called a virtual earth stage, and is common in mixing consoles and many other signal processing circuits.

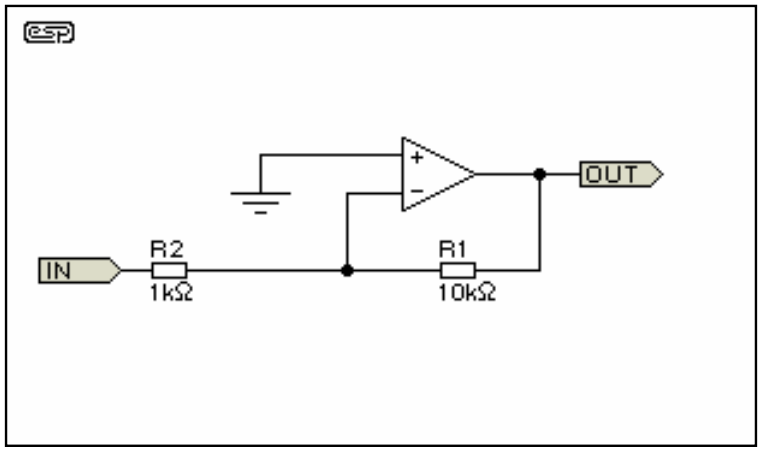

Figure 4 - Inverting Amplifier

Since +in is earthed and Rule #1 says that both inputs must be the same, -in will "appear" to be at earth potential as well (i.e. zero volts). Assume an input of 100mV DC. The output will be at -1V

DC, a gain of -10 (the minus indicates only that it is inverting, not that the circuit has "negative gain" which is actually a loss).

Input impedance is equal to the value of R2, and voltage gain is R1/R2, or 10 as shown. Note that this configuration is capable of negative gain (loss). If R2 is larger than R1 (say 20k), then the gain is equal to R1/R2 as before, so is now -0.5.

With the input at 100mV (again instantaneous AC or DC), the input current will be 100mV / 1000 (using Ohm's law), which is 100uA. The current through the feedback resistor must be exactly equal and opposite to ensure that zero volts is at the -in terminal (so we don't break Rule #1). As it happens, 1V / 10k equals 100uA, so the requirement is satisfied, since the output is negative.

As before with the non-inverting amp, the limitations of the opamp and its supply may cause Rule #1 to be broken, but the amp is now no longer operating in its linear mode, and Rule #2 will take over. Observation of the -in terminal will show a distorted waveform when the opamp can no longer operate in linear mode.

Inverting and Non-Inverting Buffers

A very common opamp application is the buffer stage, which (for the non-inverting configuration) can have an extraordinarily high input impedance, and a low output impedance. As with all opamp circuits, the output impedance may be very low (typically < 10 ohms), but the output current capability will not allow the circuit to drive such an impedance at more than the 20mA or so that is typical of most opamps. This would limit the output voltage (before clipping) to a maximum of +/- 160mV, or about 113mV RMS into 8 ohms. Distortion will be unacceptably high, and the end result is not worthy of further consideration.

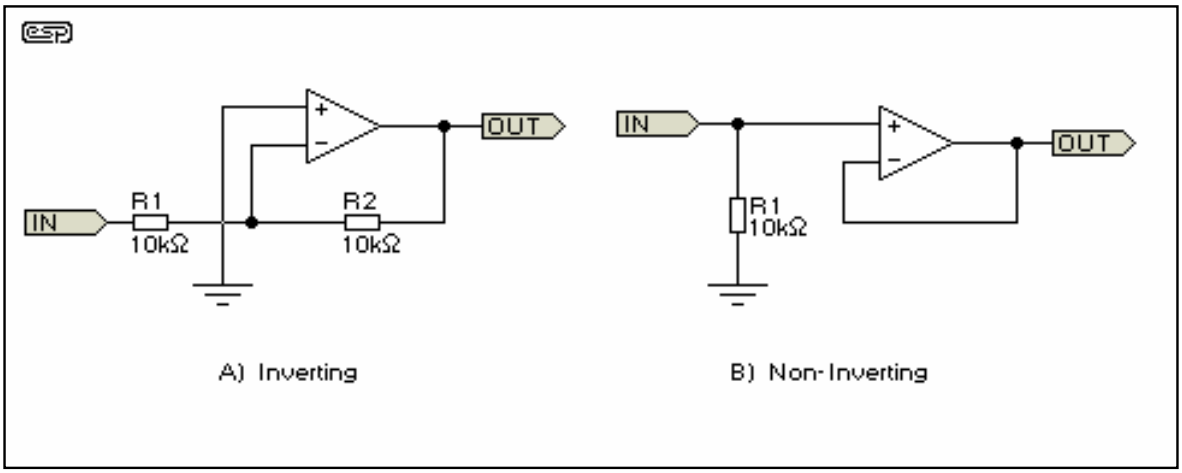

Figure 5 - A) Inverting and B) Non-Inverting Buffer

In many cases the non-inverting buffer can be replaced by an emitter follower, but performance is nowhere near as good. Input impedance is lower, output impedance is higher, and the gain is not quite unity. In addition there is more distortion and lower output drive capability.

The inverting buffer is more of a convenience than anything else, and is simply a normal inverting amplifier with unity gain. Input impedance is the same as R1, and very high values are not possible without excessive circuit noise.

Some Interesting Variations On Basic Circuits

It is now time to look at a few of the many variations on the basic circuits discussed above. It is not possible to cover all the different circuits that have been made using opamps, since there are so many that I could easily end up with the world's longest web page. I doubt that this would be appreciated by most of you :-)

I shall only cover the more common, or most interesting, as this will give a better appreciation of how versatile these building blocks really are. All of the circuits that follow will work - they are not theoretical, but real designs, and can all be made on the opamp test board.

High Impedance Amplifiers

The inverting buffer has been used in some very interesting ways. For example, a standard low cost TL071 opamp has an input bias current of about 65pA, and a claimed input resistance of 10^{12} ohms. To put this into perspective - assuming we have a way to supply the bias current without affecting input resistance - the input impedance could be as high as 10,000,000,000,000 ohms. That is 10Tohms (1 Tera-Ohm is 1000 Gig-Ohms). We will be completely unable to achieve this in practice, since the insulation resistance of a PCB is nowhere this figure, and the smallest amount of contamination will reduce the impedance dramatically.

In reality, we can easily expect to be able to get an input impedance of 100M ohms or more, but care is needed, since with high value resistors additional noise is produced. Since noise in a resistor is proportional to the voltage across the resistor and its resistance, it is easy to see how a simple circuit can become a real noise generator. Figure 6 shows the circuit and PCB layout for a very high impedance amplifier.

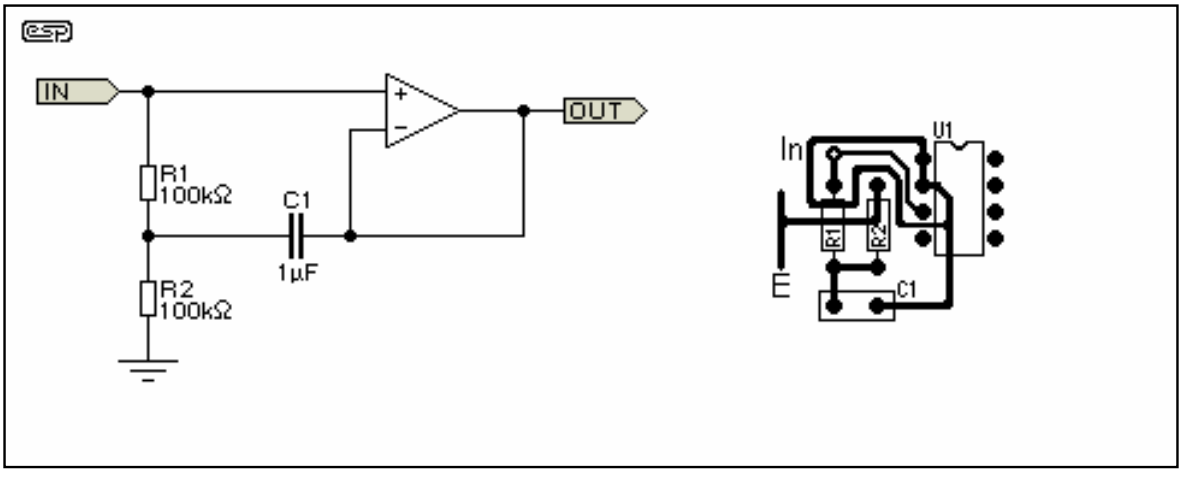

Figure 6 - High Impedance Amplifier

The bias resistor is 'bootstrapped' from the output, and this allows a lower resistance (for lower noise), while maintaining an extraordinarily high input impedance. A circuit such as this could be used for a capacitor microphone (for example), which will typically have such a small capacitance that any loading will reduce the low frequency performance to an unacceptable degree. The guard track can be seen encircling the input and the input end of R1. What on earth is a guard track? Read on ....

To prevent the resistance of the PCB from causing a problem, the input section may be 'guarded' with a section of track connected back to the output. Bootstrapping and guarding work in the same way. The guard track works by maintaining a voltage from a low impedance source around the input circuit that is the same voltage as the input. If they are the same voltage, no leakage current will flow. In reality it is not quite that simple.

Assume that the opamp has 100dB of gain at 1kHz (our test frequency). This equates to 100,000 - a little shy of infinity! Since the opamp has a finite gain, the 'unity gain' buffer will actually have a gain of 0.99999 - not 1 as we had assumed. This error reduces the ability of the opamp to bootstrap the circuit perfectly, so the 100k input resistance will only be effectively increased to 10G ohms.

But wait .... how does it increase the effective resistance at all? This is very simple. Assume an instantaneous AC voltage of 1 volt input to the amp. Normally, this would cause a current of 10uA into the 100k resistor of Figure 6. Because the bootstrapping action causes the voltage at the junction of R1 and R2 (Fig 6B) to be 0.99999V, there is actually only 1 - 0.99999 = 10uV across the resistor. The input current is now 10uV / 100k = 100pA (1 pico-amp is 10^{E-12}A). We can now calculate the equivalent resistance as R = 1V / 100pA = 10G ohms. This will fall at increasing frequencies as the opamp starts to run out of gain.

Oh yes, the term "bootstrap" comes from the unlikely picture of a man "lifting himself off the floor by his own bootstraps". As you might have guessed, the term is somewhat antiquated, but there has never been any move to change it (thank goodness). It is intended to show that the impossible can be done, but it is not really impossible, and is just a very clever example of lateral thinking.

The bootstrapped circuit cannot be used at DC, since it requires a capacitor for its operation. This is not as much of a limitation as may first be thought, since DC is quite inaudible

---

Simulated Inductor

This circuit has to be one of the all-time classics. Although it can also be done with a single transistor, the performance of the opamp version is so much better that the alternative is not really worth considering.

Inductors have always been a problem in electronics, as they are by nature relatively large, and being made from a coil of wire, tend to pick up mains hum as well as other noise in the electromagnetic spectrum. The idea of simulating an inductor using an opamp has been about for a long time. I have no idea who invented the circuit, but I am deeply impressed!

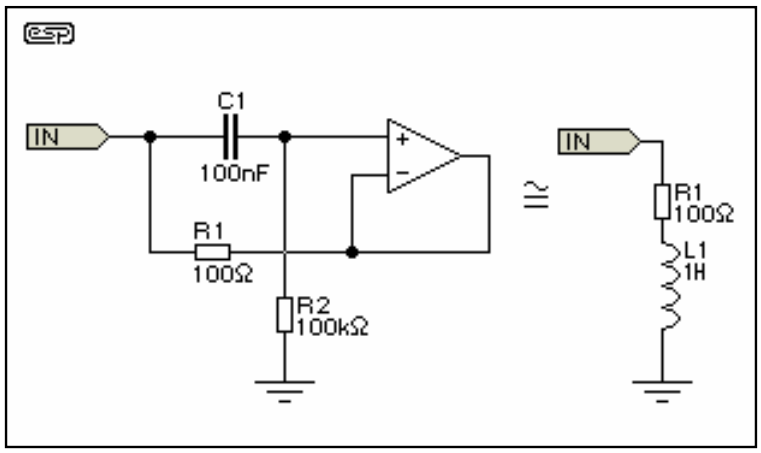

Figure 7 - Simulated Inductor

The circuit is so much smaller than a real inductor (at least for the larger values), and does not suffer from noise pickup. It does have a limited Q (quality factor), but it is rare that very high Q circuits are needed in audio, so this is not really a problem. It is also variable over a moderately wide range, something that is very difficult with the wire wound genuine article. So, how does it work?

The idea is very simple, but operation is less easy to understand. Essentially the circuit uses a capacitor, and 'reverses' its operation, thus making an 'inductor'. The essential character of an inductor is that it resists any change in its current, so if a DC voltage is applied to an inductance, the current will rise slowly, and the voltage will fall as the external resistance becomes more significant.

An inductor also passes low frequencies more readily than high frequencies - the opposite of a capacitor. An ideal (that word again) inductor has zero resistance, so will pass DC with no limitation, but will have an infinitely high impedance at infinite frequency. These limits are generally considered to be outside the audio range.

To understand how the circuit works, remember that the output of the opamp is (almost) exactly the same as the non-inverting input. Imagine a DC voltage of 1V is suddenly applied to the input, via resistor R1. The opamp will ignore the sudden load because the change is coupled directly to the input via C1. The opamp will represent a high impedance. Just as an inductor would do.

With the passage of time, C1 charges via R2, the voltage across R2 falls, so the opamp sees less and less of the input signal, and starts to draw current from the input via R1. This continues as the capacitor approaches full charge, and the opamp has close to zero input, so the output is also close to zero volts.

Eventually resistor R1 becomes the only limiting factor to current flow, and this appears as a series resistance within the inductor in the same way as the resistance of the wire in a real inductor behaves. This series resistance limits the available Q of both the simulated and real inductor, with the main difference being the magnitude - real inductors generally have much less resistance than the simulated variety.

Inductance is measured in Henrys, and for the simulated inductor is equal to ....

$$L = R1 * R2 * C1$$

A more accurate version of the formula (due to Siegfried Linkwitz) is shown below, but normally the error from the simple version will be very low with typical values - a ratio of 100:1 would normally be the lowest one would use, and this will have an error of only 1%. Component tolerance will have more effect, but for completeness, here is the accurate version ...

$$L = C1 * R1 * (R2 - R1)$$

so for the circuit shown is 1 Henry. This is a large inductance, and would be very expensive and bulky if made conventionally. The real inductance will have lower resistance and higher Q, but will need to have a large iron core to be able to withstand even a small amount of DC, and the inductance will change depending on how much DC is present. The simulated inductor is limited by the current capability of the opamp, so can handle up to +/-20mA with no change in performance.

There are some limitations to the simulated inductor.

- First (and most annoying) is that one end of the inductor is earthed. Although simulated inductors have been made that are floating (can be connected in any way you like), these are expensive and uncommon. Fortunately the standard version is quite suitable for many audio applications, so this is not too great a burden.
- The simulated inductor cannot be made with high Q, since the value of R1 cannot be made low enough to allow a Q of more than about 10. This is due to the limitations of the opamp - a minimum value of 100 ohms is usually specified for R1, although lower values are sometimes used. This represents a series resistance (equivalent to wire resistance in a real inductor.
- There is also a resistance effectively in parallel with the simulated inductor, equal to the value of R1 + R2. Although this can be measured, it is not generally a hindrance to practical circuit design.
- Although the simulated inductor acts in many ways like the real thing, it does not have the same energy storage, and cannot respond like a proper wound inductor. When the input voltage is suddenly removed from a real inductor, the collapse of the magnetic field causes a large voltage pulse of the opposite polarity - this does not happen properly with a simulated inductor, since there is no magnetic field involved. The simulated inductor will still try, but is limited to the voltage swing of the opamp, so the flyback pulse is limited to this value.

Figure 8 shows two simple LC filters. One is using a real inductor, and the lower circuit has a simulated inductor. They are both series resonant circuits, and are tuned to the same frequency (159Hz). The reference level (near the top of the graph) is 0dB, and neither circuit exhibits any appreciable loss outside the stop band.

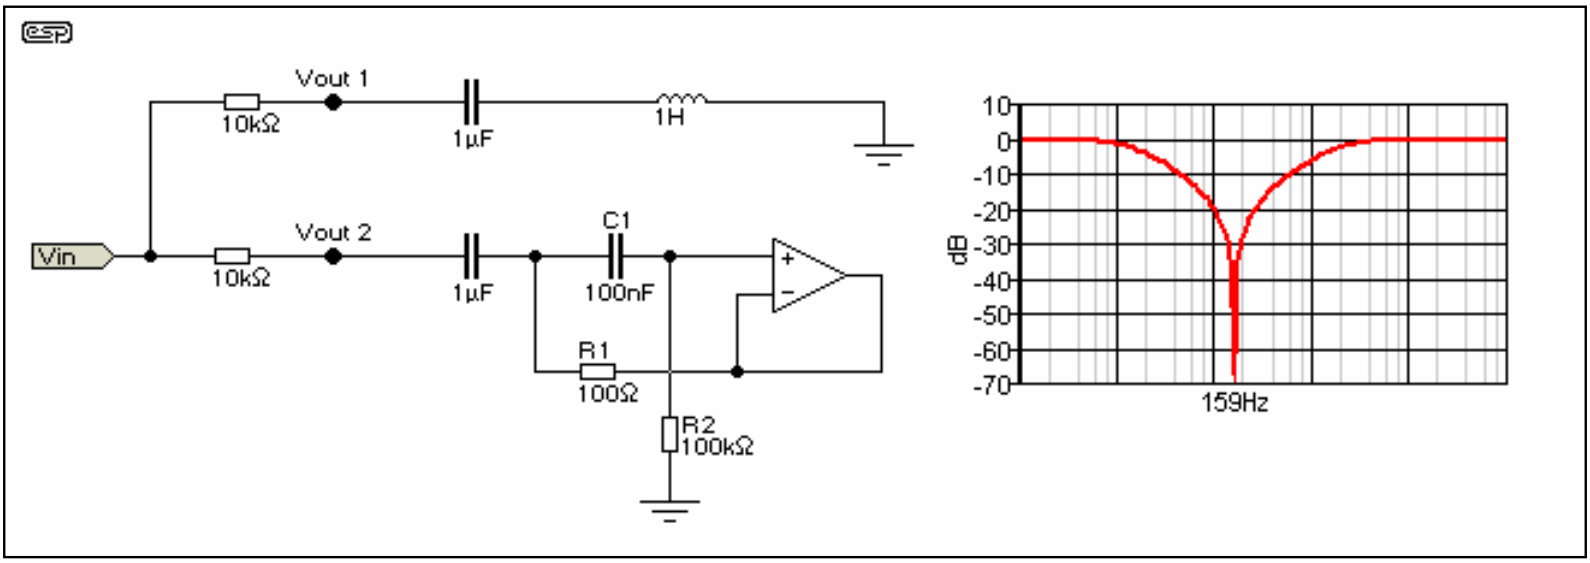

Figure 8 - LC Filters, Real And Simulated

The performance of both is almost identical as a simple filter as seen from the response plot, except the thing you don't see (mainly because I didn't include it) is that the simulated inductor has a slightly shallower notch, at about 37dB instead of 40dB. The frequency is calculated from ...

$$F = 1 / (2 * \pi * \sqrt{(LC)}) \text{ Hz}$$

A series resonant circuit has minimum impedance at resonance, and in the configuration shown will act as a notch filter, reducing the level at the resonant frequency. Because of the relatively low Q, the notch is not very sharp, but the simulated inductor is an important building block for equalisers and spectrum displays, and is quite common in audio.

Note that at the junction of Cin and the inductor, the voltage is higher than the input voltage. This is normal behaviour for a series resonant circuit.

All-Pass Filter

The all-pass filter is one of the strange ones. It passes all frequencies perfectly, with no attenuation at all within the capabilities of the opamp used. All it does is change the phase of the signal, and this circuit is used in everything from phase correction circuits for sub-woofers to guitar effect pedals. It is a versatile and useful building block, and the circuit is shown in Figure 9.

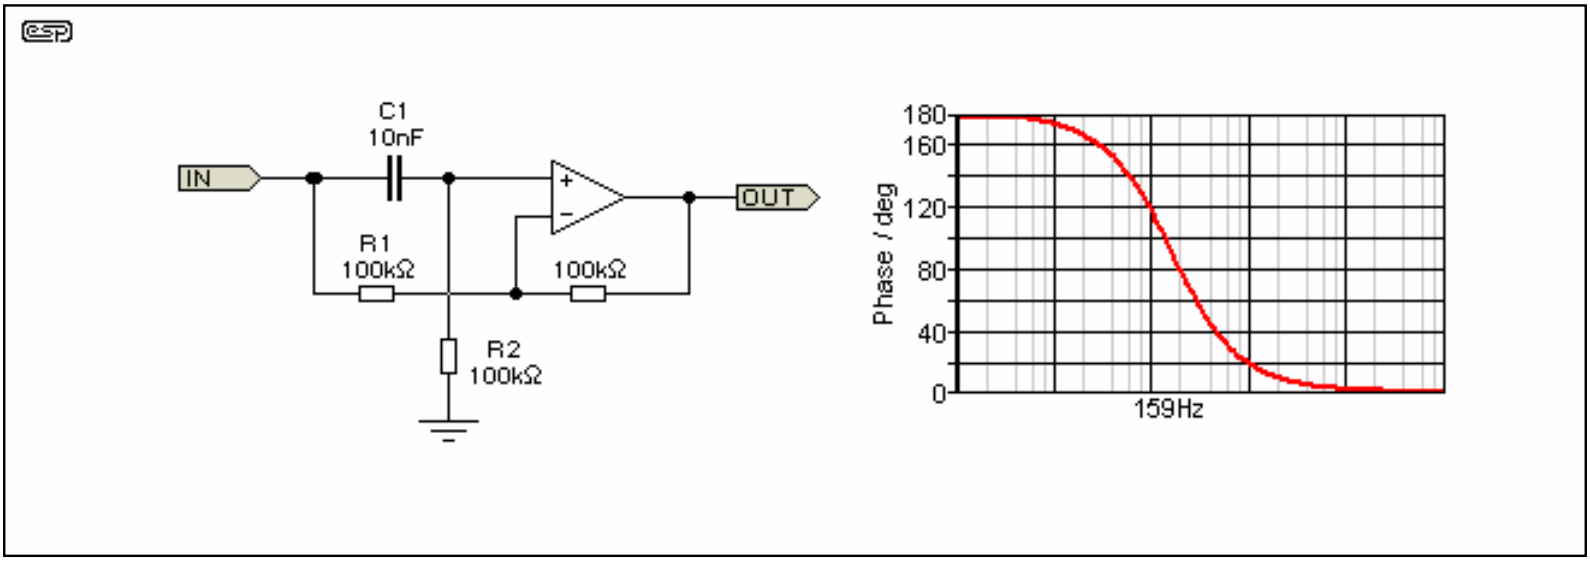

Figure 9 - All-Pass Filter

The circuit shown will have a 90 degree phase shift at 159Hz. At DC, phase shift is 180°, and at high frequencies it is 360° (note that 360° phase shift is *almost* the same as 0° - there is a subtle difference for transient signals, so the two can be considered identical only for steady state signal conditions). The shift of phase about the centre frequency is completely inaudible, but if a pot is substituted for R1, the phase can be swept back and forth. This is audible, and by cascading a number of these circuits "phaser" or vibrato (frequency modulation) effects pedals can be made. One of the latter is described in my projects pages.

The input signal is effectively applied to both opamp inputs, but there is always a small phase difference except at DC or infinite frequency. The value of C1 and R2 determine the frequency at which there is a 90° (or 270°) shift, and the frequency is determined with the formula ...

$$Fo = 1 / (2 * \pi * R2 * C1)$$ ... where Fo is the 90°phase shift frequency

A quick analysis will show how this works. Assume a DC input of 1V; at DC the cap has no effect, so the circuit operates just like an inverting buffer. The output is therefore -1V, so there is a 180° phase shift. At high frequencies, the reactance of C1 is negligible, and the full input is supplied to the opamp's +in terminal. Remembering Rule #1, the opamp output will be such that both inputs will have the same voltage, and in order to do this, the output must be equal to the input at high frequencies.

At intermediate frequencies, the combination of R1 and C1, along with R2 and R3 will ensure that the output amplitude remains constant, but the phase will change. The relative positions of C1 and R2 may be reversed, which will modify the characteristics of the circuit.

Phase Shift Oscillator

There are many things in life I do not understand, but one of the simpler ones is the phase shift oscillator implemented using an opamp. Don't get me wrong - the circuit I understand perfectly.

The bit I *don't* understand is how come (up until recently) I have never seen this circuit published - anywhere ???

In its heyday, this circuit was used almost anywhere a simple sine wave oscillator was needed, and I have seen it made with valves, transistors and even FETs. What I had *not* seen until I designed one was a phase shift oscillator using an opamp. As it transpires, although *I* had not seen this done, my trusty editor in the UK has.

He has seen it in a number of publications including John Linsley-Hood's "The Art of Linear Electronics". JLH also supplies the equation for frequency calculation ...

$$Fo = \sqrt{6} / (2 * \pi * C * R)$$

Loop gain must be 29.25 dB according to Mr Linsley-Hood, and lacking further information I must assume that the formula only applies if all resistors and capacitors are equal, and gain would be the minimum required for the circuit to oscillate.

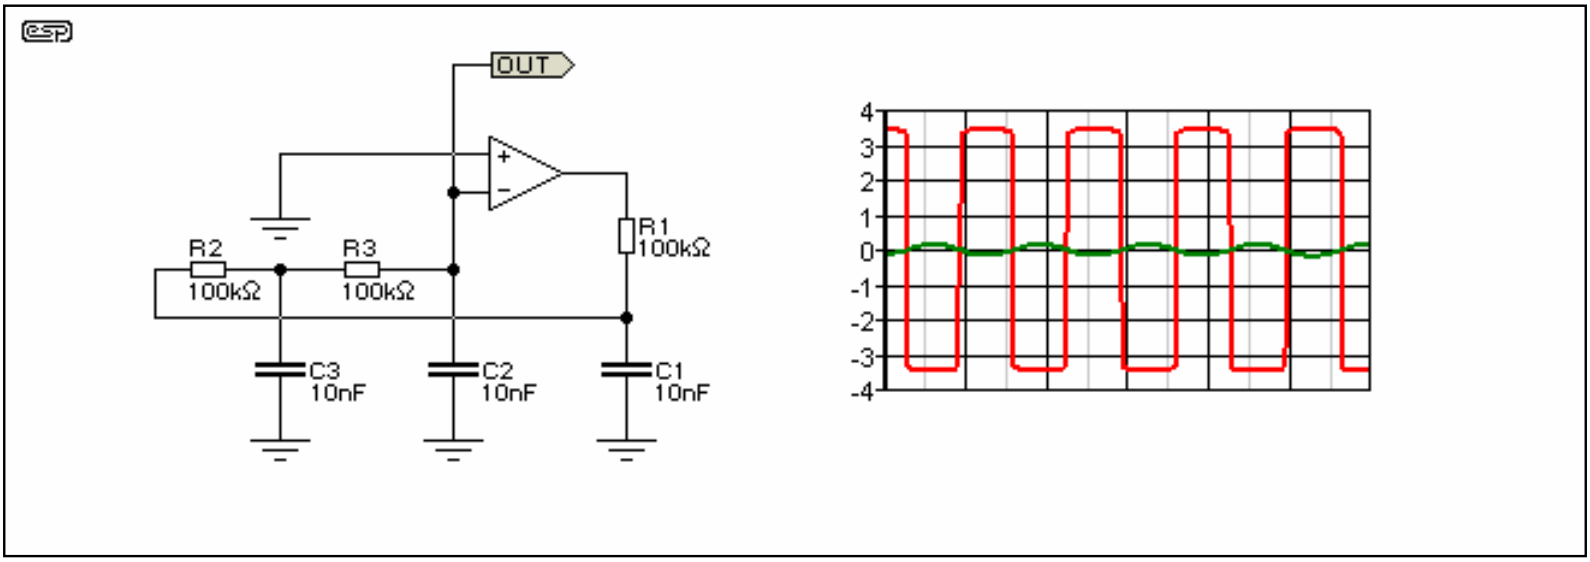

Figure 10 - Phase Shift Oscillator

The frequency stability of this circuit is quite good, but as with all phase shift oscillators the amplitude varies when the frequency is changed. Any resistor can be varied to change the frequency, and the use of a pot allows continuous variation over a 5:1 range (or more if you experiment with the component values).

This is a perfect example of an opamp being unable to obey Rule #1, and its operation is governed by Rule #2. The circuit is essentially unstable, and the opamp is always trying to play catch-up (without success, or the circuit would stop oscillating).

The frequency is a cow to determine if different values are used for R or C, and although I believe there *is* a formula, it is apparently a very tedious process (I've not seen it myself). The circuit shown above will run at about 420Hz, with a sinewave output of around 500mV (with +/-15V

supplies) - although JLH's formula seems to indicate that it should oscillate at 390Hz If you *really* want to know, you will have to build one. Changing the value of any resistor or capacitor will change both frequency and amplitude. The square wave at the output is at almost the full +/-15V supply voltage (limited only by the output circuit of the opamp).

The sinewave shown on the oscilloscope trace is obtained from the Vout terminal, and the square wave is obtained from the opamp's output (these are not to scale). The string of resistors and caps acts as a phase shift network, and oscillation takes place at that frequency where there is an exact 180 degree shift, converting negative feedback into positive feedback. The circuit is stable at DC, since it has negative feedback through the string of resistors.

Let's have a look at how it works. Remember Rule #2? Now have a look at the signal at the inverting input. As you can see, the output takes the polarity of the most positive input, so when the -in terminal is positive, the output is negative. Over a period of time based on the resistance and capacitance, the voltage on the -in terminal will fall towards zero volts, and will eventually become negative - the output promptly swings positive, and the cycle repeats. Like all filter circuits, the resistor / capacitor (R/C) network introduces a time delay, and it is this (plus the simple low-pass filter formed) that produces a sinewave with less than 1% distortion. By no means wonderful, but quite adequate for a number of simple applications.

The sinewave output is at relatively high impedance, and should be buffered with an opamp before use. Any loading will alter both amplitude and frequency.

Schmitt Trigger Oscillator

Also known as a free-running multivibrator, the Schmitt trigger oscillator is one that is much more conventional in terms of opamp designs. Like the phase shift oscillator (indeed, like all oscillators) it is an inherently unstable circuit. Also like the preceding example, this circuit cannot obey Rule #1 (since that would make it stable), so follows Rule #2 instead.

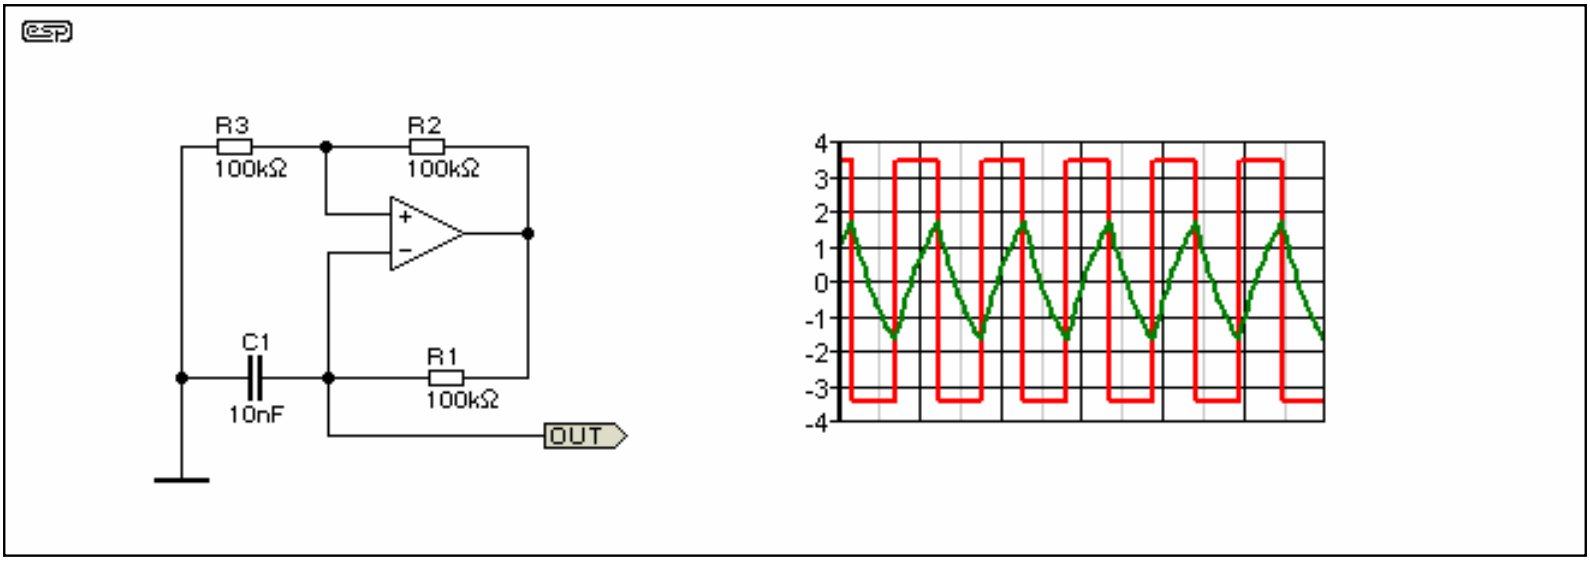

Figure 11 - Schmitt Trigger Oscillator

This circuit is very common where an oscillator is needed, but as shown produces a triangular waveform that is quite high in harmonic content. Note the use of positive feedback, via R2 and R3. This particular connection creates a Schmitt trigger, a useful and fairly inscrutable circuit for the beginner. Although this is a simple circuit, understanding how it works is not.

Assume a supply voltage of +/-15V, and ignore the losses in the opamp output stage. We shall start at the point where the opamp's output is at +15V. The +in terminal will be at 7.5V, since there is a voltage divider from the output to earth. C1 will therefore charge to a positive voltage, until such time as the voltage is very slightly greater than 7.5V. Since Rule #2 must be obeyed, the -ve input is now the more positive, so the output will swing negative. The cap now must discharge its positive voltage and start charging to a negative voltage. Once the negative voltage is less than (more negative than) -7.5V, the output will swing positive and the cycle repeats.

At least it is possible to determine the frequency of this oscillator, and it is approximately equal to ....

$$X = R3 / (R2 + R3)$$
$$Fo = 1 / (2 * R1 * C1 * \log_e((1 + X) / (1 - X))$$

For the example above (after noting that it is the natural log *not* base 10 :-) frequency is ...

$$X = 100 / 200 = 0.5$$
$$Fo = 1 / (2 * 100k * 10nF * \log_e(1.5 / 0.5))$$
$$Fo = 1 / (0.002 * \log_e(3))$$
$$Fo = 455\ Hz$$

The triangle wave output is at relatively high impedance, and should be buffered with an opamp before use. Any loading will alter frequency, but not amplitude (this is fixed by the voltage divider of R2 and R3).

Pure Audio

The next set of circuits are pure audio, and include tone controls, equalisers and filters, as well as balanced line driver and receivers. There is also a simple power amplifier suitable for use with headphones or low powered speakers.

When we speak of audio, the commonly accepted range is from 20Hz to 20kHz, and at some point someone decided that the centre frequency is 1kHz. I have never known why, since if you look at the octaves covered by the audio range we have a sequence like this ...

20 40 80 160 320 640 1280 2560 5120 10240 20480

This is a total of 10 octaves, so the centre frequency must actually be 640Hz, and indeed this is much closer to reality than 1kHz. If we were to divide the musical spectrum based on energy content, the centre frequency is about an octave lower, or 320Hz (approximately - it depends to a large degree on the style of music).

I am going to break with tradition and suggest that the 640Hz frequency is the midpoint, and 1kHz shall be ignored for other than comparative purposes.

So that the limitations of opamps in an audio circuit can be fully understood, we shall also look at the compensation curves typical of standard and high quality opamps, and examine the alternatives for very wide

bandwidth.

Baxandall Tone Controls

This is the most common of all modern tone control circuits, and was named after PJ Baxandall who came up with the idea many years ago. The original design was article was entitled "Negative Feedback Tone Control - Independent Variation of Bass and Treble Without Switches", and was published in Wireless World (now Electronics World) in 1952. This type of control is fully symmetrical, and there is no interaction between the controls, unlike the older passive controls. When centred, there is neither loss nor gain, and the opamp acts as a buffer. Frequency response is absolutely flat, provided the pots centre precisely.

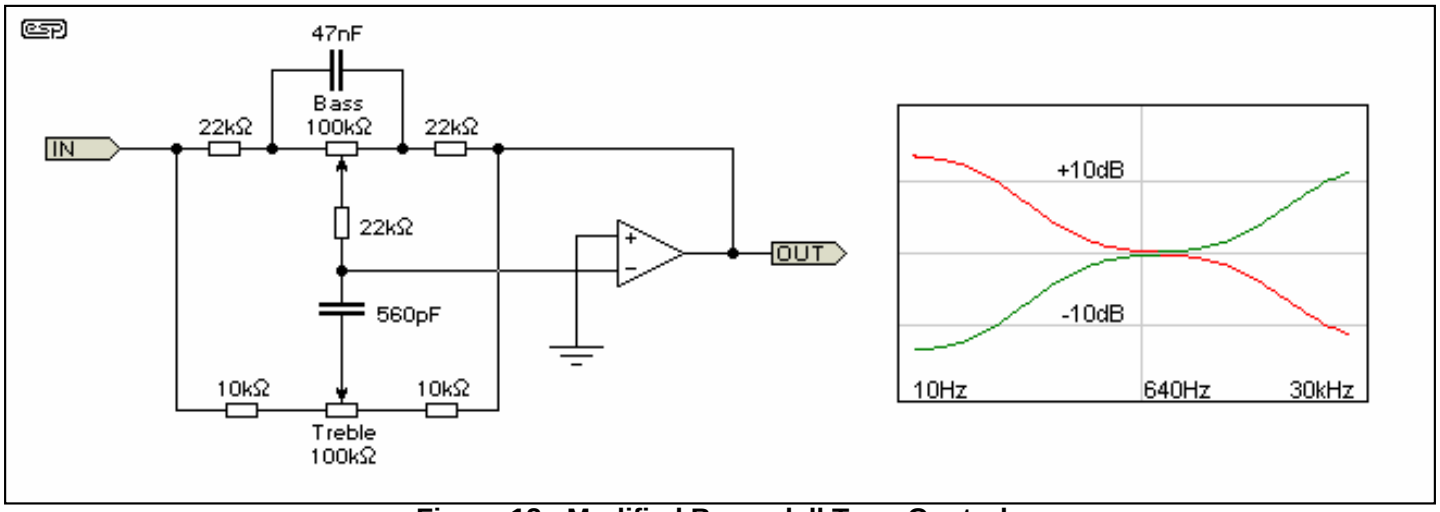

Figure 12 - Modified Baxandall Tone Controls

The circuit is a frequency dependent feedback arrangement, and provides boost and cut for high and low frequencies. It is common for designers to make the turnover frequency for both treble and bass centred around 1kHz, but this is essentially a stupid thing to do (IMHO). Ideally, bass boost/cut should start from no higher than about 160Hz, and treble boost/cut should start at no lower than around 2.5kHz - this is two octaves either side of the 640Hz nominal centre frequency for audio. In practice it will be found that this is more natural, and provides the boost where it will do the most good (or harm, for the purists!).

Figure 12 shows a more or less conventional circuit, with the turnover frequencies set to my preferred values. This has the effect of limiting the maximum boost and cut within the audible spectrum to somewhat less than the 20dB often quoted. IMO, this is an outrageous amount of control, and far exceeds what is needed for normal system balancing. If 20dB of anything is needed, then I suggest that the system is grossly inadequate, and should be replaced!

The maximum boost is about 14dB, which is still far more than necessary, the lower turnover frequency is about 150Hz, and the upper turnover frequency is about 2.5kHz. These can be changed by modifying the values of the bass and treble capacitors, and the amount of boost and cut is varied by changing the series resistors for each pot.

This circuit must be driven from a low impedance, so connecting it after the volume control (for example) is a no-no. Ideally, the output of an opamp will be the source, thus ensuring the required low impedance.

The formulae for designing these active tone control circuits are fairly simple, but can be quite inaccurate under some circumstances. At least it will give you a starting point to have the formulae, so the formulae for

the bass control lower turnover frequency (Fb0) and +/-3dB frequency (Fb1) are (respectively) ....

> Fb0 = 1 / (2 * π* C * Rv) ... where C is the cap across the pot, and Rv is the pot value
> Fb1 = 1 / (2 * π* C * Rs) ... where C is the cap, and Rs is the series resistance to the pot

These give (again, respectively) ...

> Fb0 = 1 / (2 * π* 47nF * 100k) = 33 Hz
> Fb1 = 1 / (2 * π* 47nF * 22k) = 154 Hz

The treble is a little trickier, since there is an interaction with the bass control, due to the bass feed resistance from the bass pot wiper. In theory (ha ha) the frequency is determined by

> Ft = 1 / (2 * π* C * Rb) ... where C is the treble cap (560pF above) and Rb is the bass feed resistor from the pot wiper.

While this seems reasonable, the formula comes up with a frequency of nearly 13kHz, which is obviously wrong. There are series resistances in the entire treble control network, and the interactions are interesting to say the least. In fact, the +/- 3dB frequency for the treble control changes with the pot setting. For example, at 80% of rotation, treble boost is +3dB at just over 3.5kHz, with a maximum boost of 6.3dB at 20kHz. This may seem to be a bad thing, having the frequency shifting about as the pot is varied, but in practice it works very well. To obtain the results *you* want, I suggest that experimentation is in order !

A final word about the tone control circuit. Note that it is a 'virtual earth' circuit, so the feedback at all times will maintain the -ve input at zero volts. The bass and treble content of the input waveform will force the amplifier to provide just the amount of boost or cut at any frequency to maintain the 0V condition on -in. You will find this useful as you work towards an understanding of the complete circuit.

Active Filters and Crossovers

The active filter is one of the most common opamp applications after basic amplifiers. There are essentially four different types of filter, but each can be constructed using a myriad of different techniques. I shall only use the most common arrangements, since the complete array is truly mind-boggling. The area of filters is the subject of complete books (from a number of authors) and I cannot hope to cover any but the most common.

Firstly, there are many different possibilities for filters. We shall look at each of the different responses, orders and types before anything else. The filter "order" gives us essential information about how well (or otherwise) a given filter will reject unwanted frequencies. The standard ones are:

Order	**Sections**	**Nominal Rolloff**
First	1	6 dB / Octave
Second	2	12 dB / Octave
Third	3	18 dB / Octave
Fourth	4	24 dB / Octave
"n"	Where n > 4	6 dB / Octave / section

Table 1 - Filter Orders

In audio work, the first four are most commonly used, since as the filter order increases, the transient response becomes worse and greater phase disturbances become evident. All filters affect the phase of the signal, and all filters have some effect on transient response. These are unavoidable, regardless of whether the filter uses valves, transistors or opamps, or is completely passive, using only capacitors, resistors and/or inductors.

There are 4 main responses that are obtainable from filters. Some are - or can be - derived from others, so the base types are given first. In particular, band pass and band stop filters can be simple filters with a narrow response (typically used for equalisation circuits), or band pass filters made from a combination of a low frequency high pass filter, followed by a higher frequency low pass section. These are commonly used in crossover networks.

Response	Passes ...	Blocks ...
Low Pass	Low frequencies	High frequencies
High Pass	High frequencies	Low frequencies
Band Pass	Selected frequency	All other frequencies
Band Stop	All other frequencies	Selected frequency

Table 2 - Filter Responses

Low and high pass filters are usually conventional enough, but band pass and band stop filters can be made in many different ways.

Essentially, there are also a few basic filter alignments, which are as follows (not all are included, and many are applicable to filters of more than one section, or more complex arrangements):

Filter Type	Q (Typ)	Characteristics
Bessel	0.57	Best time delay
Butterworth	0.707	Flattest amplitude
Chebychev	0.8 - 1.3	Fast initial rolloff
Cauer / Elliptical	0.7 - 1.3	Very fast initial rolloff

Table 3 - Filter Types

Of the above, the Butterworth is the most common in audio. Although some filter's responses may be closer to Chebychev, this is commonly more by accident than design. A Chebychev alignment is very common in acoustical filters (a loudspeaker - box - port combination, for example), but is not generally considered desirable in electronic filters for crossovers or other purposes.

You may have noticed that the Linkwitz-Riley filter was not mentioned in the above table. This is because it is an alignment between filters, and not an alignment type itself. The Linkwitz-Riley filter is a rearrangement of two cascaded 2nd order Butterworth filters, and relies on the characteristics of the two sections (high pass and low pass) to provide the total amplitude and phase response.

Finally, there are different circuit arrangements that are commonly used in audio to create the filters described above. As you can see by now, the combinations and permutations of all of these different

possibilities is immense.

Circuit Type	Gain	Characteristics
Sallen-Key	Unity	Simple design
Equal component value	Depends on Q	Simpler design
Multiple feedback	Depends on Q	Relatively complex
State Variable	Depends on Q	Relatively complex
Biquadratic	Depends on Q	Relatively complex
Passive	< unity	Simple or complex

Table 4 - Circuit Types

This is a condensed listing, and there is some overlap between the topologies in some cases. Indeed, in some cases it is difficult to see any appreciable difference at all. For the sake of simplicity (and to keep this section to a readable length), I shall concentrate on the Sallen-Key filter type, using Butterworth alignment.

Before we go there, we need to define some of the terms you will see. Again, I have kept this list to the minimum for the sake of simplicity, but armed with this knowledge you will be able to understand the circuits and descriptions that follow.

Terms and Definitions

- **Cascading:** Simple filters can be made with one (or none) active devices. As filter orders become greater, it is no longer feasible, so filters are joined together in series to obtain the desired response. This complicates the design (often dramatically).
- **Cutoff Frequency:** Also shown as Fo, this is the -3dB frequency of the filter, relative to the highest peak (if any exist) in the passband.
- **Decade:** A 10:1 (or 1:10) ratio of frequency. For example 100Hz to 1000Hz is one decade.
- **Decibel:** (dB) - the most common way to describe amplitude in audio. The dB scale is logarithmic, and describes the amplitude as we hear it. A 3dB drop in gain equates to half the power in an amplifier.
- **Quality Factor:** Commonly known as Q, this is the inverse of the filter's damping. For example, a Butterworth filter has a Q of 0.707, which equals a damping of 1.414. Higher Q gives more ripple for low and high pass filters, or makes a bandpass or band stop filter more selective.
- **Octave:** A 2:1 (or 1:2) ratio of frequency. For example, 440Hz to 880Hz is one octave (Musical "A" note).
- **Order:** The order of any filter determines its rolloff frequency response. First order filters roll of at 6dB per octave, and as the order increases, so too does the rolloff rate. An additional 6dB / octave is gained for each additional order, starting from first. A 3rd order filter will therefore roll off at 18dB/octave, for example.

Designing Our First Filter

The first active filter must be the first order low pass. By simply reversing the filter components, this becomes a first order high pass. In each case, the filter only consists of the resistance and capacitance, with the opamp simply isolating the filter from the following stages. Q is not variable in a first order filter, and the only options are high pass and low pass. A bandpass filter can only be created by cascading a high and low pass filter. Although the least useful of all filters, they are easy to understand, so make a good starting point.

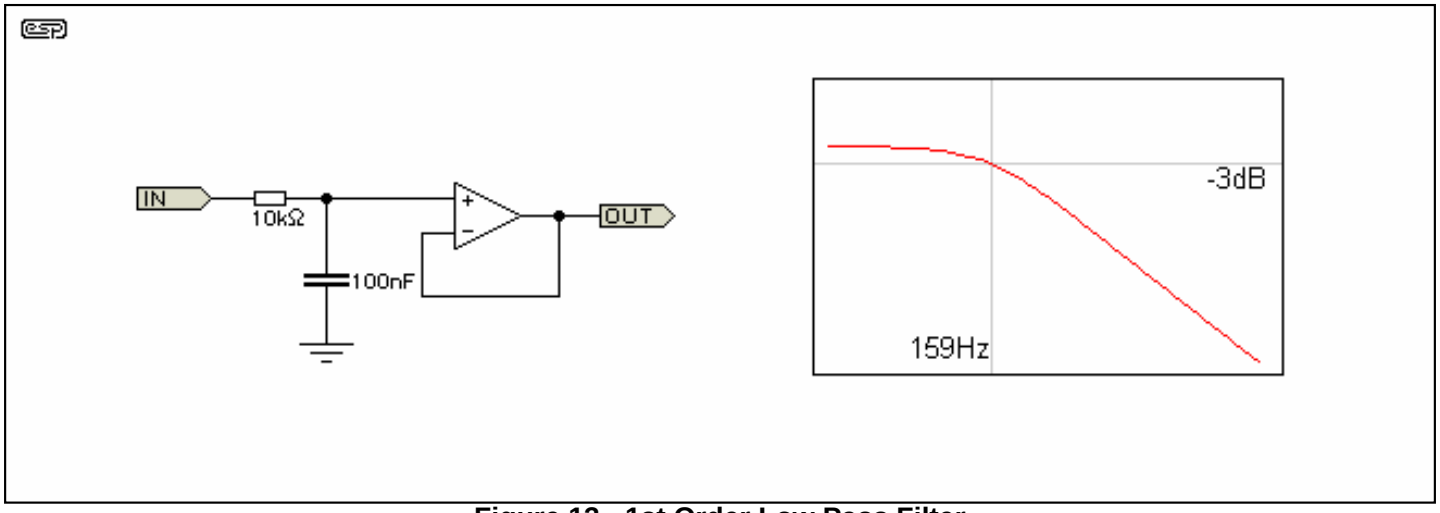

Figure 13 - 1st Order Low Pass Filter

As you can see, at low frequencies, the capacitor has little effect on the signal, which is simply passed through the resistance and buffered by the opamp. As the frequency increases, the capacitor will shunt more and more of the signal to earth, until at very high frequencies, no appreciable amount of the signal is passed. As the capacitor's reactance becomes significant with respect to the resistance, the signal will be subjected to a phase shift as well as reduction in amplitude. When the capacitive reactance is equal to the resistance, the amplitude will be 3dB lower than at low frequencies.

Rc = 1 / (2 * &pi * F * C) ... where Rc is capacitive reactance

This is the cutoff frequency of the filter, and is determined with the formula

Fo = 1 / (2 * π* R * C) commonly shown simply as ...
Fo = 1 / (2 πR C)

Note that the input of this filter *must* have a low impedance return to earth at the input, or the opamp will not have any bias current or voltage, and will not work. This rule applies to low pass filters in all cases without exception.

For the filter in Figure 13, the frequency is determined by ...

Fo = 1 / (2 π* 10k * 100nF) = 159 Hz
Rc = 1 / (2 π* 159 * 100nF) = 10k ohms

By reversing the positions of R and C, we obtain a high pass filter. The formula remains the same, and the two filters will have a complementary response centred at the 159Hz frequency. There is no need for an earth return at the input for a high pass section, as this is provided by the resistor.

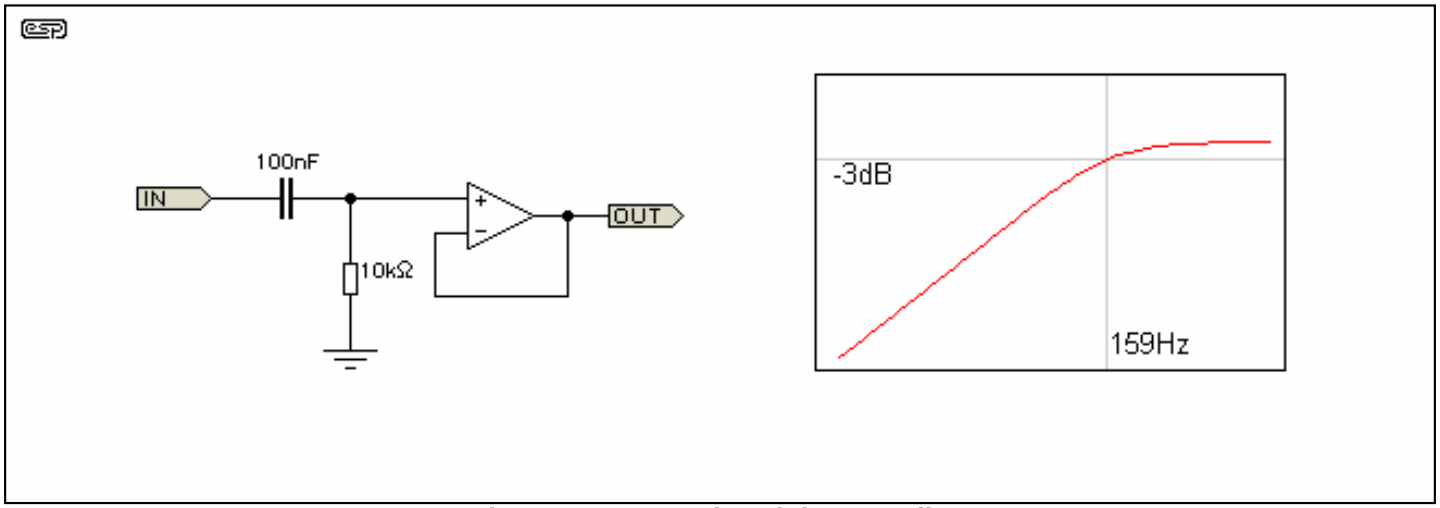

Figure 14 - 1st Order High Pass Filter

In their simplest forms, these two filter sections are also known as integrators (low pass) and differentiators (high pass). This is of some consequence, as these terms are commonly used in electronics.

A bandpass filter is created by cascading a high pass and a low pass, as shown in Figure 15. An opamp may be used in between the two sections to prevent any interaction. As shown, it is also possible to scale the first filter so that interaction is minimised. This works well enough in practice to be a useful technique. Scaling merely means that the ratio of values remains the same, but the resistance is reduced and the capacitance increased to make a lower impedance filter with the same characteristics. The generally accepted scaling factor is one decade (an "order of magnitude", or a 1:10 ratio). For Figure 15, I simply selected the lowest sensible resistor value of 1k, and the capacitor was chosen more or less at random to give an acceptable graph of the response.

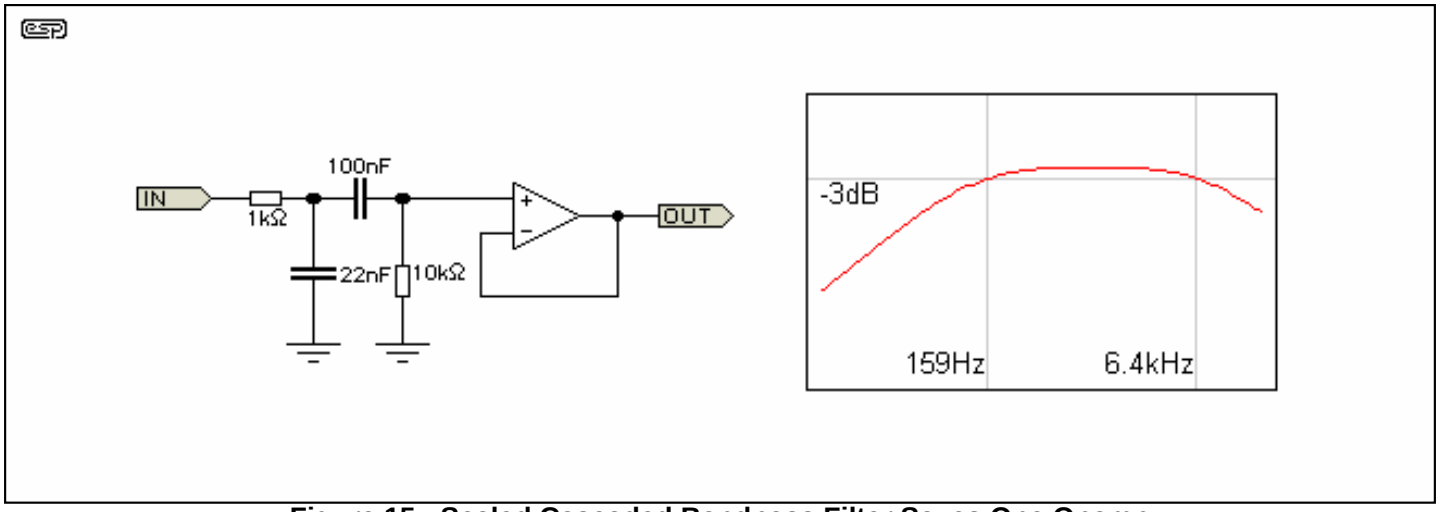

Figure 15 - Scaled Cascaded Bandpass Filter Saves One Opamp

In reality, it may be found that the value of capacitance becomes so great that the capacitor will be more expensive than a section of an opamp. Alternatively, the resistance may become so low that no opamp can drive the load. In all cases, it is essential to ensure that impedances are within the acceptable range for the opamps used. Generally, impedances of less than 1k at any frequency are not recommended. For noise considerations, very high resistance values are also not recommended, and I suggest that 100k is a reasonable compromise. There will be occasions where this is not practicable and higher values may be the only sensible solution, but these should be few and far between.

If the high pass section of Figure 15 is verified by calculation, it is discovered that the cutoff frequency (Fo) should be 7234Hz, and not 6400Hz as shown. The difference is caused because the second filter loads the first, shifting the frequency. This is a very good reason to isolate the sections using an opamp.

Component Selection

All following filter sections will use resistance within the range of 1k to 100k. This gives two decades of freedom, and this is more than enough to allow capacitors of sensible sizes to be used. Very low capacitance values are to be avoided, since the capacitance of wiring (PCB tracks etc.) will modify the filter characteristics to a possibly unacceptable degree. I generally try to keep capacitance above 1nF wherever possible, and this may save you some grief as we progress. Likewise, any capacitance above 1uF becomes large and relatively expensive, but within this range we also have two decades of freedom, and there is virtually no audio filter that cannot be designed within these constraints.

Generally, it is sensible to select the capacitor value first, as these have less available values within a decade than resistors. Capacitors have 12 values per decade (the E12 series), while resistors have up to 96 values per decade (E96 series). The latter are not usually easy to get, but the E24 series is now very common, and has (surprise!) 24 values per decade. The E12 and E24 series are shown in Table 5.

E12	1.0		1.2		1.5		1.8		2.2		2.7		3.3		3.9		4.7		5.6		6.8		8.2	
E24	1.0	1.1	1.2	1.3	1.5	1.6	1.8	2.0	2.2	2.4	2.7	3.0	3.3	3.6	3.9	4.3	4.7	5.1	5.6	6.2	6.8	7.5	8.2	9.1

Table 5 - E12 and E24 Component Values

These values are multiplied or divided as needed for any decade range from 0.1 Ohm up to 10M Ohms, and from 10pF up to 10uF. Generally it will be found that at the extremes of the ranges (such as from 10pF to 100pF), most stockists do not have the full range of values. This is another good reason to stay within reasonable limits for all component values wherever possible - not just for filter designs.

Second Order Filters

Note that all response graphs shown in this section cover the frequency range from 10Hz to 10kHz, and all but the Chebychev response are from 0dB to -20dB (the Chebychev is from +10dB to -20dB). The reference input voltage is 1V RMS, or 0dBU.

By using multiple feedback paths, a second order filter can now be designed. These are the first genuinely useful filters for crossovers and the like, and are the most commonly used in both electronic and passive crossover networks. There are some unpleasant side effects to the second order high and low pass filters, but this has never stopped anyone from using them. As we shall see, these effects can be cancelled to some extent, but unless exotic configurations are used you can never get phase coherency.

A phase coherent filter gives the design some special characteristics that are extremely useful in audio. This simply means that at any frequency within the pass band or stop band of either filter, the output signal from each is in phase, preventing any peaks or dips in the combined response. These will be covered in more detail a little later.

Of all the topologies available, I will concentrate on the Sallen-Key (also known as unity gain) Butterworth filter. The equal component value filter is useful in some areas, but is a nuisance because of the gain that

each section adds. This is sometimes useful, but mostly is not necessary, and the filter section needs more components. They are easier to design, but the difference is slight, and often the resistor needed to set the gain precisely will work out to be impossible to obtain. For the values I am using, a 14.414k resistor would be needed, which as you can see from Table 5 is not a standard value.

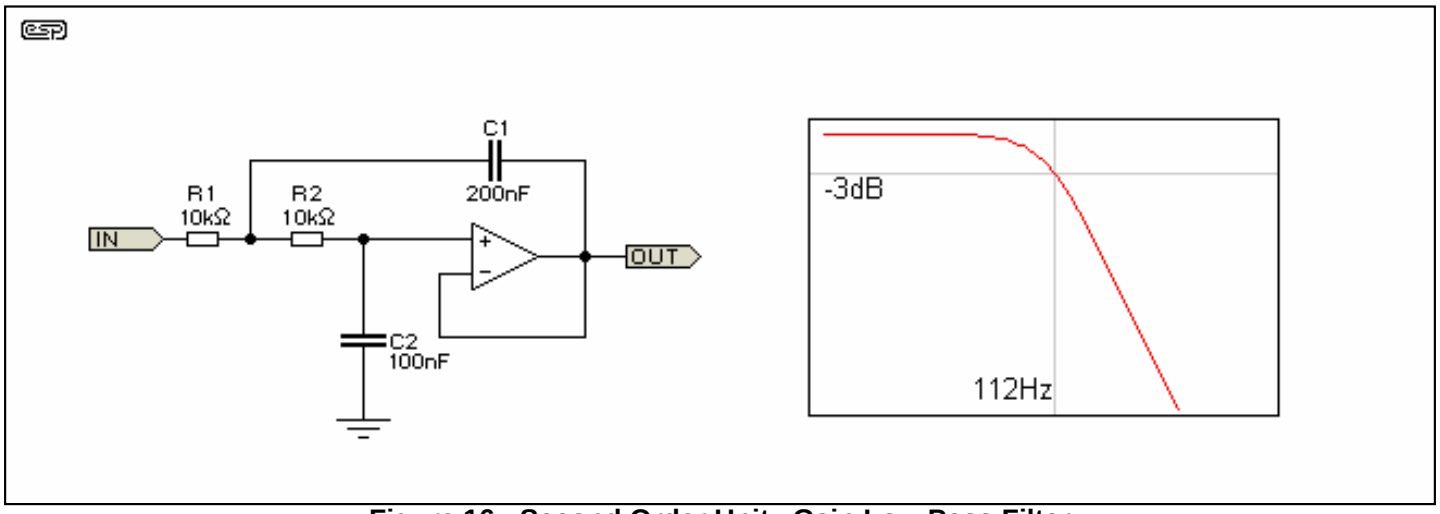

Figure 16 - Second Order Unity Gain Low Pass Filter

As you can see, the opamp is used only as a buffer, contributing no gain. For Butterworth alignment, the component values are as shown. The filter can be made into anything from Bessel to Chebychev by changing the component values about, but these other alignments are not generally as useful in audio work.

If R has been selected first, the capacitor values for C1 and C2 are chosen from the equations

$$C1 = 4 / d^2 * C2 = 2 * C2 \quad \text{... where } d = 1 / Q$$
$$C2 = 0.707 / (2 * \pi * F * R)$$

The formula for calculating the value of C1 *only* applies to a Butterworth filter. Of course if you were to follow my advice from above and select the capacitance first, you need a different formula ...

$$R1 = 0.707 / (2 * \pi * F * C2)$$

Again, the equation for resistance or capacitance for each example *only* works for Butterworth filters! For a Q of 0.707 or damping of 1.414 (Butterworth) it works out that C1 is exactly double the value of C2. R1 and R2 must be equal in value, or the filter's response will be something other than that desired.

Any change of Q by varying the resistance ratio or capacitor ratio also changes the frequency. The formulae become quite complex, and I am not going into further detail.

For example, if the C1 is four times as great as C2, this creates a Chebychev filter with a Q of 1, as shown in Figure 17 for the sake of example. Equal capacitor values would be used for a 'sub-Bessel' alignment with a Q of 0.5 - the possibilities are endless, as I am sure you can now appreciate.

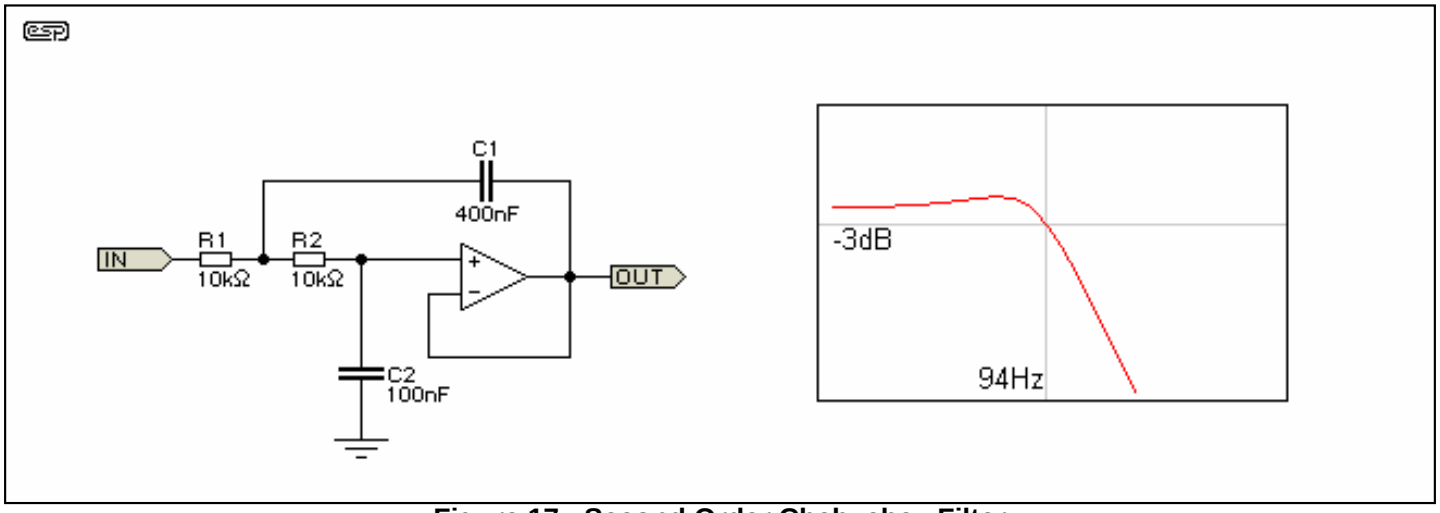

Figure 17 - Second Order Chebychev Filter

The filter of Figure 17 clearly shows the peaking obtained from a Chebychev filter. The peak amplitude is +1.25dB from the nominal 0dB value, and the cutoff frequency is determined to be 3dB below this maximum. I remain unconvinced that this is the right way to measure the cutoff frequency - I think I prefer to use the "genuine" -3dB point. Either way, the cutoff frequency is not easy to calculate, and although it would be no great strain for me to give you all the equations, I doubt that you would want to know!

The high pass equivalent of the Butterworth low pass filter is shown in Figure 18, and as you can see is a re-arrangement of the other design. Frequency is the same as for the low pass filter, but note that now C1 and C2 are the same value, and R2 is double the value of R1. Frequency is calculated on C1 and R1, and it is easy to become confused when designing the circuits just which values determine the frequency.

In both cases it is nearly always easier to use paralleled capacitors and series resistors as I have shown, since these will be more accurate than simply doubling (or halving) the values - especially so since the standard values do not always have exact double or half values. Any variation of these values will shift the response away from Butterworth and towards either Bessel or Chebychev responses, and will change the frequency.

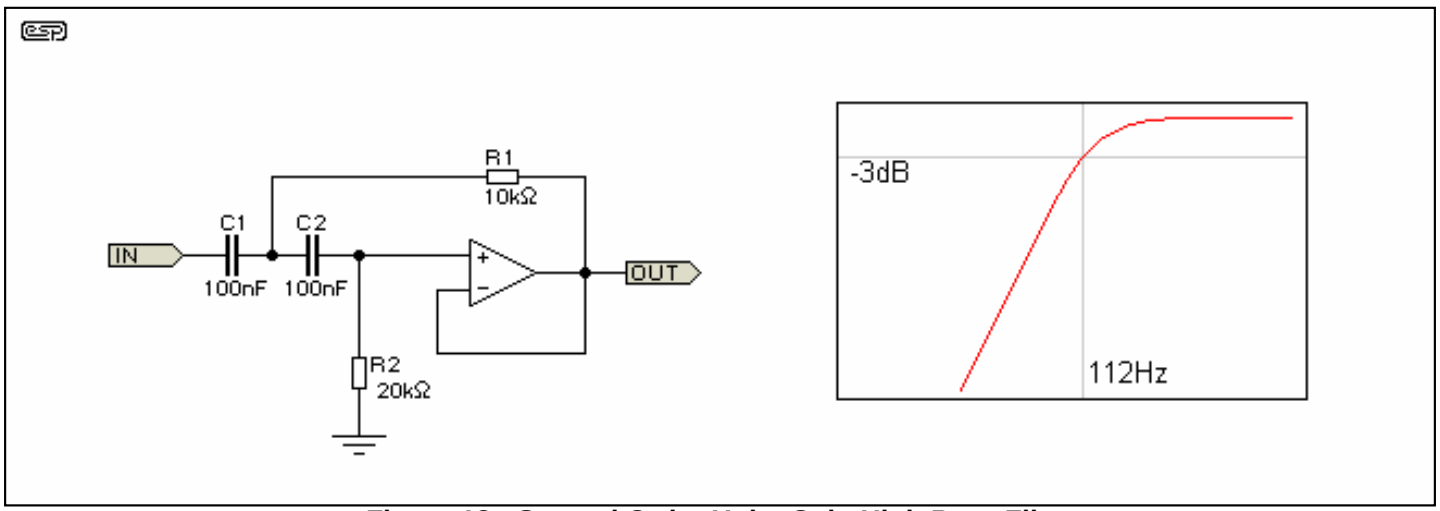

Figure 18 - Second Order Unity Gain High Pass Filter

Second order filters can also be used for bandpass and band stop, but are generally of limited use in audio circuits. They are sometimes used as equalisation circuits, and indeed the simple inductor / capacitor (LC) filters shown in Figure 8 are 2nd order types. A second order filter requires that there are two reactive

elements, with an filter LC there is the capacitance and the inductance, and with an active filter there are two capacitors.

Crossover Networks

When combined, high pass and low pass filters are commonly used to create electronic crossover networks. There are many different ways to do this, but the most common is still the second order Butterworth filter. Although these are essentially at least as good as the passive speaker level counterpart (but not all that much better), the results are often vastly superior. The reasons for this are discussed at great length in my article Bi-Amplification - Not Quite Magic (but Close) and I shall not repeat them here.

In a nutshell, using an electronic crossover eliminates many of the problems that beset loudspeaker designers when they have to design and build the crossover network. The passive crossover is influenced by any aberration in the driver's impedance, especially at or near the crossover frequency. Since the electronic crossover supplies the signal to a separate amplifier for each frequency band, there is no interaction and each amp only needs to be concerned with a much smaller bandwidth.

All crossover networks are a combination of high pass and low pass filters, although this is not always achieved in the same way. Some crossovers use an opamp as a subtracting amplifier, so rather than using a separate filter, the bass (for example) is subtracted from the main signal to provide the midrange and high frequency. Alternatively, the mid+high output from the filter is subtracted from the main signal to separate the bass, and this configuration is shown below. These crossovers are phase coherent (both outputs are always in phase at any frequency), but are asymmetrical. A typical design is shown in Figure 19, and the response clearly shows that the high pass rolloff is 12dB/octave, but the low pass is only 6dB/octave.

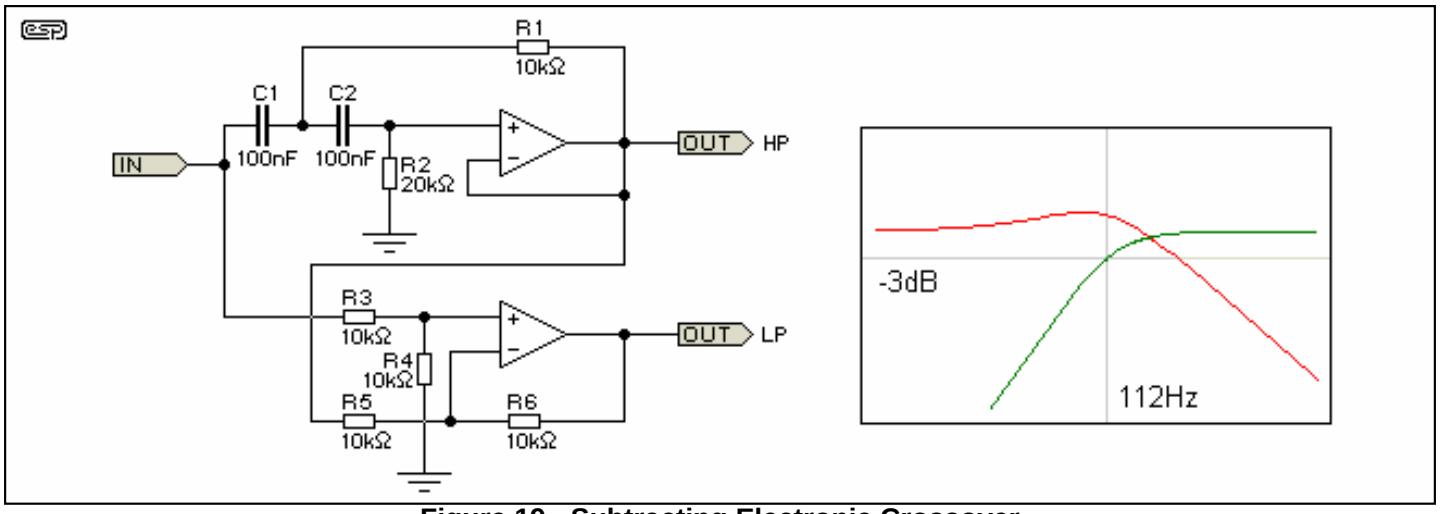

Figure 19 - Subtracting Electronic Crossover

Although these networks can be capable of excellent results, great care is needed to ensure that the driver getting the 6dB/octave rolloff can handle the increased power levels created by such a low rolloff rate. Notice that the LF rolloff peaks, and that the crossover frequency does not coincide with the actual -3dB frequency of the high pass section. Although this looks really bad, because of the phase differences the combined frequency response is completely flat. With loudspeaker drivers this will often not be the case, especially when listening off axis. Because of this, the subtracting crossover is really only useful at low frequencies (IMHO), where phase is less likely to cause major problems because the wavelength is so long. Personally I have never been a fan of this type of crossover, but the circuit is interesting, and shows the versatility of opamps.

Rather than show a multitude of crossover designs here, you can look at the Projects Pages to see a suitable sampling of crossover networks. Of these, the 24dB/octave Linkwitz-Riley is by far the best, and is highly recommended.

Notice the cunning way I introduced a new opamp configuration - the subtracting (or difference) amplifier. This (and other useful topologies) will be discussed in greater detail a little later.

Band Pass Filters

The band pass filter (as a single filter) is not normally very useful in audio reproduction. The frequency range passed is too narrow to be useful for anything other than equalisation circuits, or for test and analysis equipment. Having said this, there are many uses for bandpass filters that are very common in the *production* of music - the synthesiser, guitar wah-wah pedals, Vocoder, etc.

The range is far too great to cover in any real detail, but we can at least look at the fundamental principles, as these are common to all of the applications. The two most common parameters quoted for bandpass filters are frequency (f_o) and Q ("quality factor"). The latter may be inverted and referred to as damping.

A simple bandpass filter consisting of two reactive elements has an ultimate rolloff of 6dB/octave. When one looks at resonance, the slope appears to be much greater than this, which is fair and reasonable, since it is. Eventually, the high slope due to resonance effects cannot be maintained, and the final slope is at 6dB/octave, as shown in Figure 20. But wait! This is an article about opamp designs, and there is no opamp there, just a stupid inductor and capacitor. True, but we need to be able to understand the concept of resonance before delving into the opamp version of the circuit.

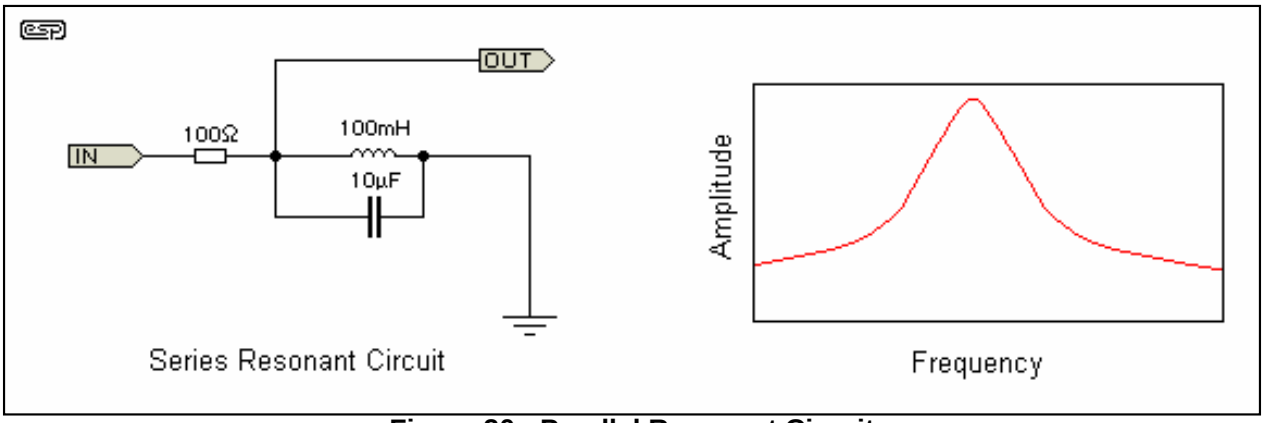

Figure 20 - Parallel Resonant Circuit

There are essentially two forms of resonant circuit - series and parallel. When only passive components are used (resistor, inductor and capacitor), the series resonant circuit has minimum impedance at resonance, and the parallel resonant circuit has maximum impedance. The formula is actually slightly different for each (the resistance of the coil changes the resonant frequency slightly in a parallel resonant circuit), but for all intents and purposes the following formula can be used with little error ....

$$f_o = 1 / (2 * \pi * \sqrt{LC})$$

Where f_o is resonant frequency, L is inductance in Henrys and C is capacitance in Farads. Any error caused

by the series resistance of the coil will generally be less than that caused by component tolerance.

In all cases, the resonant frequency is that where the capacitive and inductive reactance is equal. In the example of Figure 20, only when Xc (capacitive reactance) and Xl (inductive reactance) are the same will the circuit be at resonance. As the frequency is reduced, the inductive reactance decreases, and shunts more of the signal to earth. When the frequency is increased above resonance, the capacitor will be responsible for shunting the signal to earth. Since in each case there is the resistance and a single capacitor or inductor to bypass the signal, this is a single pole filter and will have 6dB/octave rolloff. As shown, the reactances at resonance are equal to the series resistance, so the rolloff slope is 6dB/octave. The initial slope can be increased by increasing the series resistance (and thus the Q of the circuit), but eventually the rolloff will go back to 6dB/octave.

Series resonance is especially interesting. At resonance, the circuit is almost a short circuit, so the input signal will be heavily loaded. At the junction of the inductor and capacitor there will be a voltage that is many times that at the input. This effect is described below. If enough current is available, incredibly high voltages may be obtained, and great care is needed to ensure that the voltage rating of the components is sufficiently high to withstand the voltage. Since the laws of physics and the taxman dictate that we cannot get something for nothing, the available current is very limited at the high voltage point. A circuit with a very high Q will generate much greater voltages than a circuit with low Q. The voltage magnification is equal to the Q of the circuit. With the component values as shown in Figure 21, the voltage at the output will be about 0.5 mV at resonance, but there will be 1V across both the inductor and capacitor. At resonance, the reactance of the capacitor and inductor are equal and opposite, so the circuit will appear to be almost a short circuit - input current is limited only by the wiring resistances and source impedance.

The maximum possible Q of an LC filter is dictated by the series resistance of the inductor. The Q may be reduced by adding resistance, but cannot be increased. The circuit Q is determined by the reactance of the cap or coil at resonance and the series resistance (for parallel resonance) or shunt resistance for series resonant circuits.

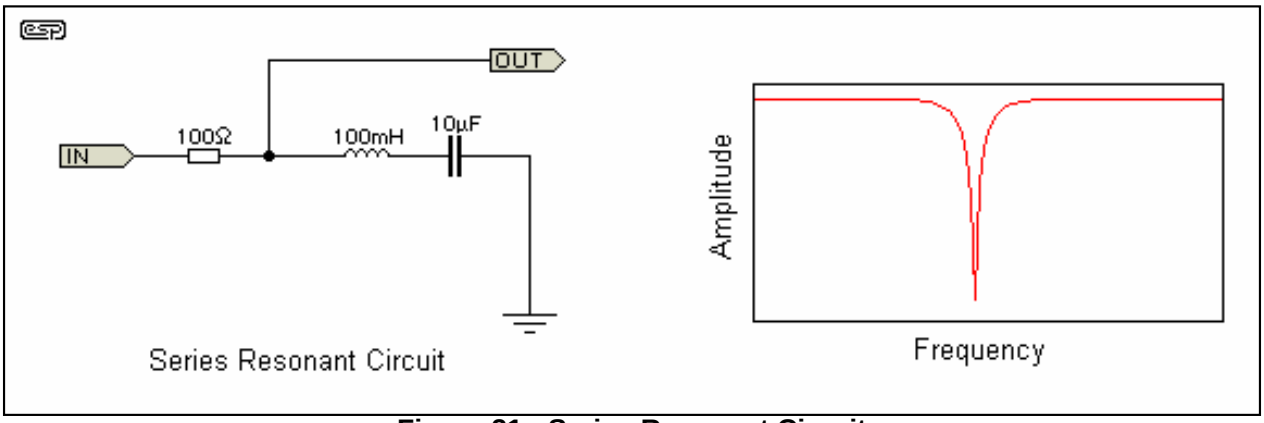

Figure 21 - Series Resonant Circuit

At very high frequencies, the so-called "skin effect" increases the apparent resistance of the inductor. The skin effect is where the electrons tend to want to occupy the outer section of the wire and are not evenly spread through the conductor. This gets progressively worse as the frequency increases. Likewise, the dielectric absorbtion of capacitors reduces their efficiency and lowers the overall Q. We shall not investigate these effects further, since they are unrelated to audio frequencies generally, and especially to opamps.

A quick word about Q. In both cases above, resonance is at 159Hz. The reactance of either the inductor (Xl) or capacitor (Xc) at this frequency is 100 ohms, so with a 1k series resistance (parallel resonance) or 10 ohm

shunt resistance (for series resonance), the circuit Q will be 10. The reactance can be calculated from ....

Xc = 1 / (2 * *pi; * f * C)
Xl = 2 * π* f * L

This basic understanding of the ratios is essential in the design of bandpass and band stop filters, and is also very much a part of the design process for passive loudspeaker crossover networks. The latter have absolutely nothing to do with opamps, but I just thought I'd mention it :-)

The Q of a resonant circuit determines its bandwidth. With a Q of 10, bandwidth of our filters above is 15.9Hz. This places the -3dB frequencies at 151Hz and 167Hz (near enough), so it is apparent that the range of frequencies allowed through is very limited. In practical audio work, this is far too narrow to be useful, so lower Qs are far more common. This is fortunate, because high Q opamp bandpass filters are difficult to design, and require opamps with very high bandwidth for proper operation at the upper end of the audio band.

Common Mode Circuits

Probably the best known common mode circuit is the single opamp balanced receiver circuit. While it has a number of perceived problems in real life, it is nonetheless a good place to start. The problems with the circuit are normally not a limitation. The schematic is shown below, and there are two circuits shown. The first shows the circuit the way it is normally used, with the input (source) connected in differential mode to the opamp inputs.

The second circuit shows how the circuit connects to the input for noise input - it is coupled (ideally) equally to both inputs at once.

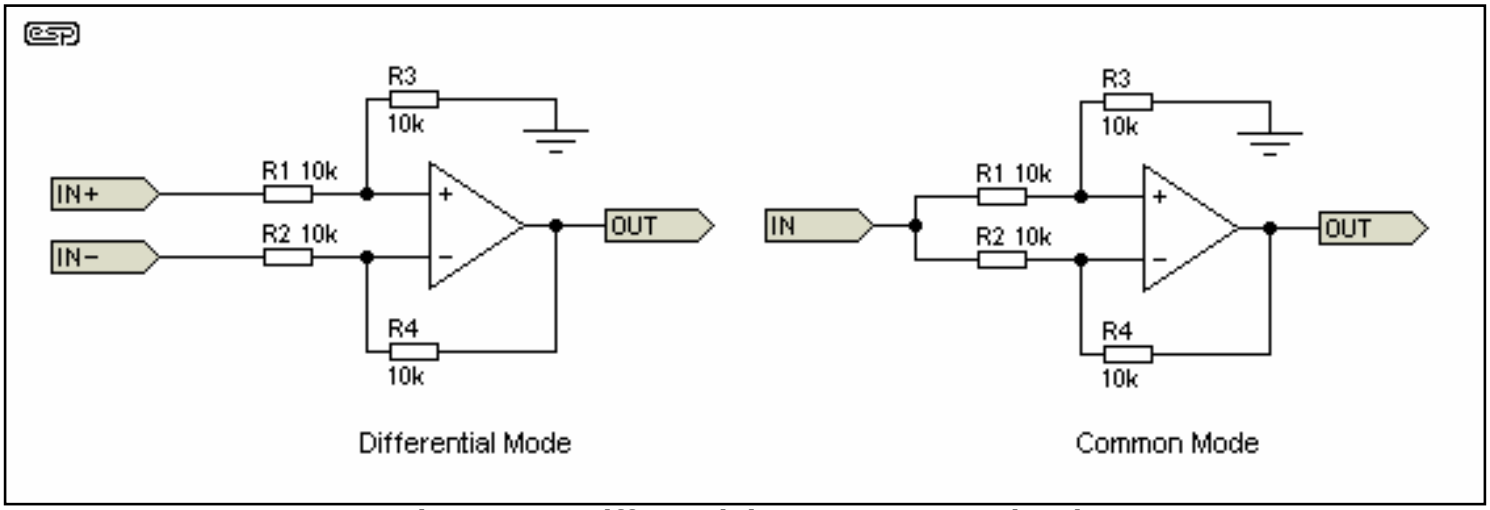

Figure 22 - Differential Input Opamp Circuit

While the wanted signal is passed directly through to the output (but is now a simple ground referenced signal at that point), any noise is presented to both inputs at equal level. This causes the cancellation of the noise, while allowing the signal to pass without alteration. This is shown in Figure 23, where we have a microphone with 10mV (differential) output, in the presence of a 100Hz 1V common mode noise signal. This is a ratio of 1:100 of signal to noise (or 100:1 noise to signal).

Although the results I obtained are simulated, the reality is not much different. At the output, the interference signal was measured at 27uV, while the signal level remains at 10mV. This means that the wanted signal is 51dB *greater* than the interference after the opamp, where the external noise level is 40dB greater than the signal at the input. The common mode rejection is therefore 91dB (1V common mode input, 27uV noise output). This is under ideal conditions, but in practice it is usually possible to get performance that exceeds the ability of the cable to maintain a perfect balance.

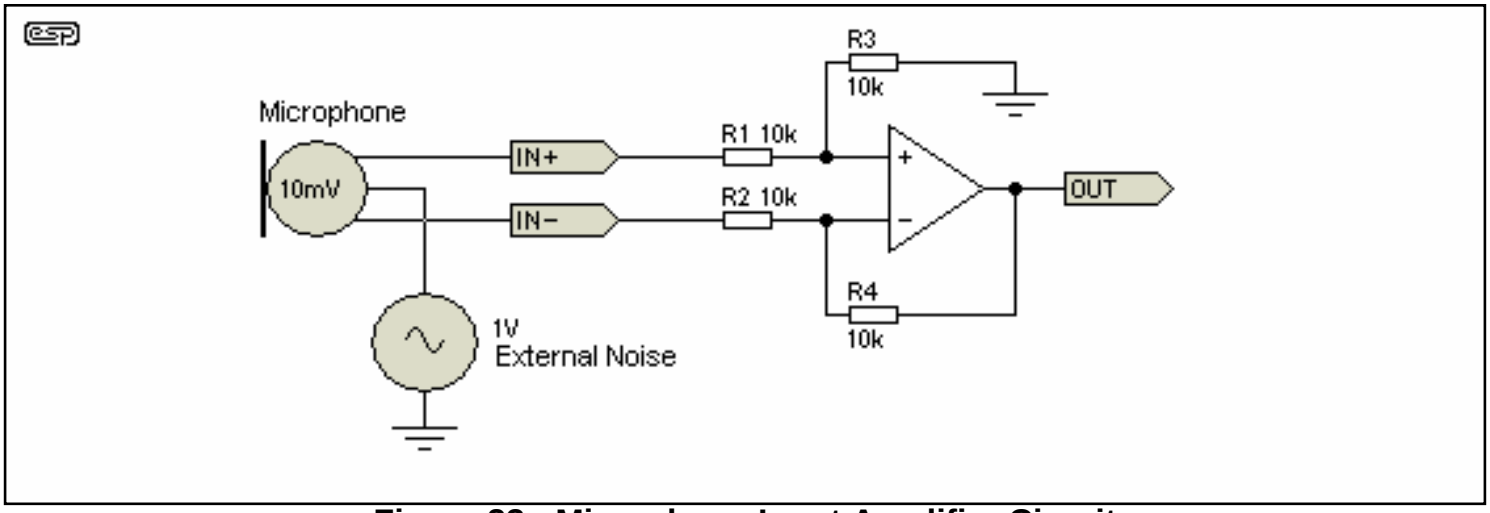

Figure 23 - Microphone Input Amplifier Circuit

Although there are a number of claimed problems with this circuit, in reality it works very well. There are better alternatives (especially for microphones), and these are well represented on the ESP site. The general principle of all balanced circuits remains the same as that shown above.

The biggest limitation of the Figure 23 circuit is that the input impedance for common mode (noise) signals is only equal if the signal applied to each input is equal. This is often claimed to cause major deficiencies in use, but in reality the common mode noise signal usually is very close to equal levels at each input, so the circuit works as described. The greatest limitation of this circuit for microphone use is opamp noise and reduced performance for high frequency common mode signals. For example, at 10kHz, the common mode rejection ratio is 6dB worse than at 100Hz.

Resistor tolerances, cable asymmetry and internal wiring will generally cause more error than the circuit limitations will impose. For optimum CMRR, the resistors should be 0.1% tolerance, and these may be selected from a batch of 1% components.

Balanced Output Circuits

Although these are discussed in depth elsewhere on the ESP site, a brief look at these essential circuits is worthwhile here. Since we have balanced input circuits, it makes sense to have a matching output circuit, allowing equipment to provide a balanced output to other (often remote) gear. The basic circuit shown below is the starting point, and is the basis of all other (often much more complex) circuits.

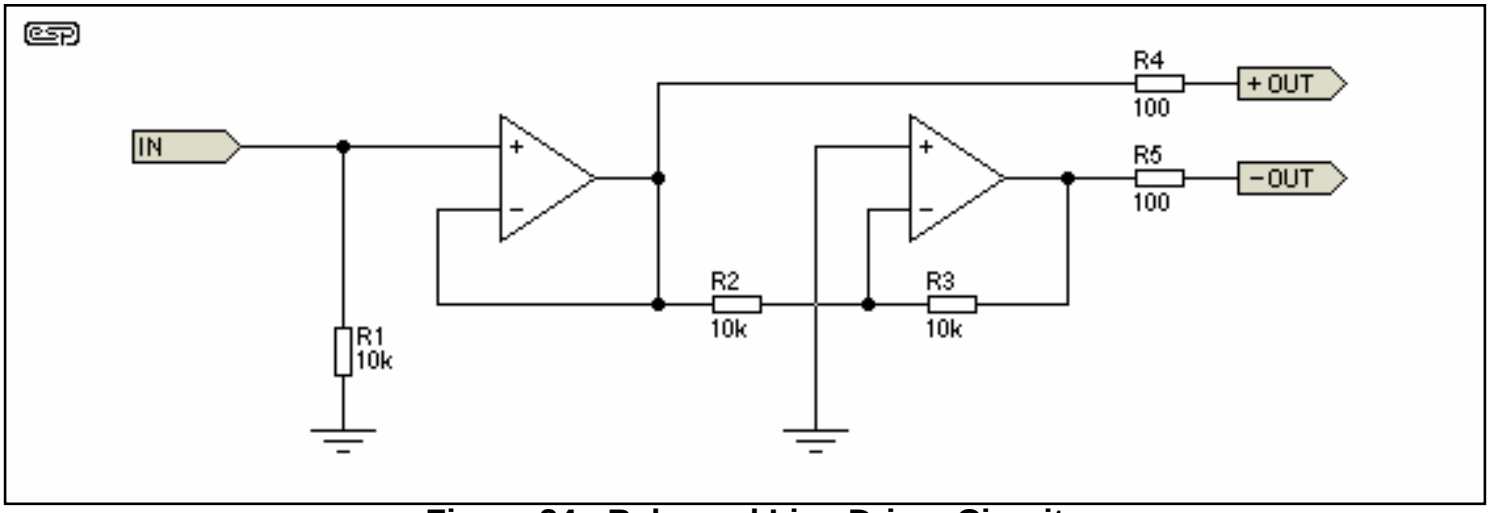

Figure 24 - Balanced Line Driver Circuit

The general idea is quite simple. A single-ended (unbalanced) signal is applied to the input, and it is buffered by the first opamp, and inverted by the second. You should recognise the inverting buffer from Part 1 of this series. The tolerance of the resistors around the inverting stage is again critical, and they should be as closely matched as possible to ensure that the two output signals are exactly the same, but with the signal from the second opamp inverted.

This is a true balanced output, but it has an inferred reference to ground. It behaves like a transformer with a grounded centre tap. While it is possible to approximate a fully floating output, in general it is not necessary to do so. It is usually essential to place a small resistance (typically around 100 ohms) in series with each output to prevent oscillation - R4 and R5. The cable connected to the opamp output acts as an unterminated transmission line at high frequencies, and this can cause the opamps to become unstable because of the reactive load. By including a resistance, the opamp's output is isolated from the reactive load and stability is usually unaffected, regardless of load.

While there is a small error caused by operating two opamps in series (therefore adding the propagation delay of each opamp), the circuit still maintains extremely good balance well above the audio band. Operating the inverting and non-inverting buffers in parallel (the inputs of both joined together), this gives a much lower input impedance and improves performance so marginally that it's not worth doing (IMO).

Summing Amplifiers

Summing amplifiers are based on the inverting buffer. Although we examined this earlier, one aspect of the circuit that was not covered at the time was just how it works. The inverting buffer is also called a virtual earth (ground) circuit, and is very common in mixing

consoles and analogue computers of old. When it was described earlier, we worked in terms of voltage, but the virtual earth amplifier is really a current to voltage converter.

Figure 25 shows the general idea. If a voltage of 1V (AC or DC) is applied to the input, that will cause a current of 0.1mA to flow through R1. Remembering the first Rule of opamps, the opamp itself will attempt to maintain both inputs at the same voltage. Since the positive input is earthed (ground, zero volts), the negative input has to stay at the same potential to satisfy the first Rule. This means the output will have the same voltage as the input, but with the opposite polarity. This is necessary because R2 must also pass exactly 0.1mA to maintain the +ve input at zero volts.

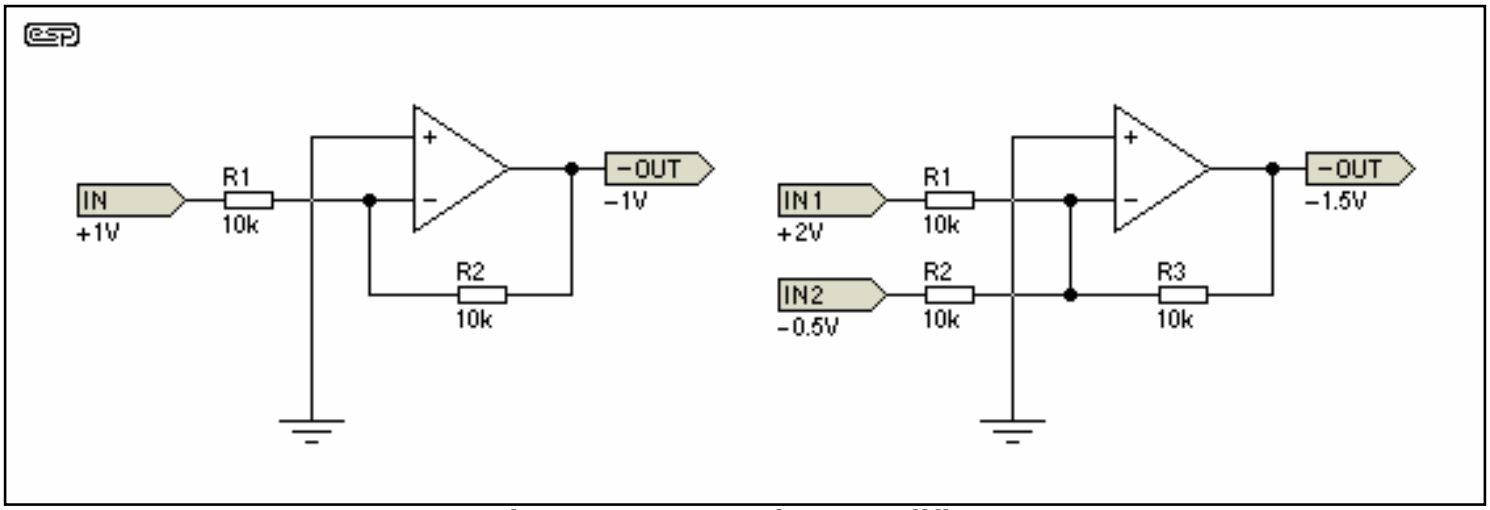

Figure 25 - Summing Amplifiers

By changing the value of R2 (relative to R1), we can modify the gain, making the output voltage larger or smaller in absolute magnitude than the input. It's all done with current - no smoke or mirrors required. Now, if we add another input as shown in the diagram to the right, we can apply another signal, and the opamp will give us a result that is the sum of the two input currents (or voltages, if fixed value resistors are used).

As shown, if one input has an instantaneous voltage of 2V, and the other is -0.5V, the output voltage will be the (inverted) sum of the two - in this case -1.5V. If both inputs were the same voltage and polarity, they are simply added together. At the other extreme, two input voltages of equal magnitude but opposite polarity will result in an output voltage of zero.

There is a drawback to this circuit though, and it is important to understand what happens when you have a large number of inputs. Think back to the inverting amp as originally described. The voltage gain is described by the formula ...

$$Av = R_{FB} / R_{IN}$$

We may decide to use several (let's assume 10 for the moment) inputs, all 10k, and all being fed with voltages from different sources (think in terms of a multi-channel mixer). For each input individually, the voltage gain is as described - i.e. -1 (unity, but inverted). What does the opamp see though? The total value of R_{IN} is 10 x 10k resistors in parallel ... 1k. The opamp therefore acts exactly as if it had a gain of 10, so input transistor noise is multiplied by 10, offset current is multiplied by 10, and bandwidth is reduced accordingly.

A small DC voltage shift caused by input offset current (the difference in current needed by each opamp input), is fine for audio. Any DC error is easily removed by adding a capacitor in series with the output. For instrumentation, the DC value may be critical, and this is why some opamps have 'offset null' pins. The designer can use a pot to adjust the offset to ensure that any DC error is 'nulled' out.

While 10 inputs is not going to cause a major problem in most cases, there is often a need for a great many more - a 32 channel mixer will need to be able to sum 32 channels, so the opamp will have a 'noise gain' of 32, even though the gain for each input individually is -1. Note that there is no polarity for noise gain - noise is random in nature, and not correlated to the input signal. Noise is noise.

The opamp also acts as if it were operating with a gain that is equal to the noise gain, even though each input individually has unity gain. As a result, the bandwidth may be (apparently) inexplicably limited, but by knowing the noise gain, we can treat the circuit as if it has a voltage gain that equals the noise gain - and indeed, this is exactly the case.

The inverting amplifier stage is actually noisier than a non-inverting stage with the same gain. For a non-inverting amplifier, the noise gain is equal to the voltage gain, but with an inverting stage, noise gain is equal to voltage gain + 1. When a large number of inputs is needed, a summing amplifier needs to have very low noise and wide bandwidth, or performance will not be as expected.

A Few More Filters

Because filters are so important in audio, it is necessary to examine a few more variations. Two additional functions will be examined - integration and differentiation. Although Part II did not make it clear, these are the building blocks of some of the most interesting filters that can be made using opamps. A simple integrator (low pass filter) and differentiator (high pass filter) are shown in Figure 26. These are conceptual - the real

world nature of opamps means that neither will work as a 'perfect' device, but must be limited to a defined frequency range. In reality, this is rarely an issue, since ideal versions of the circuits are not needed to cover the audio bandwidth.

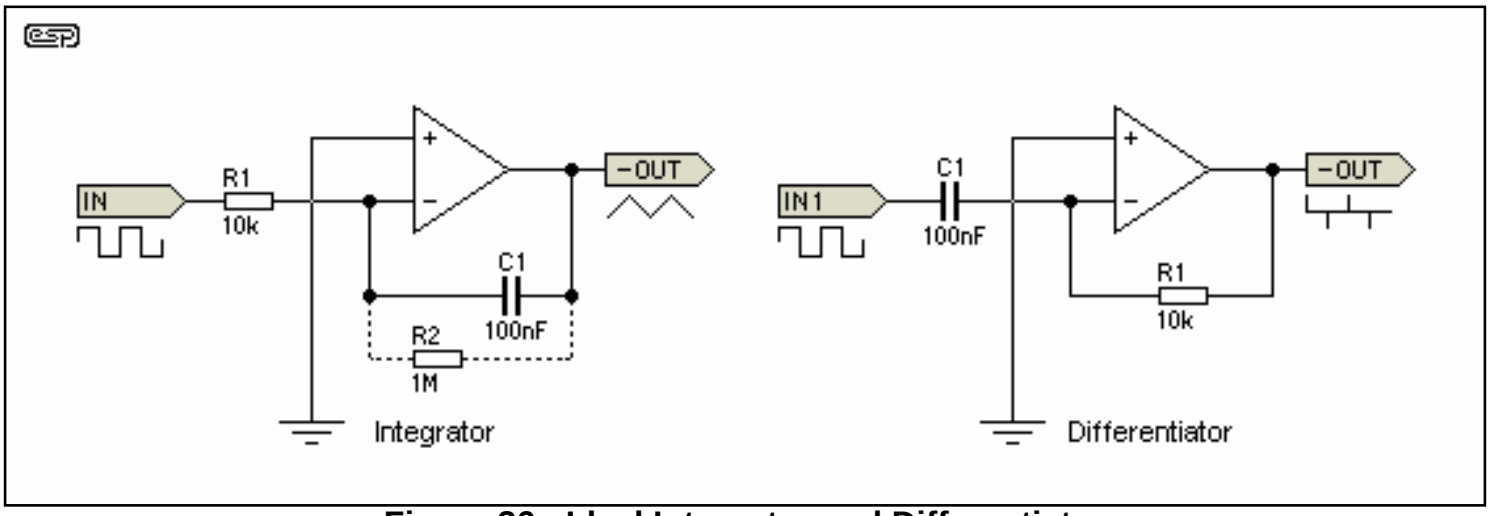

Figure 26 - Ideal Integrator and Differentiator

The differentiator will actually work as shown (albeit with less than ideal performance), but the integrator will not. The reason is simple - it has no DC feedback path, and will drift towards one supply or the other (depending on the opamp characteristics). To combat this, a resistor is needed in parallel with C1 (R2, shown dotted), with a value sufficiently low to provide DC feedback, but not so low as to cause the lowest frequency of interest to be affected. As always, compromises are a part of life.

With an input waveform of a square wave as shown, an integrator provides an output that is dependent on the input current (via R1) and the value of C1. Over a useful frequency range, the output of an integrator is an almost perfect sawtooth waveform with a squarewave input. The DC stability resistor (R2) ultimately limits the lowest usable frequency. While there are methods to get around this limitation, this level of complexity is not normally needed for audio.

The differentiator as shown is also supplied with a squarewave. The output is now based entirely on the rate of change of the input signal, so a squarewave with relatively slow rise and fall times will give a lower output than another with very fast transitions.

The integrator is a low pass filter, with a theoretical 6dB/octave rolloff starting from DC (where it has infinite gain). The 6dB/octave rolloff continues for as far as the opamp characteristics will allow. At an infinite frequency, gain is zero.

A differentiator is the exact opposite of an integrator. It has zero gain at DC, and an infinite gain at an infinite frequency. The filter slope is again 6dB/octave. With ideal

opamps, if the two circuits were connected together the output is a squarewave - identical in all respects to the applied signal. With the values shown, the unity gain frequency is 159Hz (1 / 2 π R1 C1).

To see integrators at work in a real circuit, you need look no further than the Project 48 subwoofer equaliser. Differentiators abound in all audio circuits, but in a rather crude form. Every capacitor that is used for signal coupling is a very basic differentiation circuit, in conjunction with the following load impedance. Note that the frequency where coupling circuits will actually function as a differentiator is well below the lowest frequency in audio.

State Variable Filter

The State Variable filter is probably one of the most interesting of all opamp filters. It uses nested feedback loops and a pair of integrators to define the filter Q, frequency and gain. Gain and Q are not independently adjustable in the version shown - changing one will change the other. To make gain and Q individually adjustable requires the use of two-opamp summing stage (the first opamp). A standardised version is shown in Figure 27, and with the values shown, passband gain is unity, Q is 0.707 and the centre frequency is 159Hz.

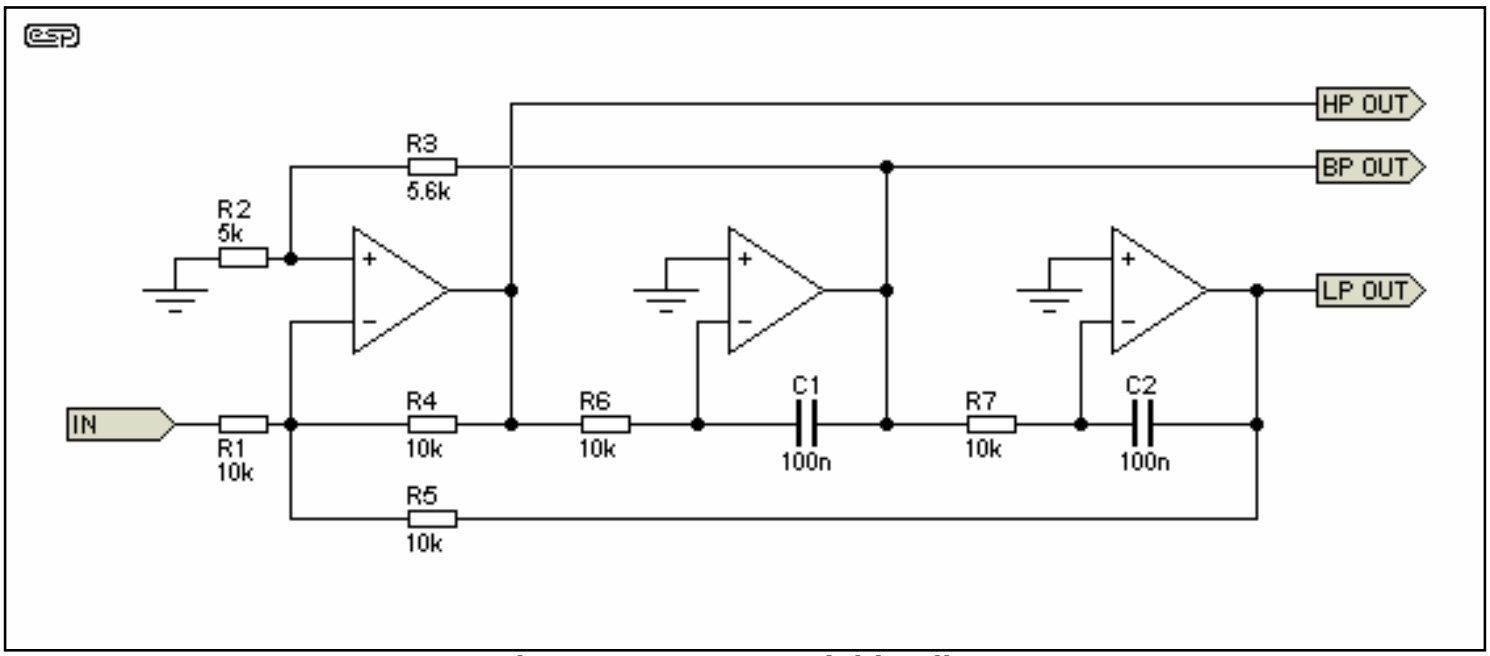

Figure 27 - State Variable Filter

As shown, the filter outputs low pass, band pass and high pass responses simultaneously. R3 sets the filter Q, and is selected as ...

$$R3 = (3 - d / d) * R2 \quad \text{Where } d = \text{damping } (1 / Q)$$

The damping is set at 1.414 in Figure 27, giving a Q of 0.707, so the filter response is

Butterworth (maximally flat amplitude). The frequency is changed by varying R6 and R7, or C1 and C2. The most common use for the state variable filter is in parametric equalisers, where a filter with variable frequency and Q is a requirement. it adding an opamp, the state variable filter allows the gain to be changed without affecting Q, so it is an ideal variable filter for audio use. Filter Q remains constant with frequency, so altering the frequency has no effect on the filter's overall (summed) response. Note that the high and low pass sections have opposite polarities, with the high pass shifted by -90° and low pass shifted +90° at the tuned frequency (f_o). The bandpass output is in phase with the input at f_o

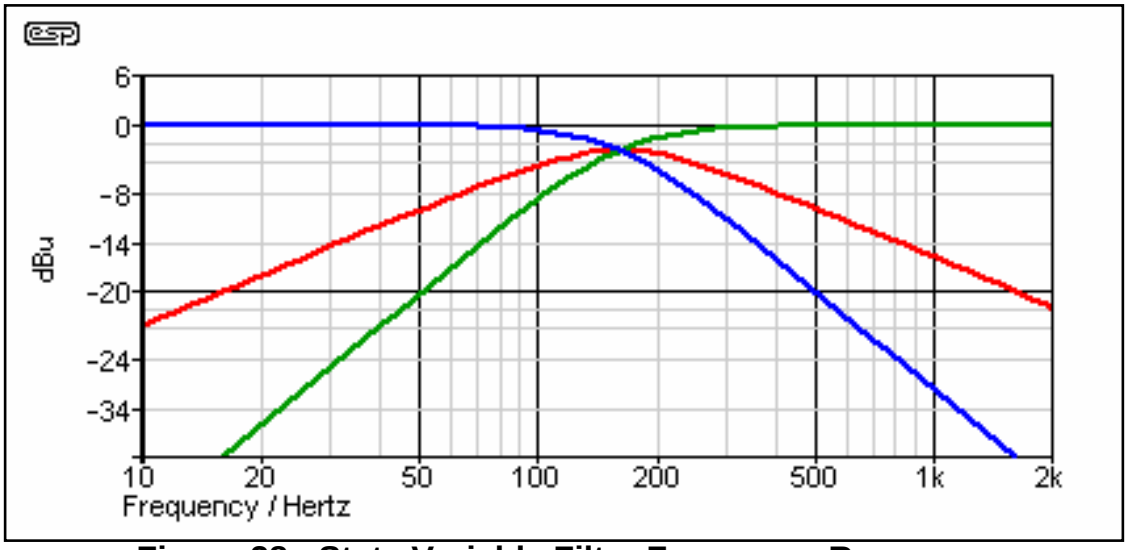

Figure 28 - State Variable Filter Frequency Response

The red trace is the band pass response, the blue trace is low pass, and green is the high pass. Remember that all of these are reproduced simultaneously, thus making the state variable filter on of the most interesting applications available. The standard state variable filter is second order, having rolloff slopes of 12dB/octave. It is also possible to make these filters with a fourth order (24dB/octave) response, but that is beyond the scope of this article.

A variation of the state variable is called a Bi-Quad (bi-quadratic). The difference between the two is subtle. With a bi-quad, as frequency changes, the bandwidth remains constant, which means that the Q must change. As you change the frequency, Q increases as frequency increases and vice versa.

Multiple Feedback Filter

The bandpass version of this class of filter has its own page on the ESP site - see Multiple Feedback Bandpass Filter for more information about this category. There are also low and high pass versions of the MFB filter, and these will be covered briefly here. The chief advantage of the MFB filter is that the opamp's gain bandwidth product (GBP) is relaxed

somewhat compared to the Sallen-Key topology. This is not normally a problem at audio frequencies and for audio applications, because very high Q values are rarely used.

Where the Sallen-Key filter requires a minimum open loop gain of 90Q² at the filter frequency, the MFB version requires only 20Q². To put this into perspective, a Sallen-Key filter with a Q of 0.707 at 20kHz requires an opamp open loop gain of at least 75 at 20kHz, while the equivalent MFB filter only needs a gain of 17 (close enough). While these figures are easy to obtain at low Q values, they become difficult or impossible if a high Q filter is needed.

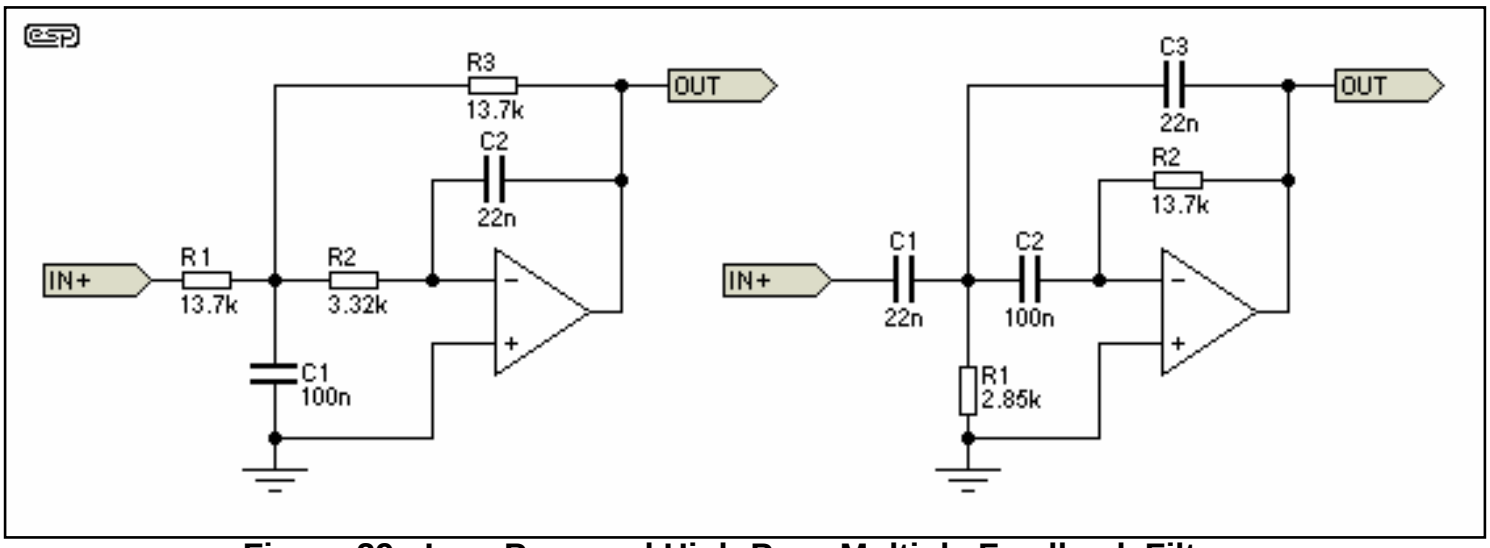

Figure 29 - Low-Pass and High-Pass Multiple Feedback Filters

The first thing to notice with these filters - the resistor (and to a lesser extent the capacitor) values are decidedly non-standard. The design formulae are also rather complex, and I eventually settled on the values shown based on a simulation. The calculations are tedious, and will invariably yield non-standard values. Simple parallel or series connections often cannot be used to get the values you need (based on others in the circuit).

There are several articles on the Web covering the low pass multiple feedback filter, but few that cover the high pass version. As a result, I didn't even try to calculate the values, but figured them out based on the low pass version. As shown, the low pass filter has a cutoff frequency of 503Hz, and the high pass filter has a cutoff frequency of 538Hz. Both have a Q of 0.707 (Butterworth response) and unity gain in the passband.

As filters, they function exactly the same as any other topology with the same cutoff frequency and Q, but as noted above are less demanding of the opamp performance. Whether this ever becomes a problem for most circuits is debatable. Note too that they are inverting, so if absolute phase is your goal, you will need to re-invert the outputs.

Notch Filter Based Bandpass

There is an almost infinite range of filter types, some are useful, others less so. An interesting idea was described in an online design website. The article, entitled "Bandpass filter features adjustable Q and constant maximum gain" shows an active notch filter followed by a difference amplifier (balanced input stage). The circuit detail is reproduced below.

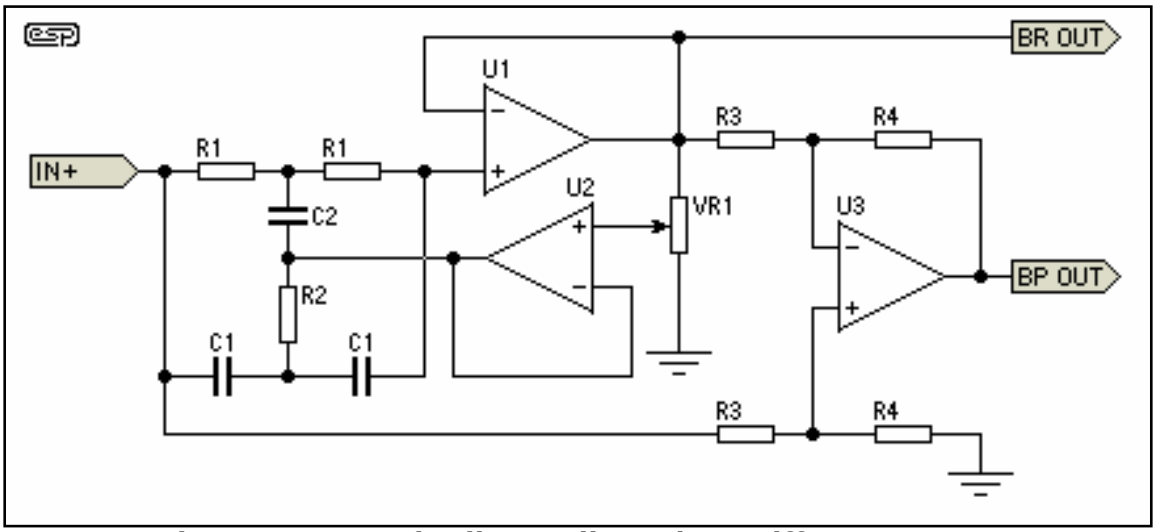

Figure 30 - Notch Filter Followed By Difference Amp

Note that all resistors and capacitors with the same designation are the same value. The 'BP' output is bandpass, and the 'BR' output is band reject (notch).

The notch filter is formed by R1, R2, C1 and C2, where R2 = R1 / 2 and C2 = C1 * 2. The output is buffered by U1, and U2 provides a low impedance feedback path to the notch filter, based on the level set by VR1. U3 is a conventional balanced amplifier, in this case being used as a difference amp. By subtracting the notch signal from the input signal, the result is a bandpass response. The output of the filter can never reach the same Q as the notch however, because phase shift reduces the attenuation of out of band signals.

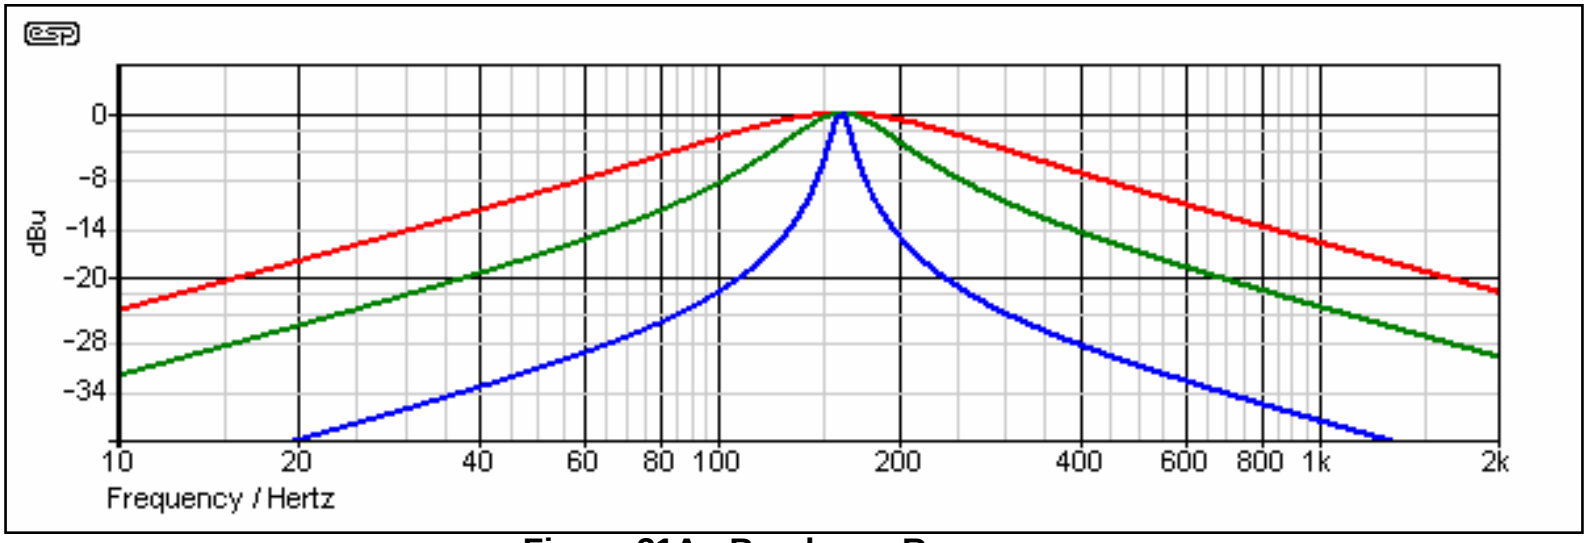

Figure 31A - Bandpass Response

The response with the pot (VR1) set at three levels is shown. The red trace shows the response with VR1 set to 80%, green at 90% and blue at 98%. Useful values of Q (for this type of filter) are only available with close to maximum feedback, but the circuit works as described.

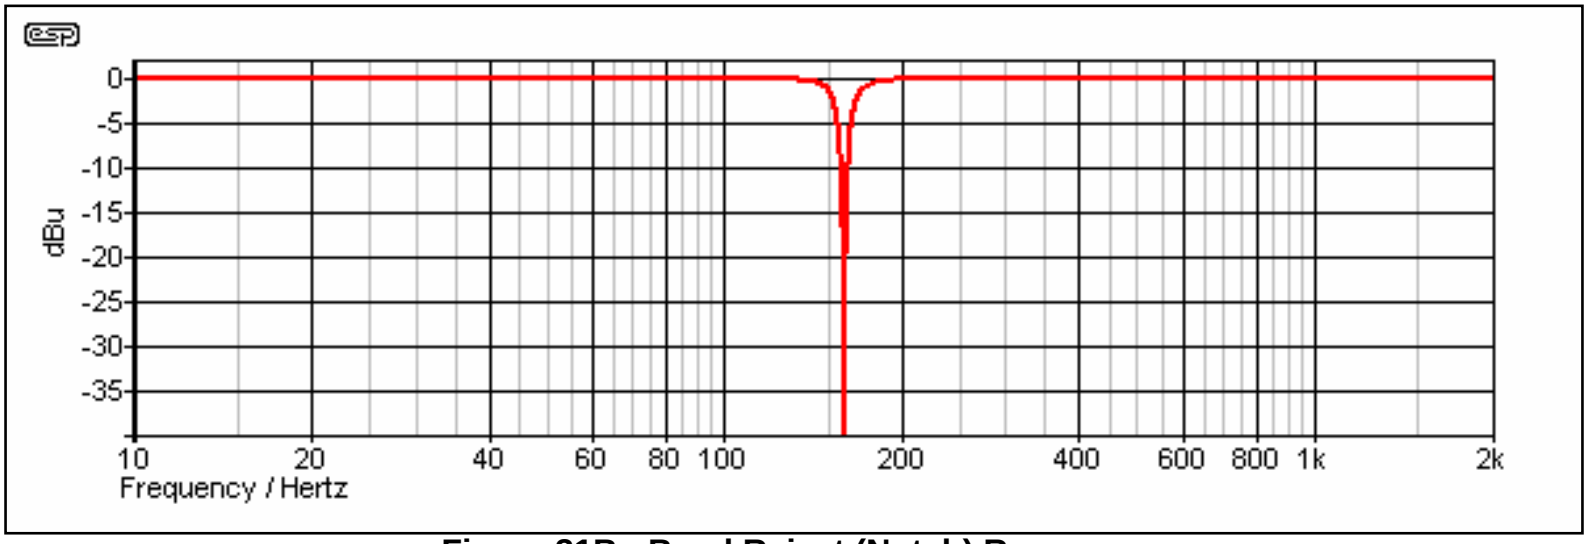

Figure 31B - Band Reject (Notch) Response

The notch filter response (shown in Figure 31B) is as one expects from the twin-tee circuit when feedback is applied. The notch itself is almost infinitely deep, and extremely narrow because of the feedback. The response shown was taken with VR1 set to 98% of its travel - almost maximum feedback applied. Applying more feedback is rather pointless, and the simulator decides that it cannot resolve the notch at all at higher pot settings.

This is another example of the huge range of possibilities for filters - there are obviously a great many more, but space (and possible value) preclude me from going any further in this direction. A web search will reveal many more, and there are also switched capacitor filters, digital filters and probably still others not yet invented.

Basic Power Amplifiers

Opamps have limited output current, usually only around 20mA or so. While this is usually more than enough for preamps and filters, a great deal more is needed to drive a loudspeaker. There are several power amplifiers that are configured in exactly the same way as an opamp, and these can be classified as 'power opamps'. While this is often a good way to get the extra current needed, in some cases it may not be considered appropriate or convenient.

Opamps also have a limited voltage swing, and operating them at the voltages typical for power amplifiers will cause failure. While there are already several opamp based amplifiers on the ESP site (as headphone amps, a small power amp, and two power opamps), the following design is different.

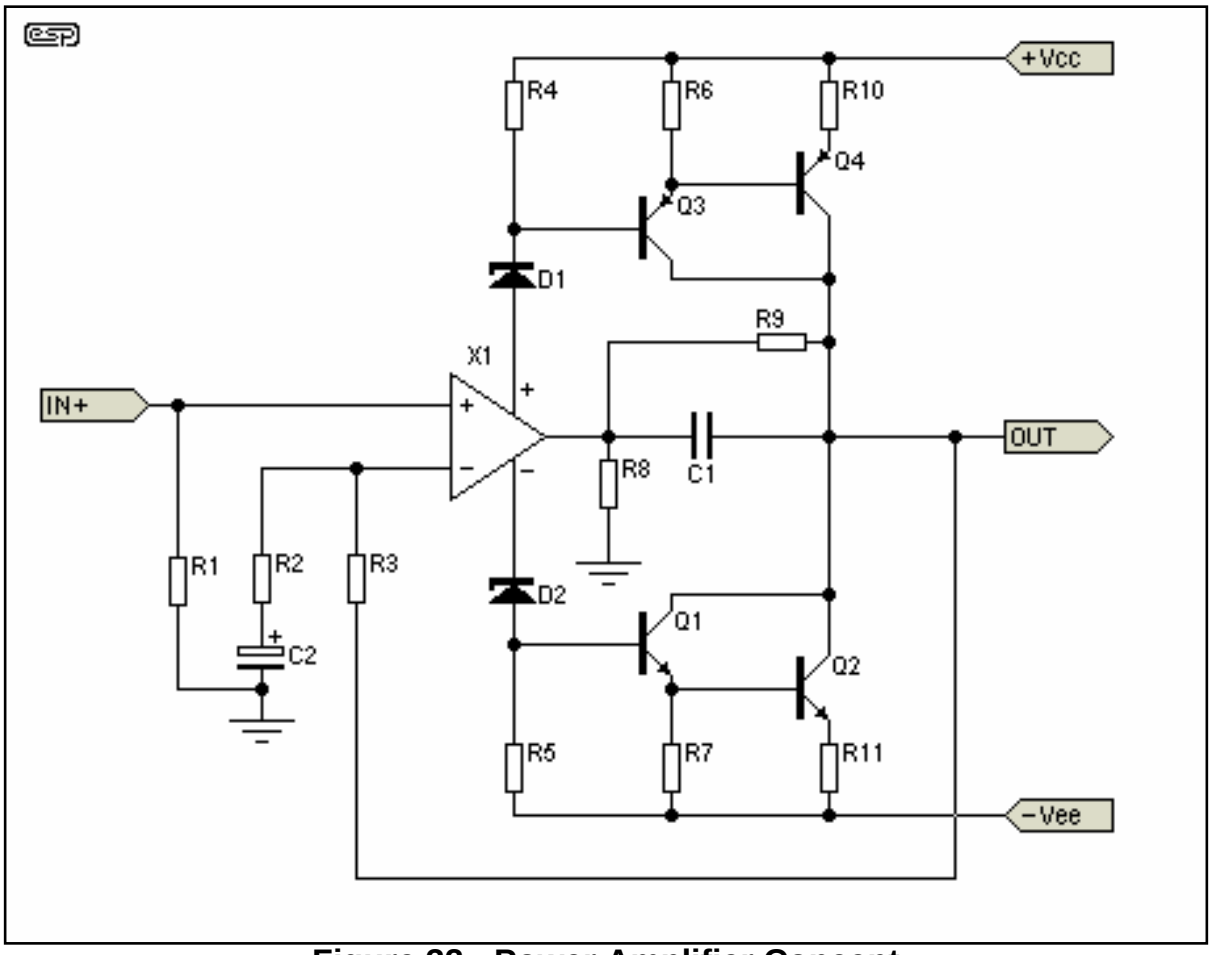

Figure 32 - Power Amplifier Concept

The circuit shown in Figure 32 is conceptional (that's why there are no component values). At one stage, this circuit was quite common, but had some major high frequency issues, as well as DC stability and a host of other problems. Although I do not recommend

that anyone even attempt to build it, the circuit is nonetheless interesting. By using the opamp supply current to modulate the transistors base current, the opamp could operate with voltages well above the normal allowed supply voltages, because the zener diodes reduced the voltage to within the allowable range. R9 was included because many years ago (when I actually contemplated using the design), it was found to work better with this in place.

Although my simulator has difficulties with the circuit, it is possible to get it to run with low output voltages. It shows low distortion, but I know from experience that this is dubious - measured (versus theoretical) distortion is higher than expected, and if I recall correctly, somewhat load dependent. Bias current stability can be very poor. This can lead to thermal runaway in the output stage, and it is very difficult to ensure good thermal stability without additional circuitry.

For other power amplifier designs that *do* work, just look through the ESP projects pages.

Basic Specifications

All in all, the specifications for even a fairly basic opamp can be daunting. There are so many terms used that it is difficult to understand what they all mean. The easiest are the absolute maximum values - these are simply a set of parameters that should never be exceeded. Supply voltage, input voltage, operating and storage temperatures are just a few of the figures quoted.

Let's have a look at the data for a TL072 ...

Abridged electrical characteristics, VCC = ±15 V, T_A = 25°C

Parameter	Test Conditions	Min	Typ	Max	Units
V_{IO} Input offset voltage	V_O = 0, Rs = 50Ω		3	10	mV
αV_{IO} Temperature coefficient of input offset voltage	V_O = 0, Rs = 50Ω		18		uV / °C
I_{IO} Input offset current	V_O=0		5	100	pA
I_B Input bias current	V_O = 0		65	200	pA

V_{ICR} Input common mode voltage		±11 -12 to 15	V
V_{OM} Maximum peak output voltage	R_L = 10kΩ	±12 ±13.5	V
A_{VD} Large signal voltage amplification	V_O = 10V, $R_L \geq$ 2kΩ	25 200	V / mV
B_1 Unity gain bandwidth	V_O = 10V, $R_L \geq$ 2kΩ	3	MHz
r_{IN} Input resistance		10^{12}	MΩ
CMRR Common mode rejection ratio	$V_{IC} = V_{ICRmin}$, V_O = 0, Rs = 50Ω	70 100	dB
k_{SVR} Power supply rejection ratio	$V_{IC} = V_{ICRmin}$, V_O = 0, Rs = 50Ω	70 100	dB
I_{CC} Supply current (each amplifier)	V_O = 0, No load	1.4 2.5	mA
V_{O1}/ V_{O2} Crosstalk attenuation	A_{VD} = 100	120	dB
SR Slew rate at unity gain	V_I = 10V, C_L = 100 pF, R_L = 2 kΩ	5 13	V/us
t_r Rise time overshoot factor	V_I = 20mV, C_L = 100 pF, R_L = 2 kΩ	20%	
V_n Equivalent input noise voltage	R_S = 20Ω, f = 10Hz - 10kHz	4	uV
THD Total harmonic distortion	V_{Irms} = 6V, A_{VD} = 1, $R_L \geq$ 2kΩ, $R_S \leq$ 1k&Omega, f = 1kHz	0.003%	

Well, it certainly does look rather daunting, so we'll look at each parameter in turn to see what it means. It must be understood that there are many different ways to specify an opamp, and the table above is intended to be representative only.

V_{IO} Input Offset Voltage

This is a measure of the typical voltage difference that may exist between the inputs when the first Rule is applied. So, while an ideal opamp will try to make both inputs *exactly* the same voltage, in a real opamp it may differ by this amount. A TL072 connected as a unity

gain buffer with zero input could have between 3 and 10mV between the two inputs (plus or minus). This is measured with zero volts at the output, and a source resistance of 50 ohms.

αV_{IO} Temperature Coefficient of Input Offset Voltage

All real devices are affected by temperature, so the input offset voltage may vary by the amount shown as the operating temperature changes. This figure can be ignored for most audio applications. It is important for instrumentation amplifiers, high gain DC amplifiers and other critical applications.

I_{IO} Input Offset Current

Even though the TL072 is a FET input opamp, it has some input current, primarily caused by gate leakage. The value is very small, having a maximum value of only 100pA.

V_{ICR} Input Common Mode Voltage

This is often an important parameter, and is very much so with the TL07x series. If exceeded, the output state becomes undefined. In the case of the TL07x devices, there can be a change of state of the output voltage if the input common mode voltage is exceeded. A signal that should just clip, has a sudden transition to the opposite polarity during the period where the common mode voltage is exceeded.

V_{OM} Maximum Peak Output Voltage

Few opamps can swing their outputs to the supply rails, and the amount of current drawn from the output affects this further. This limitation is only apparent when using low impedance loads, although there is still some loss with no load at all. By using the highest (sensible) supply voltage, this is not normally a problem.

A_{VD} Large Signal Voltage Amplification

This is usually the open loop (no feedback) condition, and is a measure of the maximum gain of the opamp for high level outputs. At a minimum of 25V / mV, this represents a gain of 25 / 0.001 = 25,000 (it is typically as high as 200,000 or 106dB at low frequencies). This is rarely a limiting value in any audio circuit.

B_1 Unity Gain Bandwidth

The frequency at which the opamp's open loop gain falls to unity is the unity gain bandwidth. When feedback is applied, it is usually desirable to have at least 10 times the gain that you specify with the feedback components. This represents an error of ~10% at the upper frequency. Unity gain bandwidth limits the maximum gain you can use for a given upper frequency.

r_{IN} Input Resistance

Nothing more complex than the input voltage divided by the input current (Ohm's law). So with an input voltage of 10V and an input current of 65pA, the input resistance is 153GΩ. The exact derivation of the value claimed in the table is unclear, since the measurement conditions are unspecified.

CMRR Common Mode Rejection Ratio

A measure of how well the opamp rejects signals applied to both inputs simultaneously. See the description of the balanced input stage for more information. Common mode rejection depends on the available open loop gain, and deteriorates at higher frequencies. This is graphed in most data sheets.

k_{SVR} Power Supply Rejection Ratio

All opamps can have some noise on the supply lines without serious degradation of the signal. PSRR is a measure of how well the opamp rejects (ignores) the supply noise or other unwanted signal(s) that may be carried by the supply buses.

I_{CC} Supply Current (Each Amplifier)

Needless to say, some current is drawn by all opamps. This is simply the typical current you expect to draw from the supply for each opamp in the package. At 1.4mA per opamp, a dual (TL072) will typically draw 2.8mA with 15V supplies.

V_{O1}/ V_{O2} Crosstalk attenuation

When there are two or more opamps in a package, it is inevitable that some signal will pass from one to the other. As specified, this will be -120dB if the amplifiers are operating with a gain of 100. In general, PCB layout causes far more crosstalk than the IC itself.

SR Slew rate at unity gain

The slew rate is simply how fast the output voltage can change. The specification says that this is measured with the opamp connected as a non-inverting unity gain buffer. In this case, the opamps is specified for a typical slew rate of 13V/us, meaning that in one microsecond, the output voltage can change by 13V. There are faster and slower opamps of course, but for audio work it is actually difficult to exceed the slew rate of any but the slowest opamps.

t_r Rise time overshoot factor

When any electronic circuit is subjected to a very sudden change of input voltage, the opamp will often not be fast enough to maintain control via the feedback loop. Once

control is lost, there is a finite time before the opamp 'catches up' to the input signal. This causes the output to overshoot the steady state level for a brief period, and the overshoot is measured as a percentage of the voltage change.

V_n Equivalent input noise voltage

This is a theoretical noise voltage that lives at the opamp's input. This noise is amplified by the gain that is set for the circuit. In this case, if the amp is designed to have a gain of 10, the output noise will be 40uV, over the frequency range of 10Hz to 10kHz. Noise is also expressed as nV√Hz (see separate article).

THD Total Harmonic Distortion

This is pretty much self explanatory. The test conditions are not always representative of real world application, but in this case appear to be reasonably sensible. The use of a unity gain amplifier is not the choice I'd make, but I didn't design the test specification.

The data above is based on National Semiconductor's data sheet and terminology. Other manufacturers may choose to use different terms for the parameters, use different test methods, or specify different operating conditions for the same test. The only way you will get to understand the terminology used is to read it - don't just look at it as gobbledygook and ignore it - you will never learn anything that way.

Comparators

The poor comparator is the (almost) forgotten first cousin of the opamp. Although comparators are very similar to opamps, they are designed based on the fact that they will never have negative feedback applied (although *positive* feedback is not uncommon!). Consequently, there are no constraints set by the necessity for stability with gain reduction caused by applied feedback. Although opamps can be used as comparators in low frequency applications, they are totally unsuitable at high frequencies. This is because of the frequency compensation applied in opamps, necessary to maintain closed loop (negative feedback) stability.

Because this restriction is removed for true comparators, they are able to be much faster than opamps, although it can still sometimes be a challenge to find a comparator that is fast enough if the operating frequency is high. Class-D amplifiers rely on a fast comparator to convert the analogue input signal into a pulse width modulated switching signal, and they need to be very fast indeed if timing errors are to be avoided.

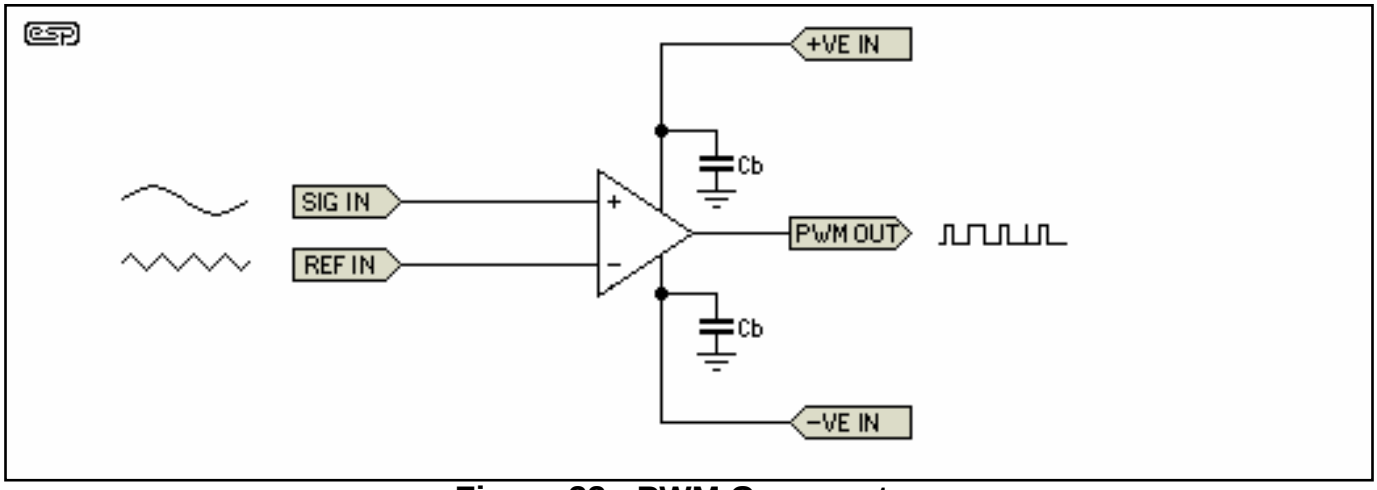

Figure 33 - PWM Comparator

Figure 33 shows the general idea for a pulse width modulator. The input sinewave is compared to the reference signal - usually a very linear sawtooth waveform. Since typical PWM amplifiers operate at a switching frequency of 250kHz or more, even a few nano-seconds switching delay becomes significant, but there are other applications where even faster operation is desirable.

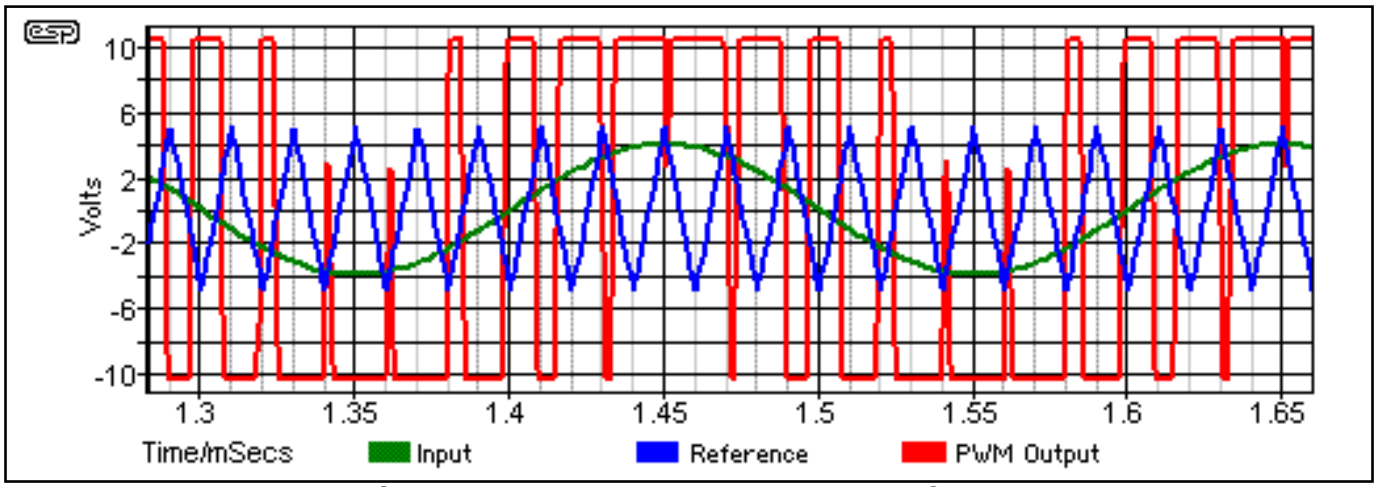

Figure 34 - PWM Comparator Waveforms

The PWM waveforms are shown above. A perfect example of the speed limitation is visible as the input signal approaches the peak value of the reference signal. The comparator is simply not fast enough to switch from one extreme to the other, resulting in the loss of pulses. This is a real phenomenon, and occurs with all PWM amplifiers as they approach clipping.

Achieving very high speed is a compromise, because high speed means that all circuit impedances must be low, thus increasing supply current. This means that the parts will get hot, unless the supply voltage is limited. For exactly the same reasons, microprocessor ICs are now using 3.3V instead of 5V, and high speed digital logic chips are all limited to 5V supplies. We can expect to see the voltage decrease even further as

the speed of digital systems increases.

Needless to say, PWM amps are not the only place comparators are used in audio. LED meter ICs have a string of comparators, they may be used for basic (or precision) timing applications, clipping detectors, etc. All analogue to digital converters use comparators as well.

Because they have no feedback, comparators *always* obey the second rule of opamps ... the output takes the polarity of the more positive input. Look carefully at the PWM waveform shown above, and you will see exactly that. Look closely - it is not immediately apparent, but it is visible.

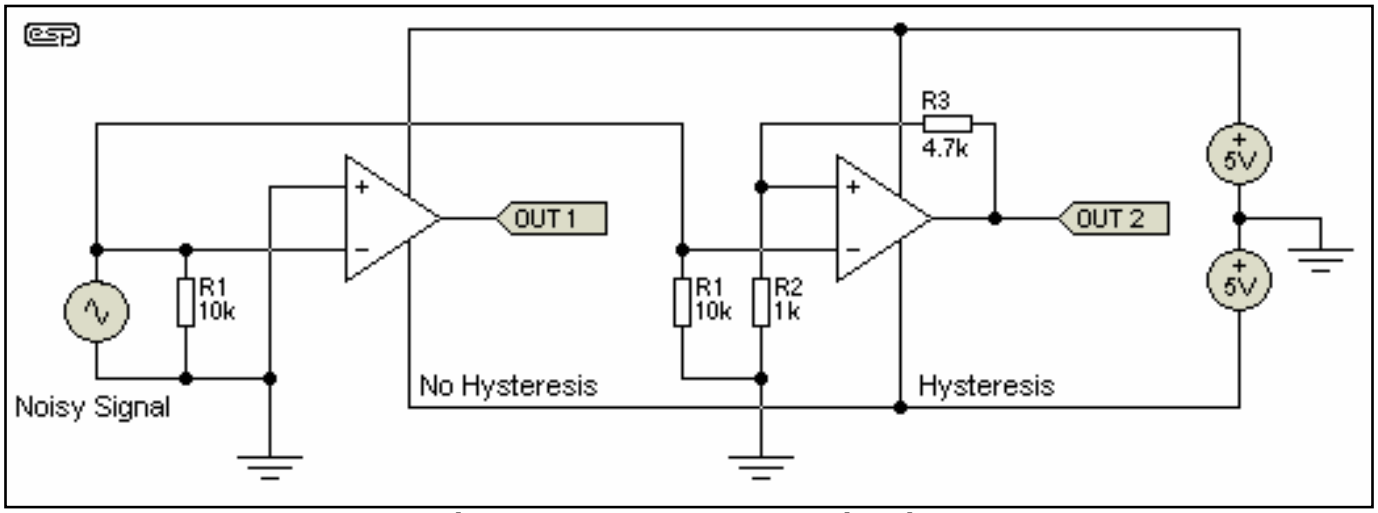

Figure 35 - Comparator Circuits

Comparators can be absolute, meaning that the output will change state whenever the signal passes the threshold. While this is needed for analogue to digital conversion and many other applications, it is often preferable to arrange the circuit so it has 'hysteresis'. This is a rather odd concept, but means that once the signal has caused an output change, it needs to change further to cause a reversal. Hysteresis can be likened to the snap-action of most switches, and indeed, this is mechanical hysteresis.

Both circuits are shown above. The waveforms are shown below. Note that both comparators are shown as inverting, because this connection provides the highest input impedance when hysteresis is added. If a non-inverting connection is used the input would be applied to the +ve input, via R2 for the version with hysteresis, and the -ve input connected to the reference voltage - in both cases this is ground (zero Volts). In a non-inverting connection, the positive feedback will create distortion on the input waveform - this can be a problem if the signal is intended to be used as an analogue waveform elsewhere in the circuit.

The polarity of any comparator can be reversed with a digital logic inverter, another comparator, or the input can be buffered to prevent positive feedback artefacts from being added to the signal. As always, there are many, many ways to achieve the same result, and the final circuit depends on your specific needs.

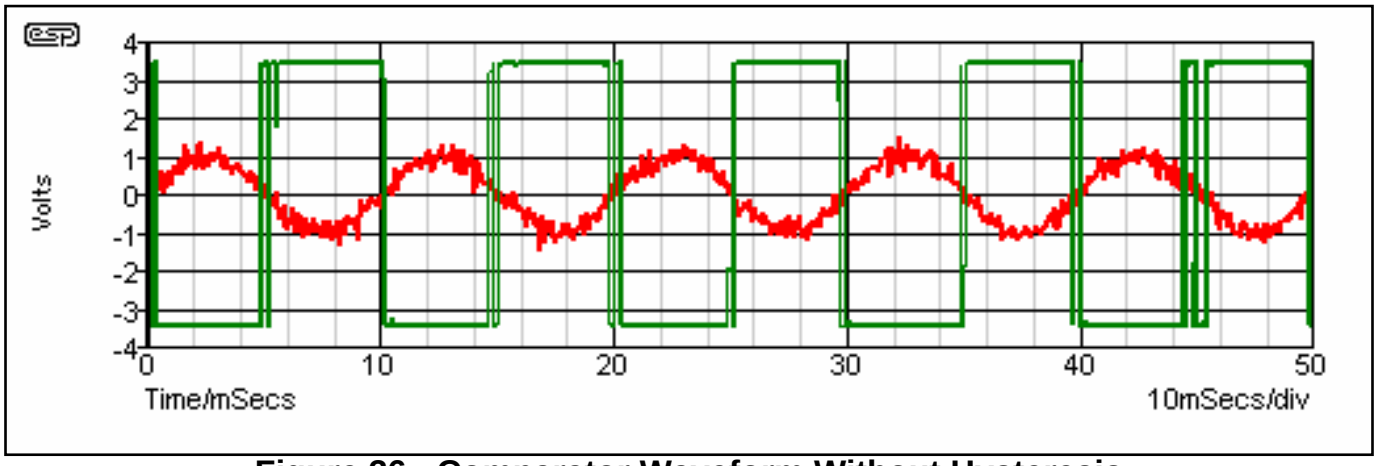

Figure 36 - Comparator Waveform Without Hysteresis

As you can see from the above diagram, if a noisy signal is applied to the input of an absolute (no hysteresis) comparator, the output shows multiple state changes as the input signal passes through zero. This happens because the noise amplitude is enough to cause the instantaneous input amplitude to pass through zero multiple times. This is usually undesirable, because comparators are commonly used to convert input waveforms into a digital representation, based on zero crossings of the input. Multiple triggerings as shown will cause an erroneous output.

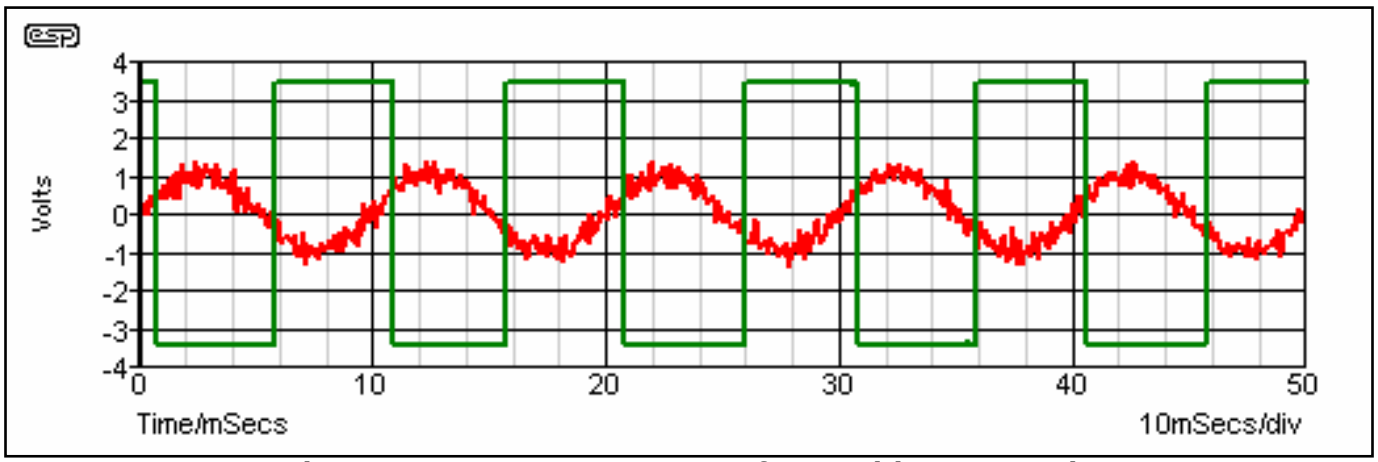

Figure 37 - Comparator Waveform With Hysteresis

Figure 37 shows the input and output waveforms of the comparator with hysteresis. The noise is ignored, because once the comparator changes state, the signal must go negative by more than the hysteresis voltage before it will change state again. The amount of hysteresis is determined by R2 and R3, and may be calculated to give a specific (and exact) level before the output will change state. This circuit is also known as

a Schmidt Trigger, and is a very common circuit. It is used in the PCB version of P39 (power transformer soft-start) to ensure accurate timing without any possibility of relay chatter as the timing voltage reaches the trigger point.

Calculating the trigger voltages for the inverting case is easy (see below), but is somewhat more irksome for the non-inverting configuration because the input and output voltages interact. Only the inverting is described here. R2 and R3 form a simple voltage divider. When the output is high (+3.5V), the voltage at the +ve input is ...

Vd = R3 / R2 + 1 = 4.7 / 1 +1 = 5.7 (where Vd is voltage division)
Vin = Vout / Vd = 3.5 / 5.7 = 614mV

The signal therefore must exceed +614mV before the output will swing negative. When it does, the input then has to exceed -614mV before the output will change state again, because the circuit is symmetrical. Any signal that does not reach the ±614mV thresholds will not cause the output to change state - such signals are completely ignored.

It is also possible (and not uncommon) to make the trigger voltages asymmetrical, and I shall leave this as an exercise for the reader to work out how this can be done. (Hint - diodes are commonly used to do just this).

This is but a small sample of comparator applications. They may well be the almost forgotten first cousin of opamps for the beginner or novice, but are extensively used in all kinds of circuitry - not necessarily audio, but they are very common there too. Most comparator applications are easy enough to understand once you have the basics, and this section is intended to provide just that - the basics.

Conclusion

Although the three articles in this series have only scratched the surface, hopefully you will have sufficient information as to how opamps work to be able to analyse any new circuit you come across. There is no doubt that there will be some applications that will cause pain, and it is completely impossible to make it otherwise.

Even though there are three fairly large pages devoted to the topic here, there are countless other applications for opamps - not only in audio, but in instrumentation, medical applications, and any number of industrial processing systems. There is almost no analogue application these days that does not use opamps, although in many cases you may not be aware they are there. Opamps are embedded in many other devices,

from analogue to digital converters and their opposite numbers, digital signal processing ICs, switchmode power supply controllers - the list is endless.

1 - Introduction

The EIA (Electronic Industries Association) and other authorities worldwide specify standard values for resistors, commonly referred to as the "preferred value" system. This system has its origins in the early period of electronics, at a time when most resistors were carbon composition with poor manufacturing tolerances. The idea is simple - select values for components based on the tolerances to which they are able to be made.

For example, based on 10% tolerance devices, we will work with a preferred value of 100Ω. It makes no sense to produce a 105Ω resistor, because 105 ohms falls within the 10% tolerance range of the 100Ω resistor. The next reasonable value is 120Ω, because a 10% 100Ω resistor will have a value somewhere between 90 and 110 ohms.

A 10% 120Ω resistor has a value ranging between 108 and 132Ω. Following this logic, the preferred values for 10% tolerance resistors between 100 and 1,000Ω is a roughly logarithmic sequence of 100, 120, 150, 180, 220, 270, 330 and so on (rounded to the closest sensible value). This is the E12 series shown in the first table below. The values in any decade can be derived by multiplying or dividing the table entries by powers of 10.

In each series, values may start from as low as 0.1 ohm, and may extend to several megohms, depending on the type of resistor and its intended purpose (and cost, of course).

The highest number of values is the E192 series, but these are normally only required where extreme accuracy is needed. For the odd occasion where a highly specific resistance is needed, it is usually simpler to use 2 or more resistors in series or parallel to obtain the needed resistance. Few suppliers stock the E96 or E192 series, so they will be difficult for most people to obtain.

3 - Capacitors

Film capacitor values normally follow the E12 series. In some cases, suppliers will decide (based on what criteria I really don't know) that some of the available values are "not needed", and they can be hard to find.

Electrolytics usually follow a limited range of the E12 series, and in the case of larger types, may not follow any particular series at all. For example, 8,000uF caps are quite common, but don't fit into any of the above tables.

Electrolytics also have rather broad claimed tolerance (up to +20% -50%), but in reality, most are remarkably close to the marked value.

Although the E6 series was used with resistors (or so I believe - I've never seen it), it is still common with electrolytic capacitors. Although the range seems very limited, it is normally quite sufficient for the typical uses of electros - power supply decoupling, input caps, etc.

E6	1.0	1.5	2.2	3.3	4.7	6.8

6 Values per Decade

4 - Zener Diodes

The following is far from a complete listing, but gives a reasonable range of voltages and power dissipation. Personally, I prefer the European designations, such as BZV85C6V8

- you can tell instantly that the voltage is 6.8V from the number. Unfortunately, these are not always easy to obtain, and the 1N series are more common (in non-European countries at least). Please note that due to the amount of data in the table, it is almost a certainty that I have made one (or more) mistakes in the translation, so *always* check the data sheet before committing yourself to a particular device. Also bear in mind that many of the devices listed will be extremely difficult to get. 1W zeners are the most commonly available, and a method is shown below to use these at much higher power levels.

	Power (Watts)							
Voltage	**0.25**	**0.4**	**0.5**	**1.0**	**1.5**	**5.0**	**10.0**	**50.0**

120		1N987	1N6026	1N3046	1N5951	1N5380	1N3008	1N2841
Voltage	**0.25W**	**0.4W**	**0.5W**	**1.0W**	**1.5W**	**5.0W**	**10.0W**	**50.0W**

Voltages that do not appear are easily made up by connecting zeners in series. If possible, keep the voltages of the two (or more) zeners as close as possible, or their current handling capabilities will be different, possibly leading to overheating of the higher voltage (and therefore higher dissipation) device(s).

Zeners should always be operated at between 10% and up to a maximum of 80% of rated power to obtain the best (most stable) reference voltage. To determine the optimum current (say 25% of maximum to keep dissipation reasonable), use the following simple formula ...

I = (P / V) / 4

where I is current, V is rated voltage, and P is rated power. For example, a 27V 1W zener should be operated at around

I = (1 / 27) / 4 = 0.00926A = 9.26mA (power is 250mW)

In many cases, the preferred current will be too high and will cause excessive heating, but it must be understood that the regulation of the zener is not very good until it is operating at the lower limit of 10% rated power.

There will be times when you really do need a high power zener, but find that the one you need is either not available or very expensive. There is generally no real need to use high powered zeners unless space is at a premium, since the simple circuit below will work in most cases.

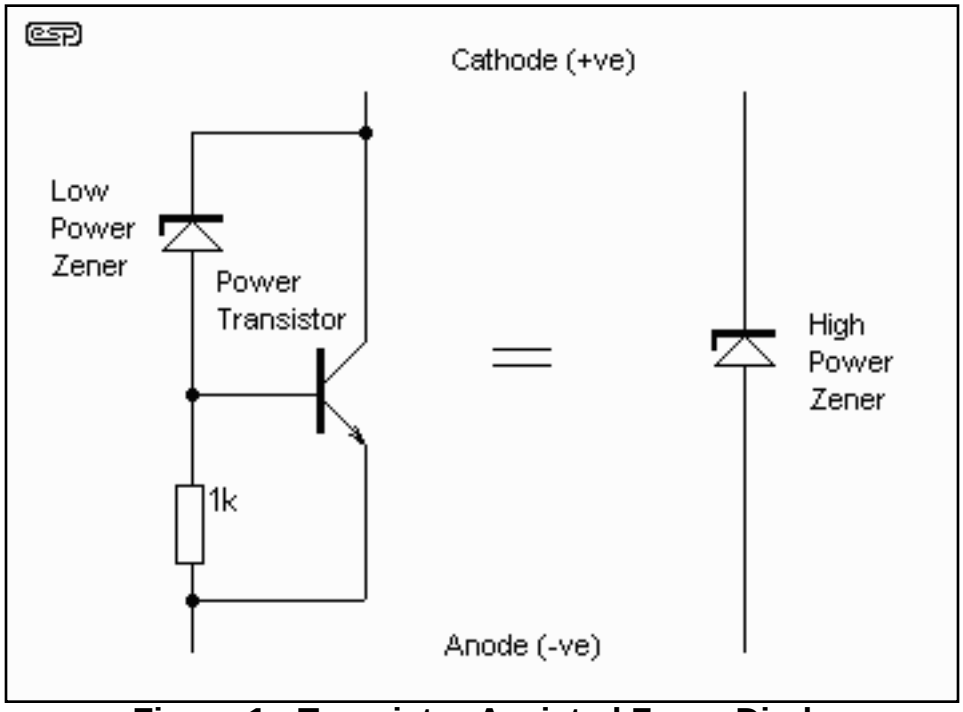

Figure 1 - Transistor Assisted Zener Diode

The circuit works by simply amplifying the zener current, the majority of which is fed directly into the base of the transistor. If the voltage attempts to rise, more zener current flows, thus more base current to the transistor. This causes the transistor to turn on until a state of equilibrium is reached, where the voltage across the 'composite zener' is held at the correct value (+ 0.65V base-emitter voltage, of course).

Since zeners are typically classified by their dynamic resistance (or impedance), it is worthwhile looking at the assisted version to see what sort of performance we can expect. Figure 2 shows the dynamic impedance of a zener by itself, and that of the assisted version.

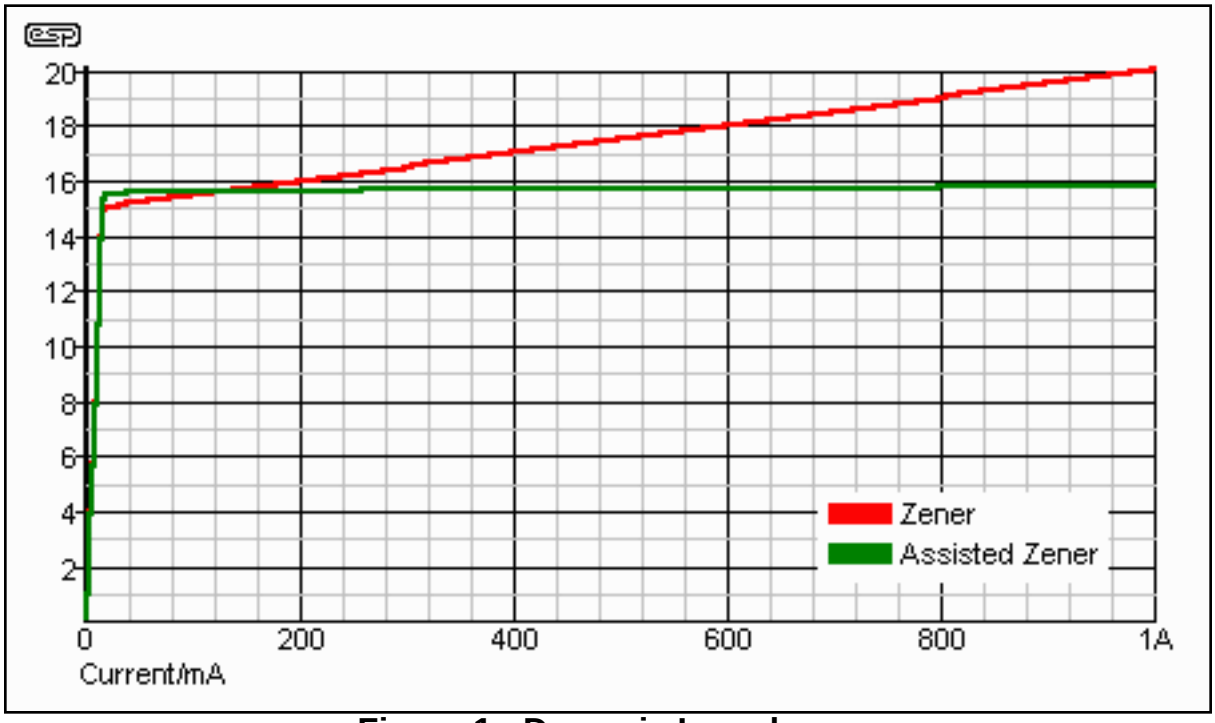

Figure 1 - Dynamic Impedance

The dynamic impedance is measured by changing the current by a known amount, and measuring the voltage change. In the case of the zener, the current was varied by 100mA, and the voltage changed by 0.4975V, therefore ...

$$R = V / I = 0.4975 / 0.1 = 4.975\Omega$$

The transistor assisted zener is a great deal better (as can be seen from the flatter curve). In this case, a current change of 100mA only achieved a voltage change of 25mV, so dynamic resistance/impedance is ...

$$R = V / I = 0.025 / 0.1 = 0.25\Omega$$

It is possible to improve this further, but I'd suggest that if you need better performance than an assisted zener can provide, then you'd be a lot better off with a proper regulator.

Note that the transistor must be chosen so that it is operating in its continuous safe operating area, and must be appropriately derated for temperature. Expect a 100W transistor assisted zener (for example) to dissipate *a lot* of heat, so don't skimp on the heatsink.

For those who have looked at a lot of the ESP site, you will notice that the P37 (DoZ preamp) power supply uses an assisted zener as the main power supply regulator.

5 - Conclusion

The main purpose of this section is to tie up a few "loose ends", and add some of the harder to find (or just plain frustrating) information that you will need from time to time.

It is probable that more loose ends will turn up in time, and this will be added to the information here as found or needed. Unfortunately (or perhaps fortunately) the range of components is so diverse that it is not possible to cover everything.

1.0 - Introduction

The moving coil meter movement (also known as a galvanometer) was invented by the French physicist and physician, Jacques-Arsène D' Arsonval in 1882. It is the basis for all modern meter movements, and the basic design principles remain the same after all this

time. The actual construction can differ quite widely, but upon examination it is obvious that there are simply different ways to achieve the same outcome.

Meters are common in audio. They are sometimes used as 'eye candy' to impress - especially on power amplifiers, but they have many real uses as well. Meters are used to display the level from mixing desks, either as a VU (volume unit) or PPM (Peak Programme Meter) display, and while LED meters save space and can be very fast acting, they have neither the coolness of an analogue movement nor the retro appeal. To many people, an analogue movement provides a better sense of what is happening, even though they lack the immediacy of a LED display. In some cases, the two may even be combined to give the best of both worlds.

Meters are also used on power supplies and many other pieces of test equipment, and although it is assumed that digital is more accurate (you can see the exact voltage displayed), this is not always the case. Although digital meters *appear* accurate, this is often an illusion (read the specifications ... 1% ±1 digit is common, and that last digit can make a big difference sometimes).

In addition, there are some applications where digital is essentially useless. If a voltage (or current) is continually changing, the readout from a digital meter is impossible to interpret accurately. With analogue, you can see peaks and dips, and it is easy to see a trend (or average) just by looking at the pointer. Analogue is far from dead, and to this day I still use many analogue meters on millivolt meters, distortion analysers, power supplies, etc.

Although many of the techniques shown in this article are aimed at analogue applications, they are equally at home with digital meters - DPMs (Digital Panel Meters) are commonly available for about the same price as their analogue counterparts. This makes them very attractive for some applications - especially since good moving coil meter movements are now quite expensive and may be hard to get. Some applications are also shown for DPMs.

2.0 - Basic Meter Movements

The basic analogue meter movement is the moving coil type. These have been the mainstay of most metering applications for a very long time, but there are others that are common in other industries. Moving iron meters are often used for mains applications (especially in switchboards and the like), and although they are non-linear this is not a limitation for the intended applications. The latter are interesting, but will not be covered

because of limited availability and lack of usefulness for audio applications. Another interesting meter uses electrostatics to display the voltage. These are restricted to very high voltage applications and apply virtually no circuit loading. Like the moving iron movements, they are not useful for general workshop use because they are too specialised. A photo of a very ordinary moving coil meter movement is shown in Figure 1.

Figure 1 - Moving Coil Meter Movement

Figure 2 shows the essential sections - yes, it is different from Figure 1. The drawing shows the way that moving coil movements were commonly constructed many years ago, which is somewhat easier to draw than more modern types. The essential parts are labelled so you get an idea of the construction of these meters. Nearly all moving coil meters are low voltage, low current devices, and the multipliers and shunts referred to in the title are used to convert the movement to read higher voltages and currents than it was designed for. This versatility is the reason that moving coil meters have stayed with us for so long. They can be made to read up to thousands of volts (or amps), AC voltage and current (with the addition of rectifiers), audio levels, or anything else where a physical quantity can be converted to an electric current.

The beauty of the analogue scale is that a plant operator (for example) can tell at a glance if the reading is normal, whereas it is necessary to actually read the displayed value of a digital meter. You don't need to read a value on an analogue meter to see if it

is normal. Look at the meter on a battery tester - it is simply labelled 'Replace' and 'Good' or similar - the exact value is unimportant, but you still see a linear scale so you can estimate 'Marginal' without even thinking about it.

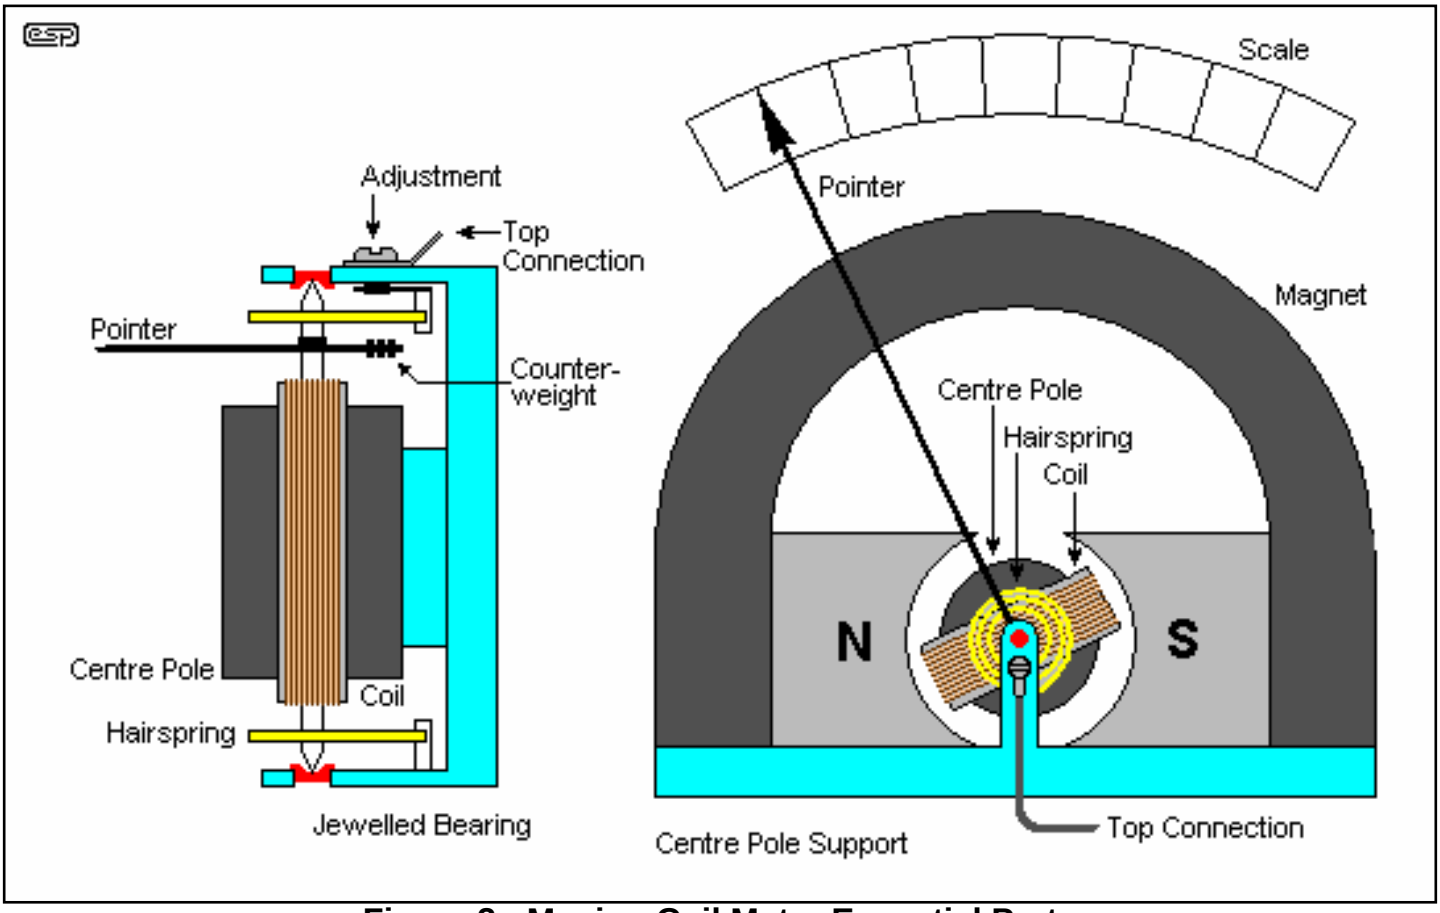

Figure 2 - Moving Coil Meter Essential Parts

The moving coil movement uses a coil former of aluminium, around a centre pole and 'immersed' in a strong magnetic field. The coil is most commonly supported by jewelled bearings (although taut-band suspension is a much better arrangement, IMHO). The coil is maintained at the zero position by the tension of the hairsprings, and one of these (almost always the top) is made adjustable from outside the meter case. This allows the user to zero the pointer. Current to the coil is carried by the hairsprings.

Taut band suspension uses no bearings, but supports the coil on a tiny flat spring (a flat wire) at each end. The flat spring acts as both suspension and restoring force, as well as providing current to the coil itself. Unfortunately, taut band movements are not very common, possibly because they are sometimes not as mechanically rugged as the traditional jewelled pivot suspension, and are very difficult to repair if the suspension breaks (personal experience!). A major advantage is that they have very low (virtually zero) hysteresis - this is caused in jewelled movements if the pivot sticks slightly because of contamination or damage.

The aluminium former is almost invariably made so that it forms a shorted turn around the centre pole. This provides electrical damping, preventing excessive pointer velocity. There is a lot more to the analogue meter movement than meets the eye, but we shall leave the topic now, so that the usage of these devices can be covered.

2.1 - Movement Specifications

All moving coil meters have a rated current for FSD (Full Scale Deflection), and this parameter is of primary importance. The FSD current determines how much load the meter will place on any drive circuitry, or for a voltmeter, how much current it will draw from the voltage source. This may or may not be important, depending on application.

Most commonly available meters are readily available with a sensitivity of between 50uA and 1mA FSD. More sensitive meters are available, but the cost goes up with increasing sensitivity. The most sensitive meter I have heard of was used by Sanwa in an analogue multimeter - 2uA FSD, taut band movement!

All meter movements have resistance, because the coil uses many turns of fine wire. The resistance varies from perhaps 200 ohms or so (1mA movement) up to around 3.5k for a 50uA movement. These figures can vary quite widely though, depending on the exact technique used by the manufacturer.

Normally, moving coil meter movements are suitable for DC only. Some (such as VU meters for audio) have an internal rectifier so that AC may be measured, but accuracy is generally rather poor, especially with low voltages.

To obtain good AC performance requires the use of external circuitry. The project pages have a design for an AC millivoltmeter, and there is an interesting array of precision rectifier circuits in the application notes section of the ESP site.

Some movements have a mirrored scale, where a band of highly polished metal is just behind the scale itself. This is used to eliminate parallax errors as you read the meter, and can improve reading accuracy dramatically. None of this is useful if the meter is poorly calibrated or non-linear. Moving coil meters *can* be non-linear if the magnetic path is not adjusted correctly - such adjustments are not recommended for anyone not trained or used to working on very delicate equipment. It also helps if you know exactly what to do, a topic that is well outside the scope of this article.

3.0 - Voltage Multiplier

When a meter is to be used as a voltmeter, a series resistor is used to limit the current to the specified FSD with the maximum applied voltage that you want to measure. This is a very easy calculation to make, since it involves nothing more advanced than Ohm's law.

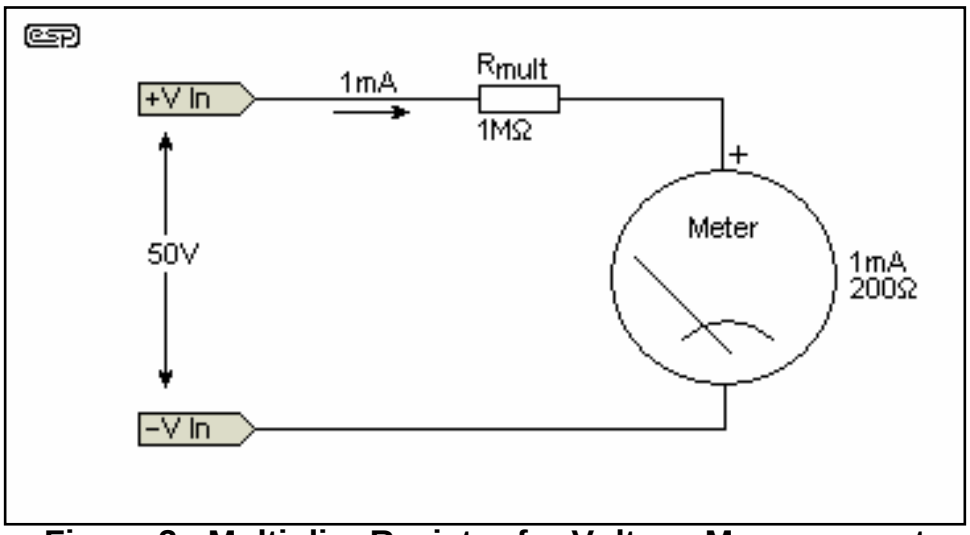

Figure 3 - Multiplier Resistor for Voltage Measurement

For example, we want to measure the voltage from a power supply, and have a 1mA meter movement available, having a coil resistance of 200 ohms. If the maximum supply voltage is 50V, then the meter should read from 0-50V. The total resistance needed will limit the current through the meter to 1mA with 50V applied, so ...

$$R_{total} = V / I = 50 / 1mA = 50k\Omega$$

Since the meter has 200 ohms resistance, the series resistor will be

$$R_{mult} = 50k - 200 \text{ ohms} = 49{,}800 \text{ ohms}$$

This is not a standard value, so will need to be made up using series / parallel resistors. Of course, one can always cheat and use a 47k resistor in series with a 5k pot, thus enabling the meter to be calibrated to a high accuracy. We do need to check the resistor power rating, because it is easy to forget that the multiplier resistor can dissipate a significant power - especially at high voltages. The resistor power is given by ...

$$P = I^2 * R = 1mA^2 * 47000 = 53mW$$

The power dissipation is well within limits for even the lowest power resistor. Be very careful when determining the multiplier resistance for high voltages. Although the power

rating may be quite low, the gradient voltage across the resistor may exceed its ratings. It is imperative that resistors are not operated above the maximum rated voltage for the particular type of resistor. This specification is not often given, so it is best to assume the worst case, and limit the voltage across any 0.5W resistor to no more than around 150V - less for 0.25W resistors.

It is generally preferable to use the most sensitive meter you can get within your price range, so in this case, a 50uA movement would be a far better proposition. Less current is drawn from the measured voltage source, so there is less loading on potentially sensitive circuits. This was always a problem when measuring voltages in valve amplifiers, because typical cheap analogue multimeters often used relatively high current movements, and this loaded the voltage under test giving incorrect readings. Analogue multimeters usually had a rating of 'Ohms/Volt' - the 1mA movement described above uses 50k total resistance to measure up to 50V, so that would be rated at 1kΩ/ Volt. The better multimeters of yesteryear were rated at a minimum of 20kΩ/V up to 100kΩ/Volt (the Sanwa meter mentioned above was 500kΩ/Volt!). To obtain even higher measurement impedance, the better equipped workshops and laboratories back then used a VTVM (Vacuum Tube Volt Meter), offering an input impedance of around 10-100MΩ. These were followed by FET input transistorised units, and finally displaced by digital multimeters. Despite their popularity, digital multimeters are still very bad at some measurements, and are often not as accurate as we tend to think they are.

Using a 50uA movement, the multiplier resistor needs to be ...

$$R_{mult} = V / I = 50 / 50uA = 1M\Omega - 3500 \text{ (meter resistance)} = 996{,}500 \text{ ohms}$$

... which works out to be 20kΩ/ Volt. Again, this resistance can be made up by series connection of different values, but a 1MΩ resistor is perfectly ok. The error is much smaller than the tolerance of the resistor or the meter movement, at 0.35%. If you need greater accuracy you will need to use a trimpot with a series resistor as described above for the 1mA movement.

That's all there is to multipliers - as stated in the beginning of this section, they are very easy to work out.

4.0 - Current Shunt

The situation is a little more complex when calculating a shunt for current measurement. Not so much because the calculations are difficult, but because you will be working with

very low resistance values. It is also important to ensure that the meter is connected directly to the shunt - even a small length of wire in series may make readings uselessly inaccurate. The schematic diagram below shows not only the electrical connection, but also the physical connection to the shunt.

In most cases, it is easier to calculate (or measure) the voltage across the meter movement for FSD. If you don't know the resistance, it can be measured with a digital multimeter. The current from most digital multimeters is low enough not to cause damage to the meter, but the pointer may swing rather violently. Connect with reverse polarity to minimise the risk of bending the pointer.

Unless you are measuring low currents (less than 1A or so), the shunt resistance can be worked out using Ohm's law, and will be accurate enough for most purposes. This is covered below.

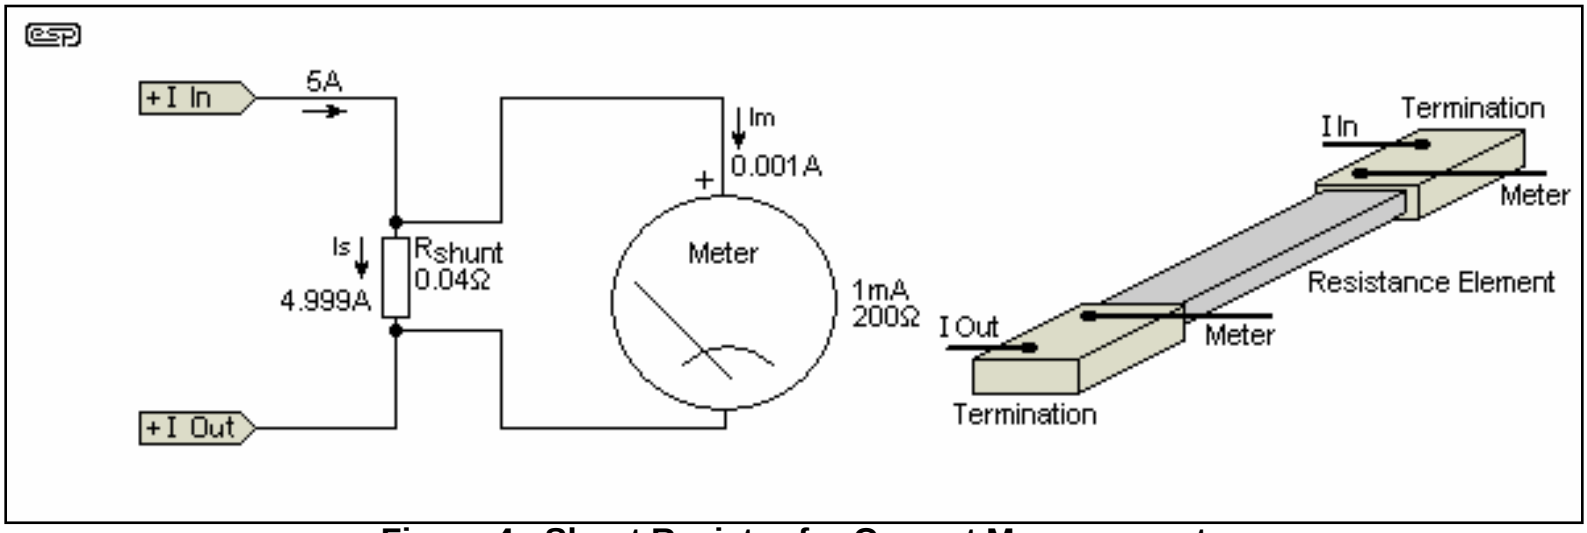

Figure 4 - Shunt Resistor for Current Measurement

Assuming a 1mA movement with an internal resistance of 200 ohms, as an example we wish to measure 5A. This means that 4.999A must pass through the shunt, with the remaining 1mA passed by the meter movement. The shunt resistance can be found with the following formula ...

> Rs = Rm / (Is / Im) where Rs is the shunt resistance, Rm is the meter resistance, Is = shunt current, Im = meter current

So for our example,

> Rs = 200 / (5A / 1mA) = 0.04Ω

If we use only Ohm's law (having determined that there will be 200mV across the movement - 1mA and 200 ohms), the shunt can be calculated as ...

Rs = Vm / I where Rs is shunt resistance, Vm is meter voltage at FSD, and I is the current
Rs = 0.2 / 5 = 0.04Ω

This method will work to within 1% accuracy provided the measured maximum current is more than 100 times the meter current. One thing we have to be careful of with shunts is that the voltage 'lost' across them is not excessive. This will reduce the voltage supplied to the load, and can result in significant errors, especially at low currents. For example, if we only need to measure 1mA, we can use the meter directly, but we lose 200mV across the meter. In the case of the 0.04 ohm shunt calculated above, we lose

V = R * I = 0.04 * 5A = 200mV

... exactly the same voltage loss! It's not a great deal, but can be critical in some exacting tests or at very low voltages. 200mV is almost nothing with a 50V supply (0.4%), but is very significant if the applied voltage is only 1V (a full 20% loss). The voltage drop can be reduced slightly by using a more sensitive movement. For a 50uA movement with 3,500 ohms resistance, the loss is

V = R * I = 3500 * 50uA = 175mV

... not much of a gain, but not many alternatives. Current measurement will always lose some voltage, so it is important that the voltmeter is always connected *after* the ammeter, so that the 'lost' voltage is taken into consideration. Where extremely low voltage drop is important, one must resort to amplification. An opamp can be used to amplify the voltage across a much smaller value shunt, but at the expense of circuit complexity and temperature drift. Digital panel meters are better than analogue movements for current measurements.

The idea of a shunt is all well and good, but where does one obtain an 0.04 ohm resistor? It can be made up of a number of wirewound or metal film resistors in parallel, or a dedicated shunt may be available. Obtaining high accuracy at such low resistances is very difficult though, and shunts are generally cut, machined or filed to remove small amounts of metal until the exact value needed is achieved. The shunt must be made from metal having a low temperature coefficient of resistance to prevent the reading being affected by changes in temperature - either ambient, or caused by the load current heating the shunt..

There is an easier way, as shown in Figure 5. The voltage drop will be a bit higher than it should be, but you only need a few millivolts extra to be able to use the technique.

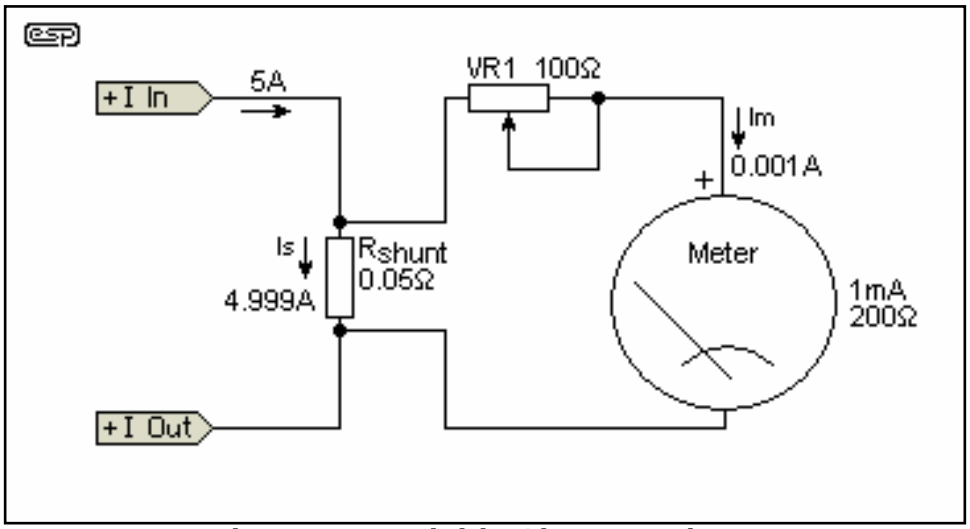

Figure 5 - Variable Shunt Resistor

Now it is possible to use 2 x 0.1 ohm resistors in parallel, giving 0.05 ohm. The voltage drop at 5A will be 250mV, but you have the advantage of being able to use standard tolerance resistors, which can represent a significant saving. The power is only 1.25W at full current, so a pair of 5W resistors will barely get warm. The trimpot can be adjusted to give an accurate reading, without having to resort to close tolerance resistors with impossible values. As an example for the above 5A meter, we could use a 100 ohm trimpot in series with the meter. The value is not particularly important, but needs to be within a sensible range.

What is 'sensible' in this context? Easy. We already know that the meter needs 200mV for full scale and that we will get 250mV across a 0.05Ω shunt, so we need a resistance that will drop 50mV at 1mA.

$$R = V / I = 0.05 / 0.001 = 50 \text{ ohms}$$

Since we are using a pot, it is advisable to centre the wiper under ideal conditions to give maximum adjustment range (to allow for worst case tolerance), so a 100 ohm pot is ideal.

5.0 - Expanded Scale Voltmeter

You may have seen expanded scale voltmeters used in cars to monitor the battery voltage. Since no-one is interested if the battery measures less than 10V (it's dead flat!), and it should never exceed 15V, a meter that measures from 10V to 15V is nice to have. This is surprisingly easy to do, and although absolute accuracy is not wonderful in a

simple application, it is more than acceptable for the purpose.

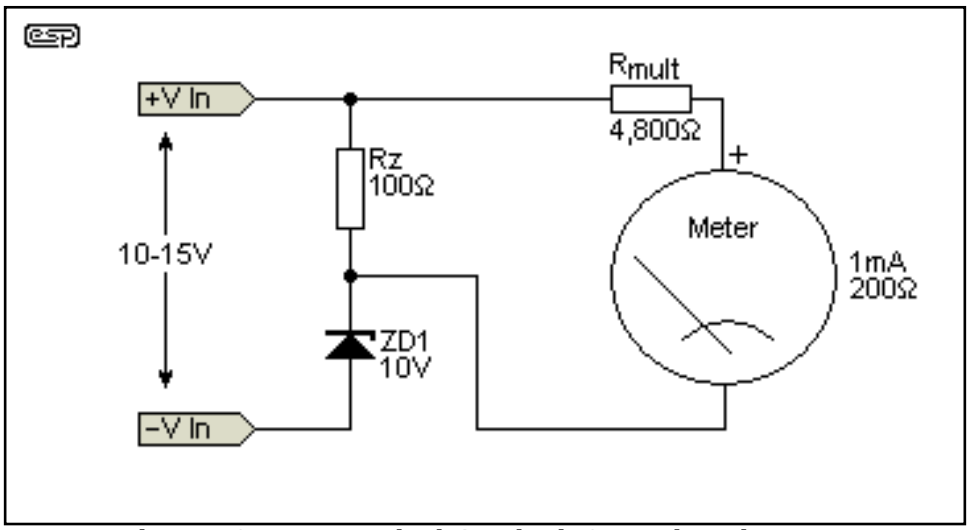

Figure 6 - Expanded Scale (10-15V) Voltmeter

By using a zener diode, a base reference is established, and the meter only measures between the reference and actual battery voltage. We will use a 1mA movement again (as shown above). This scheme can be adapted for any desired voltage. The voltmeter only needs to measure the voltage drop across the zener feed resistor, which is needed to ensure that an acceptable current flows in the zener diode. The 1mA drawn by the meter is not enough to obtain a stable voltage.

The multiplier is worked out in the same way as before ...

$$R_{total} = V / I = 5 / 1mA = 5k\Omega$$

Because the multiplier resistance is much smaller than before, we must take the meter resistance of 200 ohms into consideration.

$$R_{mult} = R_{total} - R_{meter} = 5000 - 200 = 4800\Omega$$

A 4.7k resistor will introduce a small error, but a 3.9k resistor in series with a 2k trimpot will allow the meter to be set very accurately. The zener feed resistor value is not critical, but should ensure that the zener current is between 10% and 50% of the maximum for the device. Assuming a 10V 1W zener, the maximum current is ...

$$Iz_{max} = P / V = 1 / 10 = 0.1 = 100mA$$

Using Ohm's law, we get a resistance value of 100 ohms for a zener current of 50mA at

15V. This will fall as the voltage is reduced, but extreme accuracy at 10V is not possible, so this arrangement should work fine.

6.0 - Digital Panel Meters

DPMs (Digital Panel Meters) are often very attractive, not just for their perceived accuracy, but because they can often be obtained for the same or less than a good analogue meter movement. They also have better linearity than most of the cheap movements, so there are some real benefits. Most are available with a quoted sensitivity of 200mV (199.9mV full scale), so are comparable to analogue meters in terms of voltage drop for current measurement. They have the great advantage of a (typical) 100MΩ input impedance, so voltage loading is extremely low. In addition, they will measure positive and negative voltage or current - this is available with a centre zero analogue meter, but they are hard to find.

Most DPMs are classified as 3½ digit, meaning that they display up to a maximum of 199.9mV. The most significant digit can only be blank or 1, and the other 'half' is used to display a negative sign to indicate that the input is negative with respect to the common or ground terminal. This often means that much of the range is wasted if you want to display a range other than 0-1999. Note that most DPMs do not automatically select the decimal point, and there are extra pins to allow the user to select the position of the decimal point (or to ignore it completely). Analogue meters have no such limitation, because the scale can be calibrated with any units you wish, and covering any range.

6.1 - Digital Voltmeter

Measuring voltage with a DPM is easy - most even come with instructions that show you how to do it. You do need to be careful to ensure that possibly destructive voltages cannot be coupled to the inputs. Like all ICs, the ADC (Analogue to Digital Converter) used is sensitive to excess voltage, and the IC can be destroyed.

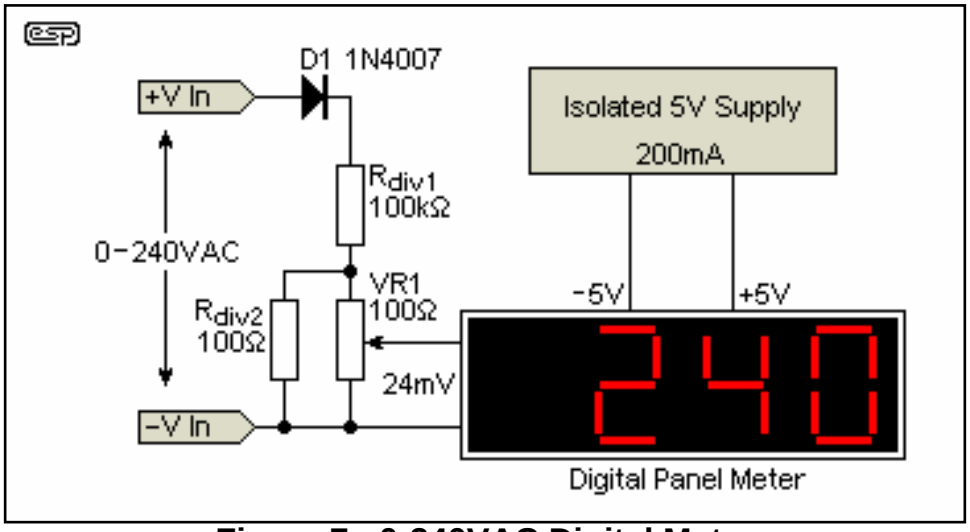

Figure 7 - 0-240VAC Digital Meter

Figure 7 shows the circuit of a DPM voltmeter I built recently. This is designed to monitor the output from my workshop Variac (variable transformer). To ensure an adequate voltage rating for R_{div1} 4 x 100k 1W resistors were used in series parallel, maintaining the peak voltage across each to 170V (the peak of 240V AC is 340V). 1W resistors were not used for their power rating, but to have a large resistance section, maintaining a relatively low voltage gradient across the resistor surface. Because it is only used for 0-240V, the voltage to the DPM will be 0-24mV, and this is a half-wave rectified signal. The meter averages the applied voltage. Note that the 5V supply *must* be isolated, because it could have the full mains potential on all terminals if the active (live) and neutral conductors are ever swapped around. This is critically important - the entire circuit (including power supply) must be considered as being at mains potential.

To obtain the (approximate) average value of ½ wave rectified AC, you divide the peak voltage by 3.12. Based on this and for an average signal of 24mV, the average input voltage is 109V (340 / 3.12), so the voltage divider needs a ratio of

$$Vdiv = Vin / Vout = 109 / 24mV = 4542$$

For all reasonably high voltages, the division ratio is so high as to cause significant errors, and the use of a trimpot to adjust the value is strongly recommended. Since I used 100k for Rdiv1 (because I had 100k/1W resistors handy), the parallel combination of Rdiv2 and VR1 needs to be slightly more than

$$Rdiv2 \cong (Rdiv1 / Vdiv) - 1 \cong 22 \text{ ohms}$$

50 ohms (as used) allows VR1 to be roughly centred, and there is plenty of adjustment range. Needless to say, exactly the same technique can be applied to an analogue meter

as well, but you need to allow for the much lower input impedance (perhaps 100 ohms rather than 100M for the DPM that I used). As it turns out, with an average voltage of 108V and a resistance of 100k, the current is 1.08mA, so the meter can be driven directly (leaving out Rdiv2 and VR1). You will need to readjust the resistance though, because the (in)accuracy is 8% - much better results can be obtained. A pot is highly recommended because the AC waveform is not very predictable, and severe errors may result from waveform distortion.

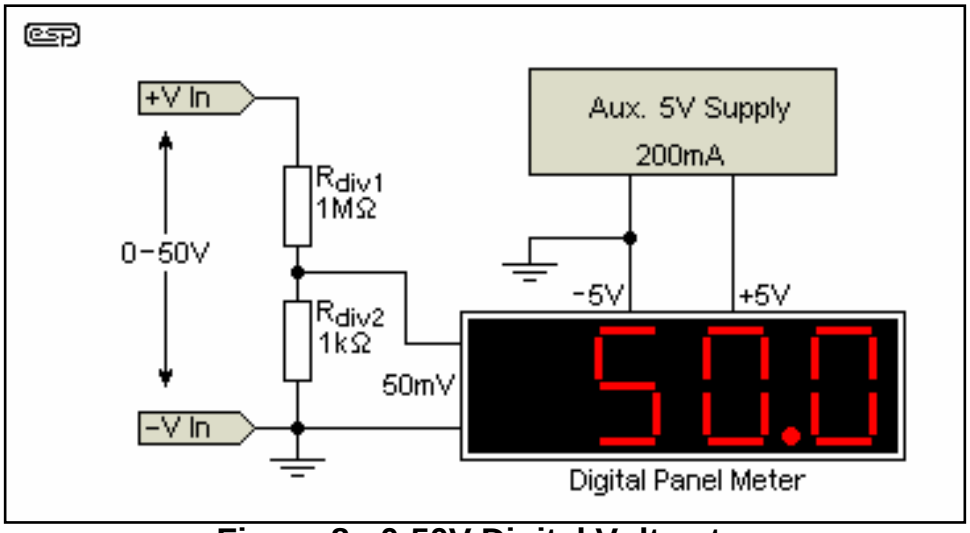

Figure 8 - 0-50V Digital Voltmeter

For a more conventional application, Figure 8 shows a basic 0-50V digital meter. The resistor values are fixed in this case. Because of the high input impedance of the DPM, we can use 1M for the upper divider resistor. The division ratio is determined the same way as before ...

Vdiv = Vin / Vout = 50 / 50mV = 1000
Rdiv2 = Rdiv1 / Vdiv = (1M / 1000) - 1 = 999Ω

Using a 1k resistor is not an issue, because the resistor tolerance is much wider than the 1 ohm difference in the calculated values. The same result can be achieved using 10k and 100 ohms, but there is not normally any need to aim for very low impedances. You may find that the meter displays 'rubbish' values in the least significant digit - this means that noise is being picked up, and a lower impedance will reduce that. If you need the circuit to be accurate, then you will need to use 0.1% resistors or add a pot so it can be adjusted. A pot is a lot cheaper and easier to get than 0.01% resistors, especially if you end up with odd values.

6.2 - Digital Ammeter

DPMs have a benefit as ammeters, but usually only if you don't need the full scale. Since the typical sensitivity is 200mV, by using only a part of the maximum reading, you can use lower shunt resistances than with analogue movements.

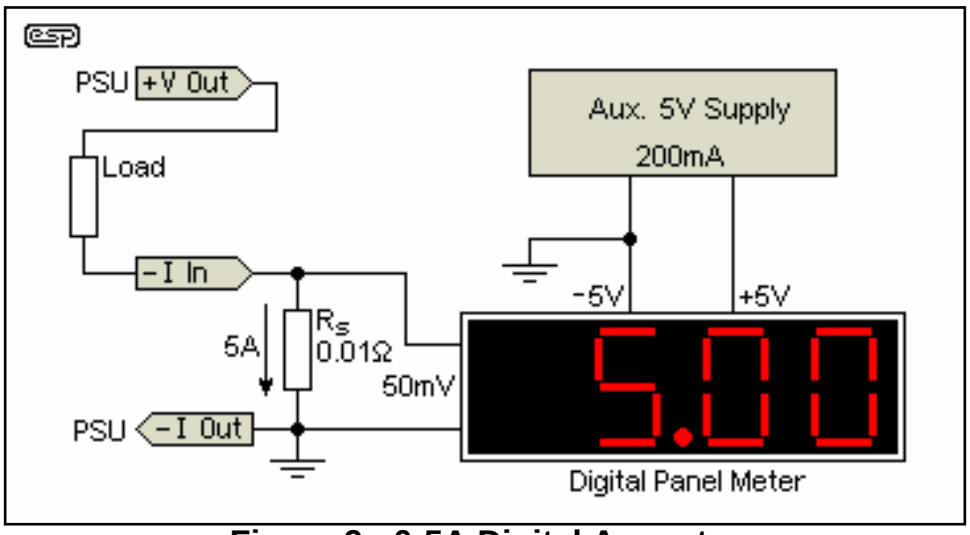

Figure 9 - 0-5A Digital Ammeter

The procedure for calculating the shunt is exactly the same as for an analogue meter, except that there is no meter current. You simply need to calculate the shunt based on the meter voltage for the desired current reading ...

$$R_s = V_s / I = 50mV / 5A = 0.01\Omega$$

This gives a much lower shunt resistance, because only 50mV is needed at the meter input. The circuit shown will work up to 20A (19.99A to be exact) with the same 0.01Ω shunt resistor. Note that the input is shown on the negative supply, with the +ve input going to the positive supply via the load. If the input and power supply -ve terminals are not at the same potential, then the supply for the meter *must* be floating - it cannot be grounded. If you wanted to monitor the current in the positive supply lead for example, you need a floating auxiliary supply.

7.0 - Make Your Own Multimeter

In general, this would have to be considered a silly topic. After all, one can buy a multimeter quite cheaply, and the switching is a nightmare. For specialised applications though, there may be perfectly good reasons for making a multi-range meter. Bear in mind that the circuit shown below does not include protection for the DPM, so if 2kV were applied when the 200mV range was selected, the meter will be destroyed.

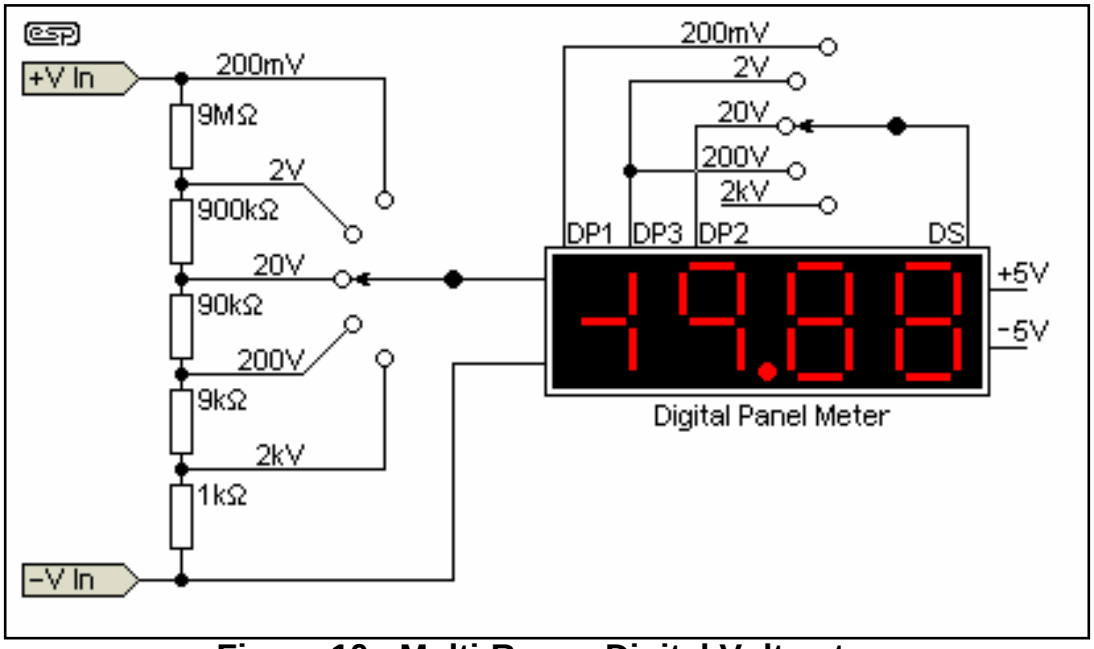

Figure 10 - Multi-Range Digital Voltmeter

You need a 2-pole 5-position rotary switch, and the insulation must be sufficient for the maximum voltage. Any protection circuit that you add must not load the external circuit, otherwise the meter may appear as a short circuit to high voltages. As noted, this is basically a silly idea, but it may be useful (even essential) for some applications where a conventional multimeter would be inappropriate. No, I can't think of such a situation either .

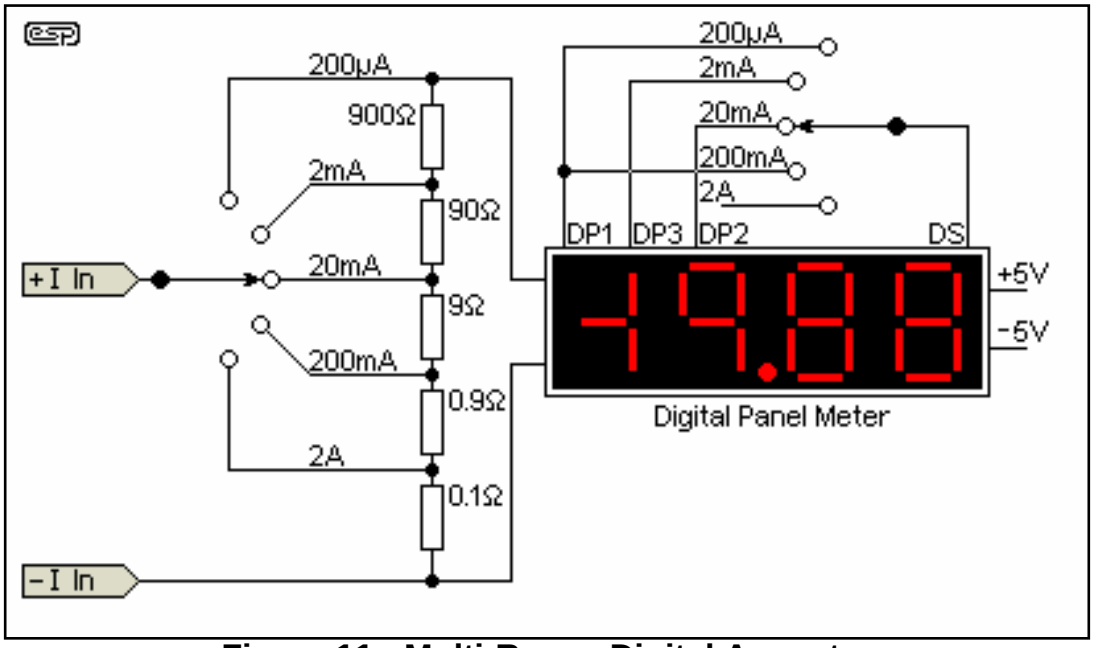

Figure 11 - Multi-Range Digital Ammeter

Similar comments apply to the ammeter. In this case, the resistors and switch must be capable of handling the current, although this only becomes an issue on the highest current range. Like the multi-range voltmeter, the usefulness of Figure 11 is somewhat

dubious, although it would be nice on a laboratory power supply. The ranges can be expanded or moved - for example you may find that ranges from 2mA to 20A suit your needs. Simply reduce all resistance values by a factor of 10, and that's what you have.

It almost looks like this section is pretty useless, but the final application allows you to do things that no normal multimeter will - measure very low resistances.

7.1 - Measuring Resistance

There are many reasons one may want to measure very low resistance values. Transformer windings, loudspeaker crossover inductors (assuming you are actually interested in passive crossovers), or perhaps you need to be able to measure current shunts .

For very low resistance values you have two choices - either use a very sensitive voltmeter, or a high measurement current. Both methods have disadvantages. High sensitivity is difficult for DC amplifiers because of drift. Changes in temperature cause opamp offset voltage and current to change, and that affects the readings. While there are methods to (almost) eliminate drift, they are beyond the scope of this article.

High measurement current can cause the device under test (DUT) to heat, and that will affect the resistance. Some things that have low resistance may not be able to even tolerate the kind of current that you may need to be able to measure them. In general, a maximum current of around 1A will allow most low resistance measurements without too many risks, but naturally the current source can be made variable, with switched ranges to provide a wide measurement range.

With a measurement current of 1A you will get a meter that can measure 0.2Ω full scale, so very low resistances can be measured. Needless to say, battery operation is not recommended if you aim to make a resistance meter that will provide 1A.

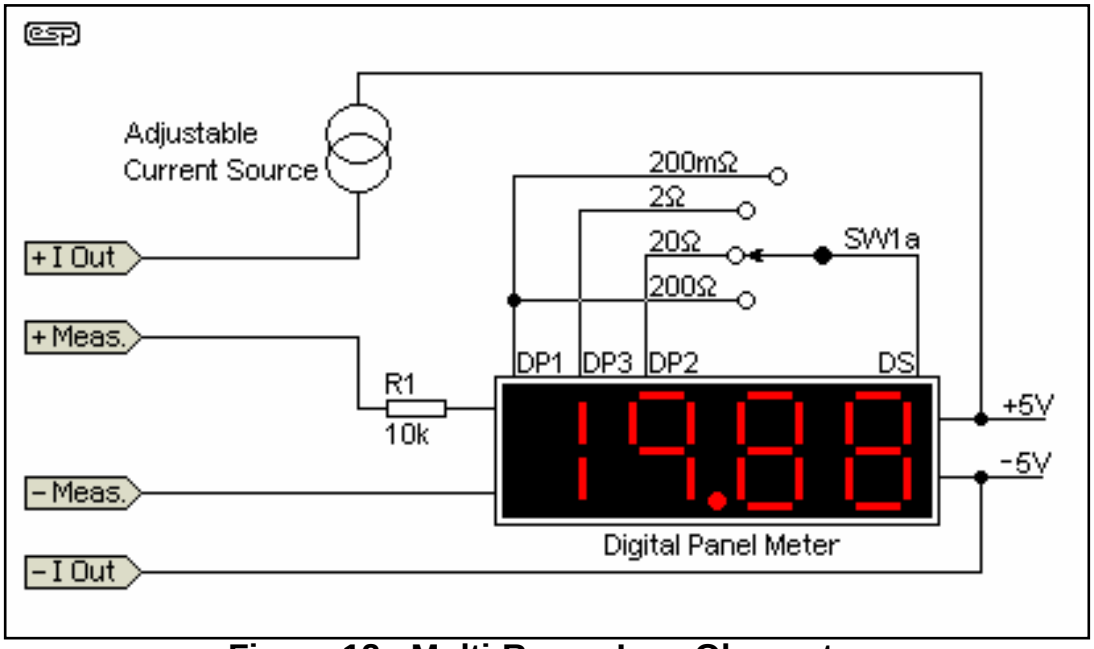

Figure 12 - Multi-Range Low Ohmmeter

The use of 4 terminals is essential for very low resistances. Two wires carry the current to the DUT, and the two measurement leads are then connected as close as possible to the device itself, with a component lead length equal to what will be used when the component is installed. This technique avoids errors caused by lead and connection resistances. While it is possible to null out the lead resistance, connection resistance tends to be variable, and can cause substantial measurement errors. This method is very common for this type of instrument. R1 is used to prevent possible damage to the DPM if it is subjected to an over-voltage condition.

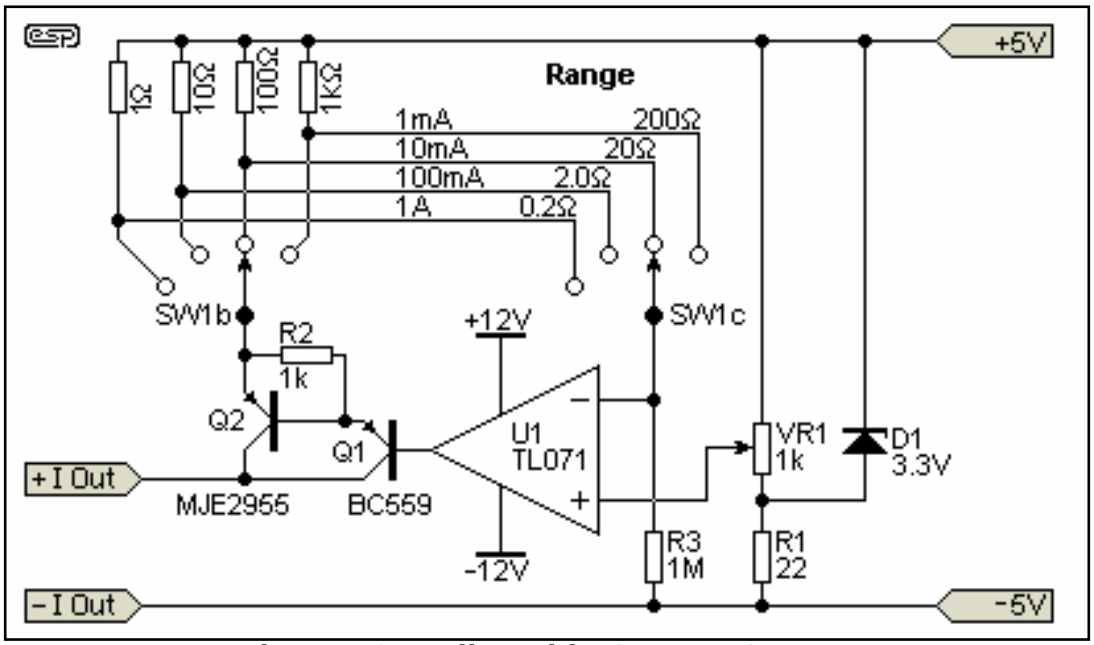

Figure 13 - Adjustable Current Source

The adjustable current source requires accurate calibration, and will be as good as your

construction and choice of components allows. Temperature drift is always a problem with precision circuits like this one, but the circuit as shown will be quite accurate within the normal ambient temperature range. The current setting resistors (those connected to SW1b) need to be as accurate as possible.

The greatest difficulty is the switch used to select current ranges. Even the smallest amount of resistance will cause large errors. By switching both the resistor and the measurement point (the opamp's inverting input), the error is minimised because the switch resistance does not form part of the measurement circuit. R3 is included to ensure that the current source is switched off as you change ranges.

VR1 is adjusted so there is exactly 1V between the opamp's positive input and the 5V supply. When exactly the same voltage (1V) is developed across any of the current setting resistors, the current through it must be as specified. A tiny error is introduced because the base current of Q1 is added to the total, but this should amount to less than 0.1%. The 5V supply needs to be well regulated, and capable of at least 1.5A without any appreciable change of voltage. If the 0.2 ohms range is not needed, you can leave out the 1 ohm resistor and simplify the switching accordingly. Q2 can then be changed to a BD140.

Although a zener is not the most ideal voltage reference, they are easy to obtain. Precision voltage reference diodes are available, but they are relatively expensive and only stocked by a few major parts suppliers. The zener is deliberately operated at a relatively high current (about 100mA) so that it will get reasonably hot. This helps to stabilise it against ambient temperature variations, so the circuit will take a few minutes to settle down after power is applied.

This circuit can also be used as a stand-alone low ohms adaptor. It obviously needs the power supplies, but you can use your multimeter to measure the voltage across the DUT. The resistance is read as a voltage (the same way that your meter does it internally), with the appropriate conversion based on the current source setting.

The second section of the low ohm meter circuit can be used in conjunction with an analogue movement if you prefer. You will need to apply your own multiplier to the scale and add any necessary extra resistance for calibration, but it will work just as well. You will have to make your own scale - see conclusion, below.

8.0 - Conclusion

The metering systems described here should be considered a guideline, rather than usable circuits in their own right. By following the information shown, you will be able to create a meter for almost any measurement for which meters can be used. If AC metering is needed, then I suggest that you look at the various meter circuits in the Projects pages.

Although it may seem unlikely, this article has only covered the basics. Metering is widely used for many different applications, and it is impossible to cover every possibility in a short article. It is hoped that the information proves useful to anyone who has been wondering exactly how to go about adding a meter to their latest power supply project, or who has a real need to measure low resistances.

One final point - scales. It is often difficult (or impossible) to get a meter scale that is calibrated with the units you want. The resolution of modern printers is more than acceptable to allow you to create your own scale, which can then be printed. Ink-jet photo printing paper gives an excellent finish, and after you have cut the scale to fit, it can be attached over the existing scale with spray adhesive. Make sure that there is sufficient clearance for the pointer, and avoid 'whiskers' of paper that can cause the pointer to stick. While the meter is dismantled, be careful to ensure that no magnetic materials (iron filings, etc.) are allowed to enter the gap, as these will cause the meter to stick and are a real pain to remove (personal experience).

Introduction

The humble potentiometer (or pot, as it is more commonly known) is a simple electro-mechanical transducer. It converts rotary or linear motion from the operator into a change of resistance, and this change is (or can be) used to control anything from the volume of a hi-fi system to the direction of a huge container ship.

The pot as we know it was originally known as a rheostat (or reostat in some texts) - essentially a variable wirewound resistor. The array of different types is now quite astonishing, and it can be very difficult for the beginner (in particular) to work out which type is suitable for a given task. The fact that quite a few different pot types can all be used for the same task makes the job that much harder - freedom of choice is at best confusing when you don't know what the choices actually are, or why you should make them. This article is not about to cover every aspect of pots, but is an introduction to the subject. For anyone wanting to know more, visit manufacturers' web sites, and have a look at the specifications and available types.

The very first variable resistors were either a block of carbon (or some other resistive material) with a sliding contact, or a box full of carbon granules, with a threaded screw to compress the granules. More compression leads to lower resistance, and vice versa. These are rare in modern equipment, so we shall limit ourselves to the more common types :-)

Basic Pots and Knobs

It is worthwhile to have a look at a few of the common pot types that are available. Figure 1 shows an array of conventional pots - both PCB and panel mounting.

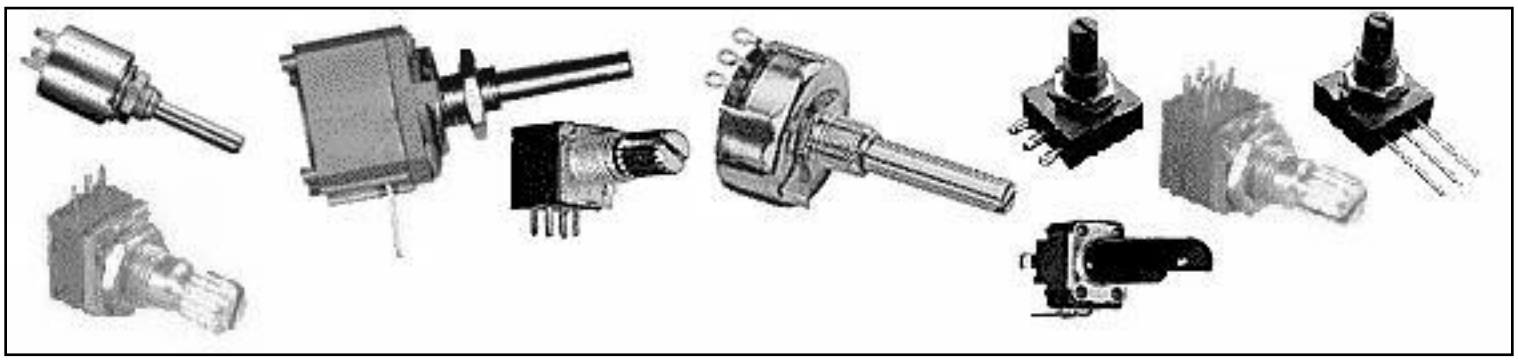

Figure 1 - Some Examples of Pots

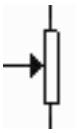
Note that these are not to scale, although the relative sizes are passably close. Apart from the different body shapes and sizes, there are also many "standard" mounting hole and shaft sizes. Probably the most common of all is the one in the centre of the picture. A panel mount, 25 millimetre (1") diameter pot. This uses a 10mm (3/8") mounting hole, and has a 6.35mm (1/4") shaft. These pots have been with us almost unchanged for 40 years or more.

The remainder show a few of the many variations available. The fluted shaft types are commonly referred to as "metric", but will accept a standard 1/4" knob - albeit with a little

play (it is less than a perfect fit, but is acceptable if the grub screw is tight enough). Metric pots are also available in 16mm round and 25mm round formats.

Most rotary pots have 270 degrees of rotation from one extreme to the other. A "single turn" pot is therefore really only a 3/4 turn device, despite the name. There are some other rotary types with only 200 degrees or so, and some specialty types may have less than that again.



The standard schematic symbol for a pot is shown to the left (although some people insist on using zig-zag lines for resistors and pots, I don't, so don't expect me to start now :-). A little later, we shall look at the many ways a standard pot may be wired, as well as some further explanations of the different "law" or taper used. Project 01 has been on this site for a long time now, and is a simple and effective way to create an almost logarithmic taper from a linear pot - but I am getting ahead of myself here.

First, we need to continue with the examination of the basic types (and you thought the above small sample was enough :-) Well, as they say ... "You ain't seen nothin' yet!"

Knobs

Before we look at other pot types, a quick sample of knobs. Yes, I know that everyone has seen knobs, but a dissertation on pots would be less than complete if I didn't include these.

Figure 2 - Some Examples of Knobs

Of these, only one deserves special mention - the one on the left. This is a multi turn vernier readout (analogue in this case) for a standard pot. Typically used with precision wirewound or conductive plastic pots, these used to be common on equipment where very accurate (and repeatable) settings were required. They are expensive, but in their day were almost indispensable. Now, a digital panel meter is cheaper, and considered much more "high tech" - such is progress, but at the expense of the "olde worlde" charm of a mechanical contrivance. And yes, you can still get them!

The remainder are perfectly ordinary knobs, and again, are but a very small sample of those available from a multiplicity of manufacturers. Most cheap knobs are plastic, but they are available with brass inserts, in solid aluminium (brushed, anodised, etc.), plastic innards with a thin aluminium outer shell or just an insert. The list is endless, but I shall end it here.

Trimpots

Then of course, there are trimpots (aka trimmers) - pots designed for "set and forget" applications. They are used for "trimming" the value of a resistor, and are commonly used for calibrating instruments, setting the bias current on power amplifiers, and a host of other areas where a circuit cannot be relied upon to give an exact gain, output voltage, or current. Naturally, a normal panel pot can be used, but these are very much bigger, and any calibration or setup control should not be made available for everyone to fiddle with as they please.

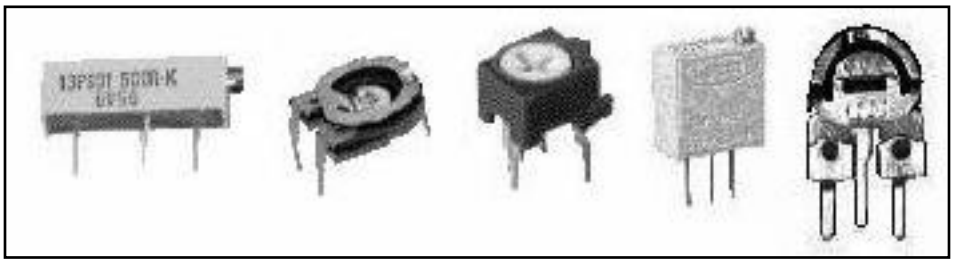


Figure 3 - Some Trimpot Styles

This is a very small sample of those available. The first and fourth are multi-turn types, and these should be used when a very precise setting is required. Because they are sealed, they are relatively immune from contamination, and for all but the most trivial application, should be used instead of the open types (#2 and #5). Trimpots (as shown) are generally available as vertical or horizontal - the choice is usually made based on ease of adjustment of the final circuit.

Potentiometer Tapers

The taper (also called "law") of a pot is important. We need not worry with trimpots, since they are almost always linear, and I do not know of a supplier of anything other than linear trimpots. For all panel pots, we must be aware of the use the pot will have, and select the correct type accordingly.

The most common use of a pot in audio is as a volume control. Since our hearing has a

logarithmic response to sound pressure, it is important that the volume control should provide a smooth variation from soft to loud, such that a given change in position of the pot causes the same sensation of volume change at all levels.

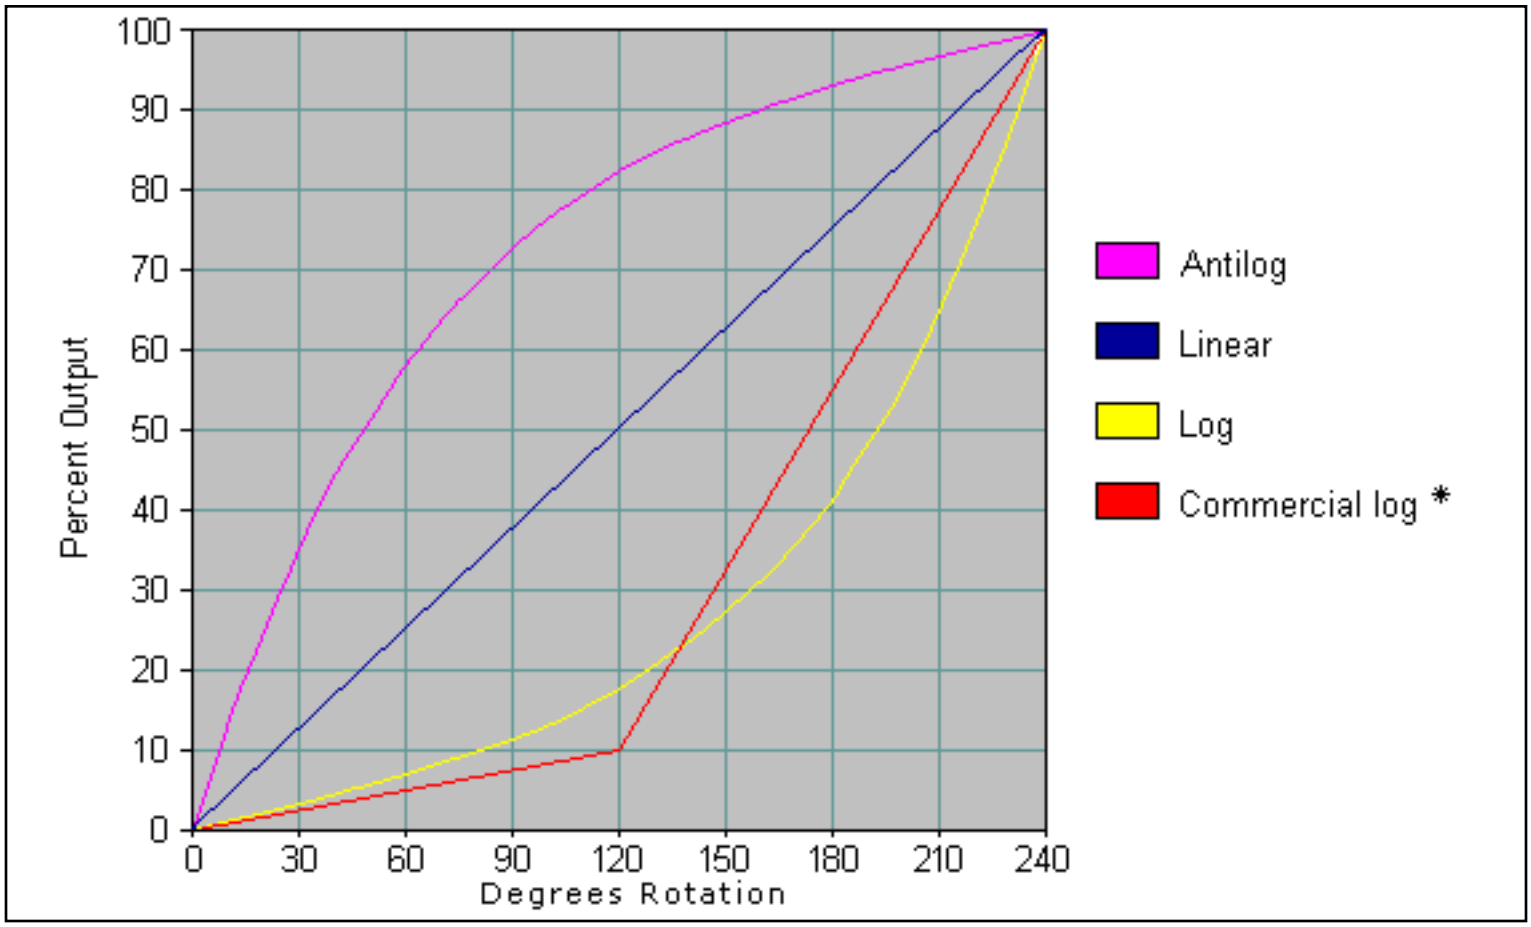

Figure 4 - Potentiometer Tapers

First, the term "taper" needs some explanation. In the early days, when an audio taper (logarithmic, or just log) was needed, the resistance element was indeed tapered, so that it provided a different resistivity at different settings. By changing the physical taper, it was possible to make a pot provide the exact gradient of resistance needed. By definition, a linear pot has no taper as such (the resistance element is parallel sided), but the term has stuck, so we might as well get used to it.

The violet curve in Figure 4 shows an antilog or reverse audio taper pot. These are quite uncommon, but used to be used for balance controls using a log/antilog dual section (commonly called dual gang) pot. It is shown on the graph mainly for its interest value, but they are generally an historical component now.

All this tapering proved a rather expensive exercise, so manufacturers economised ("they" won't notice the difference!), and worked out a method of using two resistance elements of differing resistivity, and joining them to create what I referred to as the

"Commercial log" taper. In short, it doesn't work (not properly, anyway), and the discontinuity where the two sections join is almost always audible with cheap "log" pots.

Project 01 showed how this can be fixed, and I will explain the logic and maths a little more as we progress. In the meantime, I suggest that you get an old pot and dismantle it so that you can see exactly what is inside. I could show you some photos, but there is nothing like doing it yourself to really get to know the subject.

Pot Markings

Now, this should be dead easy - a simple code to indicate the resistance and law of a pot should cause no grief to anyone, right? Wrong! It wouldn't have been so bad if someone hadn't decided to change it, and even then, it wouldn't have been so bad if there was no overlap between the "old" and "new" "standards" ... I think you can see where this is headed by now.

Taper	Old Code	New Code	Alternate
Linear	A	B	LIN
Log (Audio)	C	A	LOG
Antilog	F	N/A	N/A

Wasn't that a nice thing to do? It is obviously important to check before you make assumptions, or you can easily get the wrong type - especially if working on older equipment.

At least the resistance marking is usually sensible, so a 100k pot will be marked as 100K - but not always. The coding system used for capacitors is sometimes used as well (especially on small trimpots), so a 100k pot could also be marked as 104 - 10, followed by 4 zeros, or 100000 (100k) ohms.

Because they are variable, there is a much smaller range of potentiometer values, almost always in a 1, 2.5, 5 sequence. Common values for panel pots are 1k, 5k, 10k, 25k, 50k, 100k, 500k and 1M - 2.5k and 250k went missing along the way, and these are not stocked by very many distributors. 25k pots are becoming harder to get as well. Not all values are available in log and linear, and in some cases you may even find that for a particular type, you can get them in any value you want, as long as it's 100k (for example).

Trimpots suffer a similar fate. The only way to know what you can get from your local

supplier is to check their catalogue. In reality, everything is available, but you may have to go a very long way to get it.

Power and Voltage Ratings

For most audio applications, these are of little on no consequence. In many other applications however, exceeding the specified ratings could lead to the destruction of the pot or yourself! Neither can be considered a good thing.

Power - A pot with a power rating of (say) 0.5W will have a maximum voltage that can exist across the pot before the rating is exceeded. All power ratings are with the entire resistance element in circuit, so maximum dissipation reduces as the resistance is reduced (assuming series or "two terminal" rheostat wiring). Let's look at the 0.5W pot, and 10k is a good value to start with for explanation.

If the maximum dissipation is 0.5W and the resistance is 10k, then the maximum current that may flow through the entire resistance element is determined by ...

> **$P = I^2 * R$** ... therefore
> **$I = \sqrt{P / R}$** ... so I = 7mA

In fact, 7mA is the maximum current that can flow in any part of the resistance element, so if the 10k pot were set to a resistance of 1k, current is still 7mA, and maximum power is now only 50mW, and not the 500mW we had before.

Voltage - Two separate issues here. One is directly related (in part, at least) to the power rating, and is important to ensure that the life of the pot is not reduced. Knowing about the other might save ***your*** life.

Voltage across resistance element - The maximum voltage across the example pot from above is 7mA * 10k, or 70V. This will rarely (if ever) be achieved in an audio system, but is easy with many other designs. As the resistance increases, so does the voltage - a 0.5W 1M pot will pass only 700uA at maximum power rating, but the voltage needed to create this current is 700V. Unless the pot is actually rated to withstand 700V across the resistance element (rather unlikely), it will fail - maybe not today, or tomorrow, but it ***will*** fail eventually. Special pots are made (custom jobs, of course) for high voltages, and standard pots should never be used beyond their rating - assuming that you can find out what the rating is, of course.

Dielectric Voltage - The dielectric (insulation of pot "guts" to the body) rating is especially important if the pot is connected to mains operated, non-isolated equipment. Wall mounted lamp dimmers and such are typical examples. This is not commonly specified, but for safety, should be at least 2.5kV. A common way to achieve this is to use a plastic shaft, with the body of the pot insulated from the chassis, and inaccessible by the user (*even if the knob falls off or is removed!*) This point cannot be stressed highly enough.

Most standard pots will safely withstand (maybe) 100V or so between the resistance element and terminals, and the body and shaft. Miniature types will usually be less than this. Never, *ever*, use a standard pot with a metal shaft to control direct mains operated equipment.

Potentiometer Types

"But we already covered that, didn't we?" Not really - I merely glossed over the basics. Now, we shall look at a few examples of pots you may come across. Firstly, there is the resistive material and some typical characteristics ...

Material	Manufacturing Method	Common uses	Power (Typ)
Carbon	Deposited as a carbon composition ink on an insulating (usually a phenolic resin) body	Most common material, especially for cheap to average quality pots. Has a reasonable life, and noise level is quite acceptable in most cases. (DC should not be allowed to flow through any pot used for audio control)	0.1 to 0.5W
Cermet	Ceramic/metal composite, using a metallic resistance element on a ceramic substrate	High quality trimpots, and some conventional panel mount types (not very common). Low noise, and high stability. Relatively limited life (200 operations typical for trimpots)	0.25 to 2W (or more)
Conductive Plastic	Special impregnated plastic material with well controlled resistance characteristics	High quality (audiophile and professional) pots, both rotary and linear (slide). Excellent life, low noise and very good mechanical feel	0.25 to 0.5W

Wire wound	Insulating former, with resistance wire wound around it, and bound with adhesive to prevent movement	High power and almost indefinite life. Resistance is "granular", with discrete small steps rather than a completely smooth transition from one resistance winding to the next. Low noise, usually a rough mechanical feel.	5 to 50W (or more)

Bear in mind that the above list is a rough guide only, and is not intended to be be the "last word" on the different resistive types or their characteristics. In all cases, if you really want to know the full details about any one of those listed, get the manufacturers' data for the pot - it will be a lot more accurate (and specific) than the brief explanations above.

In addition to the resistive materials, there is also the physical type of pot. I am not going to describe the size and shape, but how the pot is configured mechanically and electrically.

Actuator	**Configuration**	**Type**	**Typical uses**
Rotary	Single gang	Single turn	Single channel controls for monoblock amplifiers, guitar amps, or anywhere that a single control is sufficient for the application.
Rotary	Single gang	Multi turn	Precision trimpots for critical applications. The resistance range is covered in anything from 10 to 25 turns of the screwdriver slotted actuator. There are some multi turn panel pots, but these are quite rare and expensive. Multi turn dual pots are also very uncommon.
Rotary	Dual gang	Single turn	Stereo applications, or anywhere it is desirable to change two separate resistances at once. Nearly all dual gang pots have equal resistances and tapers, but it may be possible to rebuild a dual gang pot using intestines removed from another pot of the same make and type (not needed very often though)
Rotary	Dual concentric	Single turn	Commonly used in (cheap) car radios and some consumer goods. These feature dual concentric shafts, allowing a single pot position to provide (for example) volume and "tone". The knobs are designed to fit the separate shafts (which are usually of different diameters). Almost impossible to buy from retail outlets or manufacturers in small quantities. (Usually to special order)

Linear	Single gang	Slide	Commonly used as "faders", unless they are of high quality, best just called slide pots. They are available in a variety of lengths, from 30mm to 100mm or more of linear travel. True faders will normally be relatively long, and generally are conductive plastic (and rather expensive :-(
Linear	Dual gang	Slide	As above, but for stereo mixers. Otherwise identical comments apply.

Again, this is a simplified listing. If you are willing to pay for 10,000 units, most pot makers will quite happily build you a triple gang pot with unequal resistances and different tapers, or an eight gang pot so you can build a variable stereo crossover network. In fact, almost any configuration is possible, but for various reasons may not be plausible or sensible.

Nearly all manufacturers and distributors have settled on a limited range of "standard" values and types, based on the most common uses for their products. That other configurations used to be available but were withdrawn due to lack of consistent sales is a lamentable fact, brought about by "economic rationalisation", which basically means that if they don't sell them in good quantities, they will be neither made nor stocked by anyone (unless you are happy to pay through the nose, of course).

Most problems of this type can be solved by throwing money at them until the problem disappears, but few of us can afford this approach - besides, I think the military establishments of the world have a patent on that method :-)

A standard single gang pot is shown in Figure 5. The important external bits are shown so you can refer to them as needed. I have (somewhat arbitrarily) numbered the terminals as 1, 2 and 3. Terminal 2 is the wiper. For a "standard" volume control application, 1 is normally connected to ground, the input is applied to 3, and the output taken from 2 (wiper) allowing the output to be varied from ground (no signal) to input (maximum signal).

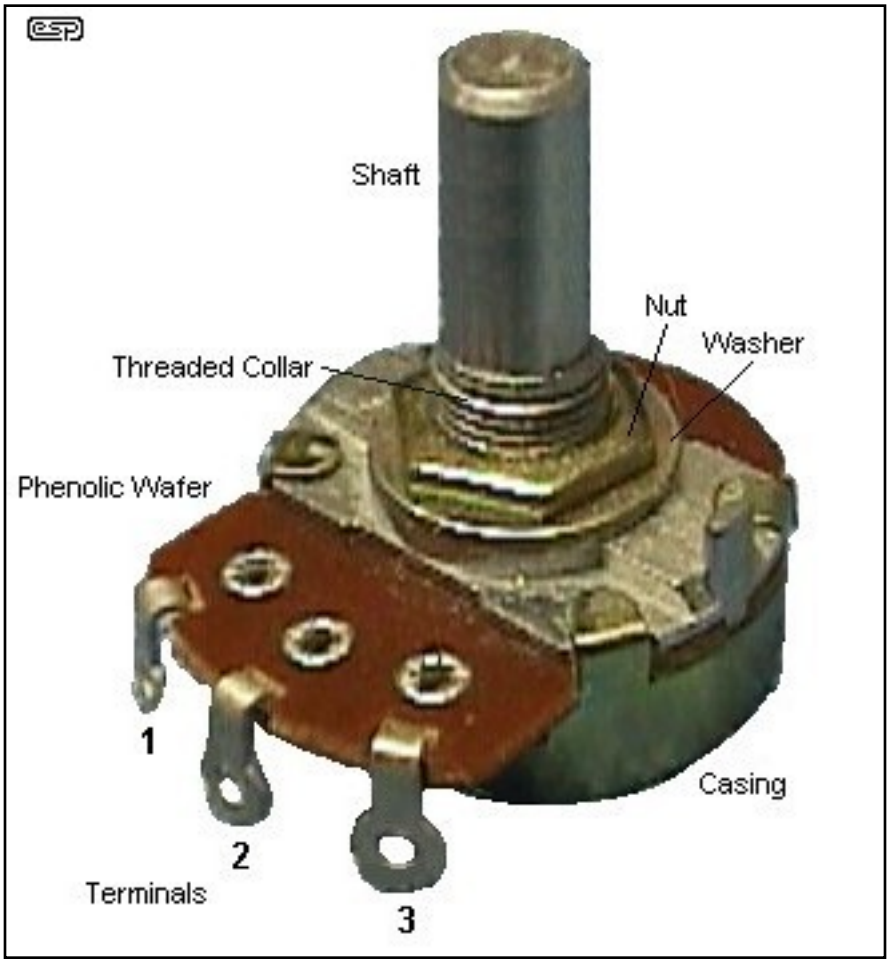

Figure 5 - Single Gang Pot Detail

In addition, there are a few odd-ball additions to the list. These include pots with integral switches (as used in small transistor radios - hint as to where to get one if you need it badly enough). The switches may be rotary, so in the minimum volume position, the switch is off, or they may use a push-pull switch. Older car radios often use a combination switch and dual concentric pot, so that power, volume and tone can all be controlled with one knob complex.

As before, the possibilities are almost endless, limited only by imagination and budget. There are few mechanical constraints that will prevent a special design from being feasible, although expecting accurate tracking on a 100 gang pot might be asking too much :-) Could it be made though? But of course - leave your large sack of money at the door, sir, and come on in.

Oh yes, I almost forgot. Motorised pots. Standard (or high quality) rotary or slide pots that are driven by small DC motors to allow remote control. Even a cheap pot will usually outperform an expensive "digital" volume control, with the added advantage that it can be operated by hand or with the remote. These are quite common, and even some of the (relatively cheap) Chinese made subwoofer "plate" amps use them for

remote control.

Ah! Another one ... Most pot "gangs" are 3 terminal types, but there are some with a tapping partway along the resistance element. This was used in the bad old days to create a "loudness" control, where the bass and treble are increased at low levels to compensate for the way our hearing reacts to different levels. Because there was rarely (if ever) any attempt to match the acoustic power levels, the loudness control was always wrong. To get it right requires source, preamp, power amp and speakers to have a known gain/ sensitivity, and ideally a preset control would have been incorporated to ensure the system could be calibrated. This was never done by the vast majority of manufacturers - Yamaha appears to be the *only* maker who even made an attempt (I don't know how good it was, never having seen a system that used it).

Putting Your Pot to Use

Well, that part is simple, isn't it? Judging from the number of e-mails I get asking about how to wire pots, the answer is obviously "no". Being 3 terminal devices (for a single gang), there are quite a few different ways that they can be wired. Connection to a single terminal is rather pointless, so at least that eliminates three "possibilities". At this point, a diagram is needed ...

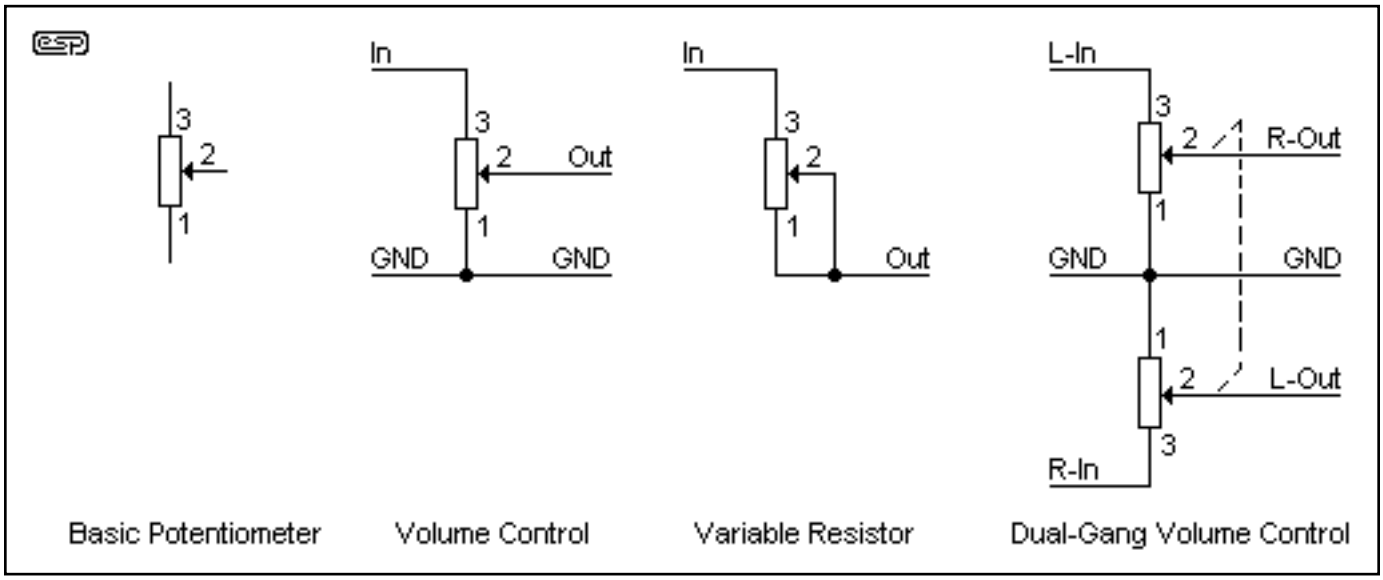

Figure 6 - Potentiometer Terminals and Connections

As shown in Figure 6, a pot is usually wired using all three terminals, and I have used the same numbering scheme as in Figure 5. One terminal (1) is earthed (grounded) for use as a volume control - the most common usage. This allows the wiper to be turned all the way to zero signal for maximum attenuation. Note that if the earth terminal were

to be left disconnected, all we have is a variable series resistance, whose effectiveness will be minimal in typical circuitry. This is still a common usage however, but for different reasons (see below).

Turning the shaft clockwise (CW - by convention, to move pin 2 physically closer to pin 3, and increase (for example) volume) will select a different point along the resistance element, and forms a voltage divider, so the attenuation of the signal is proportional to the rotation of the shaft. At the fully clockwise position, there is close to zero ohms in series with the signal, and the full resistance of the pot to earth. Attenuation at this setting is zero (assuming a zero or low impedance source - this is often overlooked!), and this is full volume (maximum signal level).

The source impedance should normally be no greater than 1/10th (0.1) of the pot's stated resistance. Further, the load resistance or impedance should be 10 times the pot's resistance to prevent the taper from being adversely affected. You may (of course) be deliberately loading the pot as described below, but the following stage must still present a high impedance unless its impedance has been included in your calculations.

The second form of connection is a variable resistor. Not usable as a volume control, but still extensively used for other applications. It is common (and preferable) to join two of the leads together - the wiper, and one end or the other. The actual connection depends on what you are trying to achieve, and since there are so many possibilities, I won't even try to explain them all. When used in this mode it is most commonly refererred to as a variable resistance or resistor - the word rheostat is somewhat dated (to put it mildly) and is not a term that I use in any of my articles.

To get an idea of the different configurations that are in common use, have a look at the ESP Projects pages, and those on other web sites. The number of possibilities is actually not that great, but people use different conventions as well. For example, in Australia, we use the term "anti-clockwise" or ACW. In the US, this is "counter-clockwise" or CCW. At least the term clockwise seems to be common to both countries :-) Naturally enough, these are only two conventions, and I am unsure of the terminology in other countries - especially if they don't use English (and why would they, if they already have a language of their own).

As a completely irrelevant side issue, the Web is changing this quite quickly, as the majority of web sites are in English.

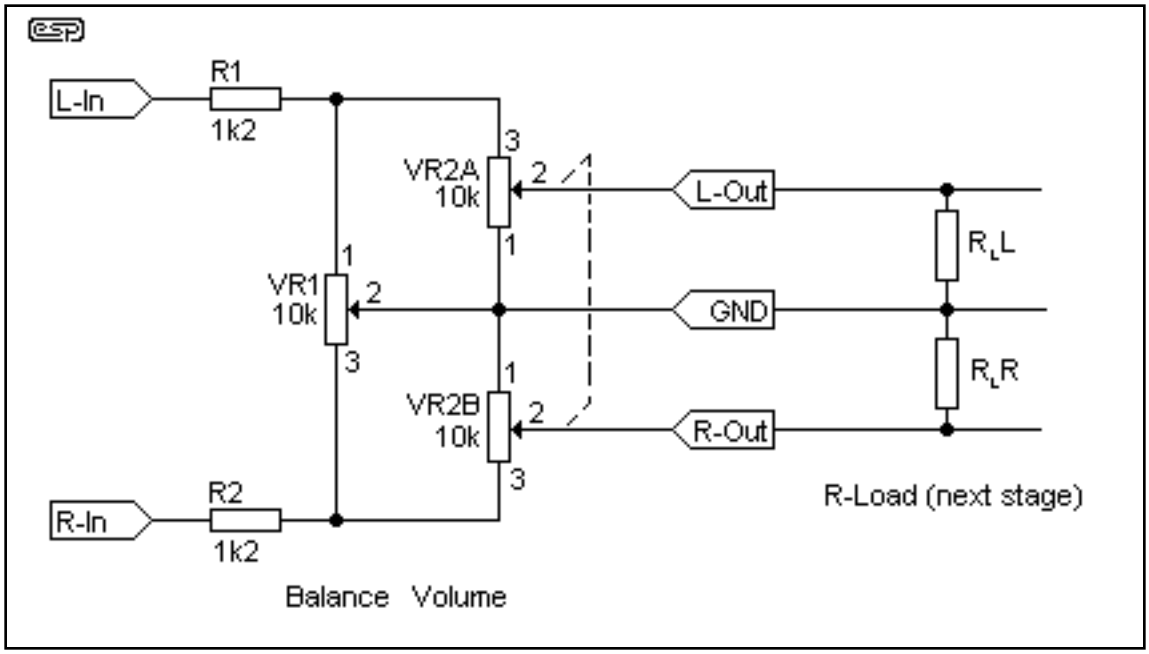

Figure 7 - Volume and Balance Controls

Figure 7 assumes the use of a log pot for volume. The balance control can be done in many different ways, with that shown being but one. Quite a lot of Japanese equipment uses a dual gang pot for balance, but the resistance element only goes for half the travel. When set in the centre position, there is no loss at all, and rotation in either direction attenuates the appropriate channel, but leaves the other unaffected. This is yet another type of custom pot, made for a specific purpose. I know of no manufacturer that sells such an item through the normal distribution channels, so home builders have to come up with different ways to achieve the same (or similar) things. The balance control as shown above (with the values shown) will give a response very similar to the more complex version described in the next section.

Changing the Law of a Pot

Using pots can be done in the conventional way, or you can get adventurous and achieve a lot more. A good example is the "Better Volume Control" shown in Project 01. The other ideas presented also show how you can make modifications to the way a pot behaves, just by adding a resistor (R). The "ideal" value by calculation is 22k for a 100k pot, and this gives a maximum deviation of +1.58 and -1.7dB from a real log curve. This is contrast to the original article, where 15k was suggested, and although the error is greater (+2.89dB and -1.12dB), the overall behaviour is almost ideal in listening tests.

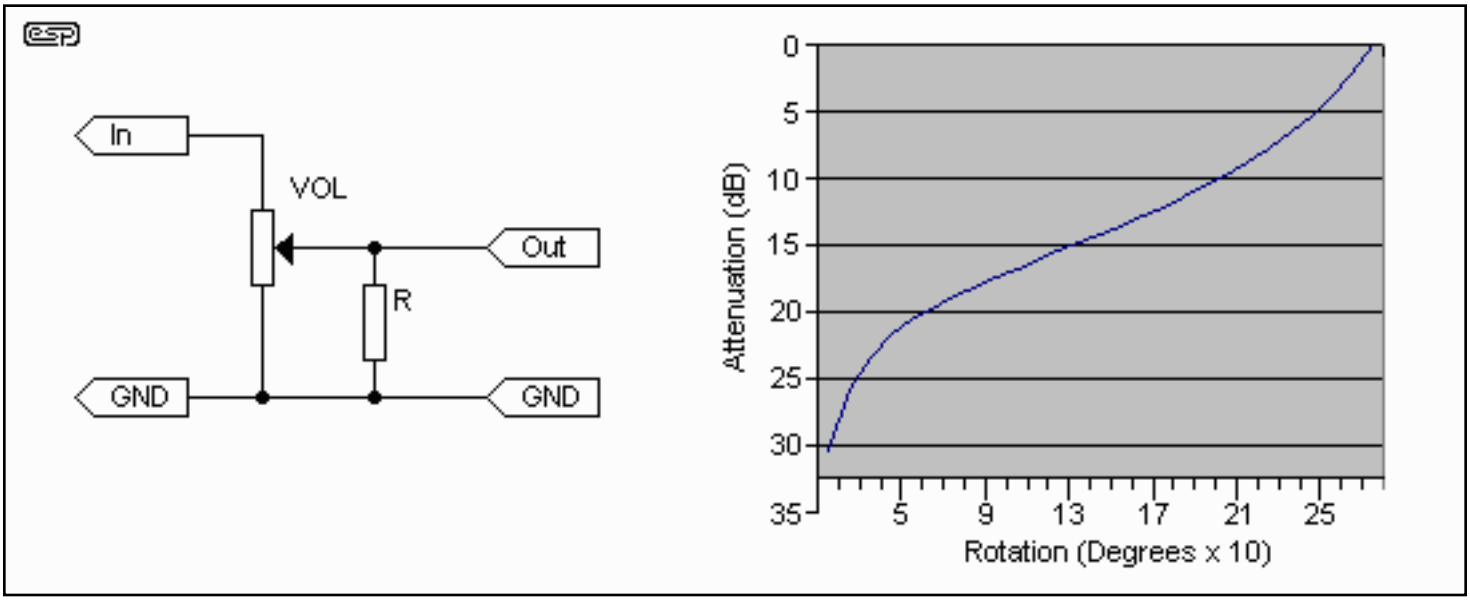

Figure 8 - A Better Volume Control

Take a look at the balance control (below) as an example. The conventional balance control requires either a log/antilog pot (virtually impossible to obtain), or one of the special types commonly used in Japanese consumer hi-fi gear. About the only way you'll get one of those is to remove it from the equipment - again, they are virtually impossible to get from normal hobbyist suppliers.

Add a couple of resistors to a dual gang linear pot, and the problem is solved. Not only is the pot heavily "centre weighted", but will also maintain a relatively constant sound level as the balance is changed from full Left to full Right. The centre weighting means that for most of the pot's travel, the balance is shifted subtly, so it provides a very fine resolution around the central position - there is little requirement for only one channel (other than testing), but that is still available. In short, lots of benefits, and few drawbacks.

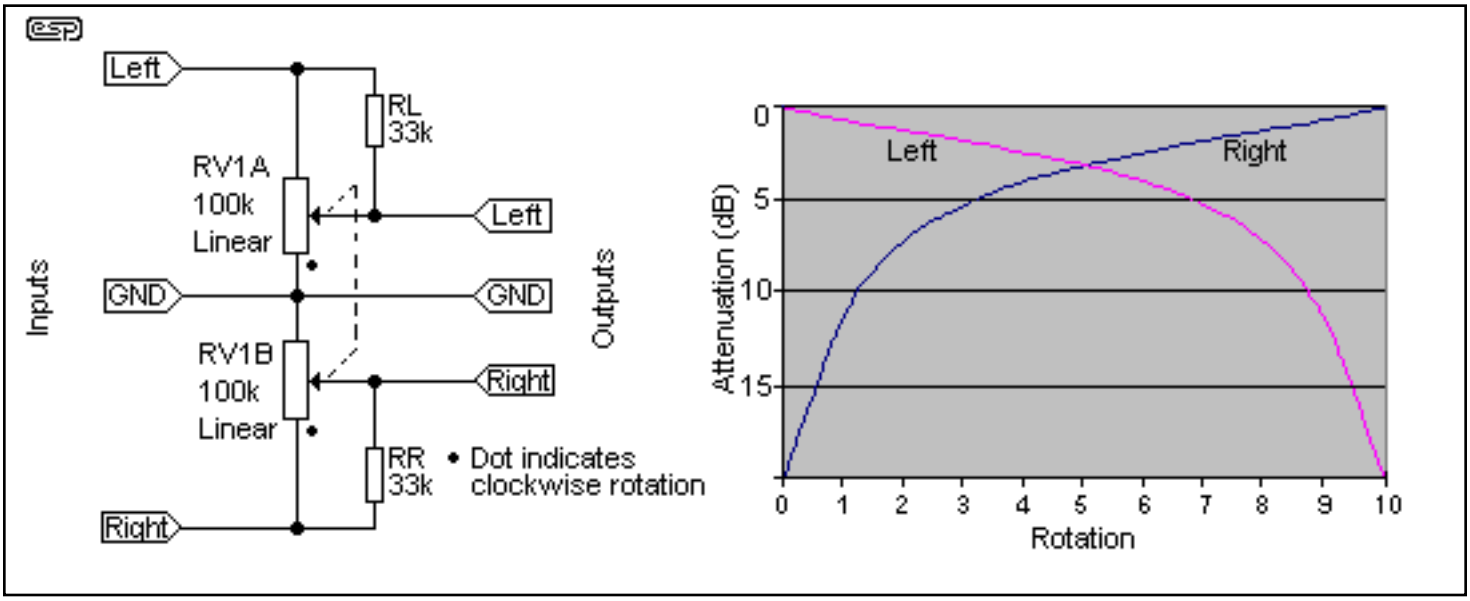

Figure 9- Centre Weighted Balance Control

Needless to say there are many other configurations that can be used, and this is but one. The resistor value (RL and RR) is fairly important - it really should be 35k for a 100k pot, but the error when using 33k is minimal (about 0.16 dB at centre position).

One of the goals of circuit design is to utilise available components. This is not necessary if you make 10,000 of something, since at these quantities special orders will cost little or no more than the normally available components. When you are making one for yourself (or perhaps two - one for a friend for example), specially designed components are not an option due to the setup costs (this could easily be thousands of dollars / euro / pounds). Even in quantities of several hundred, available components are still (usually) cheaper.

The balance control above is an example of a dual log / reverse log pot, created with a standard dual gang pot and a couple of resistors ... and it works better than a commercial offering is likely to - even if you managed to find one.

For more information on this configuration, see Project 01. Note that as shown, the balance control here is not optimised for any significant impedance at the output, so its performance will change if you connect a volume control to the output.

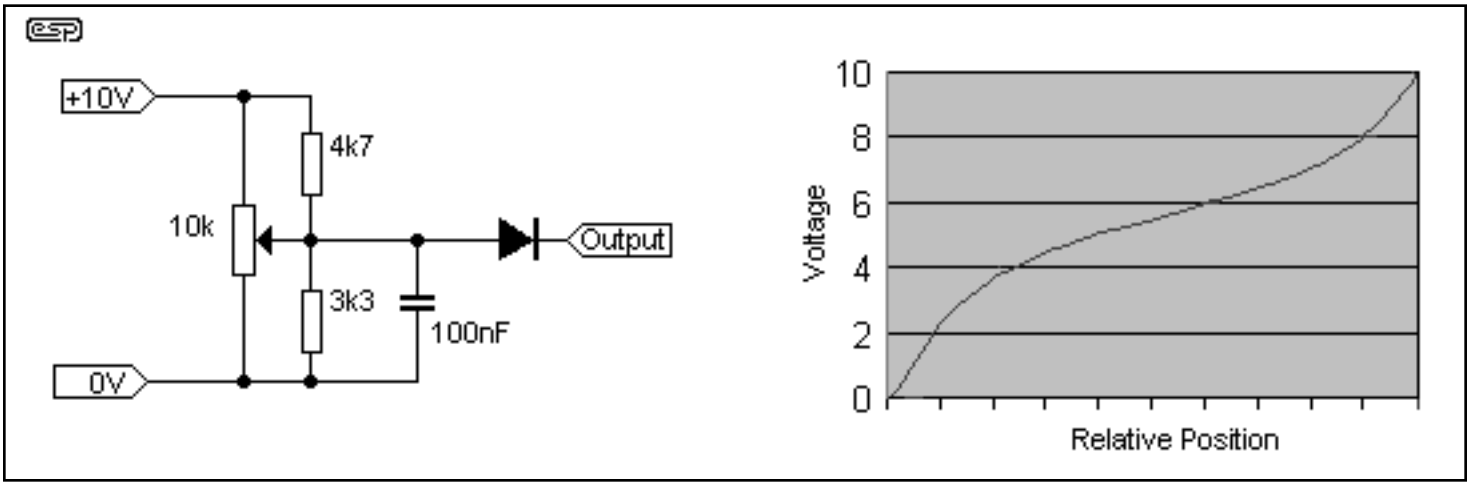

Figure 10 - Creating an "S" Curve for Lighting

Another example of modifying a pot to make it do what you want is shown in the LX-800 Lighting Controller. The faders need an "S" curve, to compensate for the non-linear behaviour of lamps and our eye's sensitivity to light levels. This is also achieved with a couple of resistors across a normal linear pot.

If you don't like the shape (because of the lamps you use, for example), you can simply change the resistor values and modify the curve to suit your exact needs. Since even ordinary log pots are not actually logarithmic anyway, can you imagine getting a pot that would give you an S-Curve? Even worse, if you found that it was not suited to certain lamps, then you would be hard pressed to modify the law to get what you needed. In some cases it would be impossible.

Elliott Sound Products **Amplifier Power Ratings**

Page Last Updated 25 April 2005

Main Index

Articles Index

This article was originally fairly superficial and frivolous, but has been expanded (a little) to explain the matter better. Amplifier power ratings are usually honest in Hi-Fi equipment, but become very silly when it comes to the 'mass market' systems.

'Exceedingly silly' happens when you look at computer speakers and 'boom boxes' - most of which boast power ratings that (if true) would do a fine job of amplification for a large hall or small stadium. This is quite obviously not the case, as anyone who has used them is aware - well below the point of mild discomfort, it is obvious that distortion is abundant, and the sound (almost literally) falls to pieces. Perhaps on this basis, they should be referred to as power *rantings*

I have a set of computer speakers that are rated at 480W PMPO (yes - four hundred and eighty Watts). I have measured them at less than 5W each before clipping. There is no rhyme or reason that can explain such a difference, except ....

Power Ratings In The New Millennium (and Beyond)

Much has been said - and will no doubt continue to be said - about amplifier power ratings. There has been a disturbing tendency over the last few years to revisit the bad old days where terms such as PMP (Peak Music Power) and PMPO (Peak Music Power Output) have once again raised their ugly heads.

Admittedly, these 'new' power rating are not used by hi-fi manufacturers, other than in

the low-end equipment. These new terms are soundly (no pun intended) based on the science of *marketing*, having nothing to do with actual science or physics. PMPO is mathematically expressed as

$$PMPO = P_{REAL} * k$$

where $\mathbf{P_{REAL}}$ is the real power as calculated by the formula below, and **k** is a constant whose value is approximately equal to one's grandmother's age, divided by the square root of the distance from the office to the advertisement writer's normal place of abode - measured in millimetres, inches, furlongs, statute miles or pounds per square inch (as appropriate) to provide the number you first thought of.

In the unlikely event that the value of **k** cannot be calculated from the above formulae to provide a totally meaningless (but plausible-looking) final result, a randomly selected value of between 20 and 75 should be used.

An alternative (and equally useless) way to measure PMPO is to multiply the supply voltage by the instantaneous short-circuit current from the amplifier - the amplifier does not have to survive this test, and the current only has to exist for around 1us to obtain a satisfactory rating ...

$$PMPO = V_{supply} * I_{peak}$$

where $\mathbf{V_{supply}}$ is the total supply voltage and $\mathbf{I_{peak}}$ is the instantaneous (and possibly destructive) short-circuit current. Given that a 12V plugpack (wall wart) supply may be capable of perhaps 30A for a microsecond or two, this is perfectly acceptable, and gives a PMPO of ...

$$PMPO = 12 * 30 = 360W$$

This is a perfectly acceptable figure, and may be used with gay abandon (in the hope that someone will actually believe it).

Thus (using the first equation) we can now compute the power of an amplifier which manages to impress a voltage (which need not be sinusoidal - an harmonic distortion of up to 400% is considered perfectly acceptable - albeit mathematically impossible) of 8V across a speaker of 8 ohms. Actual (real) power may be calculated by

$P_{real} = V_{RMS} * I_{RMS}$

Since 8V across an 8 ohm load provides 1 Ampere of current, we obtain

$P_{real} = 8 * 1 = 8$ Watts

or, using the power formula

$P_{real} = V^2 / R$ (Voltage squared, divided by impedance in ohms)

thus

$P_{real} = 8^2 / 8 = 64 / 8 = 8$ Watts

PMPO may now readily be calculated, using a median value of 45 which results in a totally satisfactory advertising power (P_a) of

$P_a = 8 * 45 = 360$W PMPO

You will notice that by fiddling with the figures to suit my goal, I have been able to make the PMPO figure the same, using two completely different 'test methods' and 'formulae'. Therefore, the figures *must* be correct, and the result must therefore be genuine .

What ? You think I'm *lying* ? Well spotted gentle reader - the whole process is unadulterated horse-feathers.

It goes without saying that using the complete formula, the final P_a rating could be anything from 500uW (totally unacceptable from a marketing perspective) to several Mega-Watts. Although figures in this latter range have considerable merit, it is probable that even the most gullible of Boom-Box or computer speaker buyers will be a little suspicious, especially when the plug-pack power supply offered (as an option) announces that it provides a mere 1A at 12V (or 12 Watts DC power output - as much as 7 (legitimate) Watts of audio may be obtained from such a supply).

True, this figure will not be comprehensible *per se*, but suspicions may be aroused when a friend's genuine 20W system completely drowns them out with sound. A 160 Watt rated unit's apparent lack of power by comparison is easily explained by the fact that

"This tape/CD/FM radio station was recorded at really low level" or some similar self-delusion.

This is a little more difficult to shrug off nonchalantly if one's Ghetto-Blaster were to be rated at 1.6MW for example. Even those who pay more for their sneakers than others might spend on a tailored suit (I think i may have had one of those ... once), or a real Hi-Fi system, will be forced to wonder why their unit was not supplied with a small nuclear power station to achieve such power.

It is worth noting that it is possible to merely think of a 'good' (i.e. impressive looking) number, call it Watts (PMPO), and use that instead of the potentially tedious mathematical approaches above. This method is just as invalid as the more technical methods described, but is not as much fun.

Warning

There are sites on the net where the author(s) seems to think that there is some logic (however perverse) in the PMPO rating. For example it has been claimed that PMPO is calculated as the maximum instantaneous power an amplifier can deliver, albeit under unrealistic conditions. Such claims are as false and misleading as PMPO - there is *absolutely zero* logic or science involved in making up a PMPO figure, as demonstrated by the following simple exercise.

Let's assume that an amplifier has a supply voltage of 14.8V DC. A little under 15V (unloaded) is not uncommon for so-called 12V plug-pack supplies. For the sake of the exercise, we shall further assume that the manufacturer used a 3,300uF filter cap (this is probably unrealistically high, but will do for the time being). The energy storage of the cap is measured in Joules (Watt/seconds). One Joule is 1W delivered for 1 second. For our 3,300uF cap, charged to 14.8V, we get ...

$$E = \tfrac{1}{2}C * V^2 = \tfrac{1}{2}3{,}300^{E-6} * 14.8^2 = \tfrac{1}{2} = 0.361 \text{ Joule (0.36W/s)}$$

This number is obviously of no use as is, but if we assume that the cap is discharged in 1ms, that gives an instantaneous figure of 360W PMPO, which is much more satisfactory. Goodness me, I seem to have used yet another (almost completely) bogus formula to arrive at the number I first thought of .

Note: The formula for energy in Joules is correct, as is the conversion from seconds to milliseconds. The bogus part is the simple fiddling with numbers to arrive at the answer I wanted.

It pretty much goes without saying that I can think of several other equally meaningless equations that will also give the figure of 360W, but there is absolutely no point in doing so. Just remember that if you see PMPO 'power' listed for an amplifier, the figure is false, and has no meaning at all. Before purchase, try to locate something on the package or in the instruction page that specifies the power in RMS or DIN. Failing that, obtain written assurance from the sales person that the claimed power is real, test it when you get home, then return the product next day. Explain that you were assured that the amplifier was indeed 1kW, but you were unable to obtain more than 5W from it - therefore, the product must be faulty.

Advertising, 1970's Style

In the above mentioned bad old days, there was still a modicum of perverse logic used to calculate 'Power'. Advertisers (after consulting - sorry, interfacing - with someone who could count to more than 10 with their shoes (or trousers) still on), would use the peak value of the RMS voltage (Volts * 1.414), or the more adventurous could even use peak-to-peak (double the peak value).

Using the same value of voltage and impedance as above (namely 8V RMS, 8Ω load), one can calculate the P_{A70} (Advertising Power, as used in the 1970's) to a high degree of uselessness, thus

$$P_{A70}(\text{Peak Music Power}) = (8 * 1.414)^2 / 8\ \text{Ohms} = 16\text{W}$$

Or ...

$$P_{A70}(\text{P-P Music Power}) = 16 * 1.414)^2 / 8\ \text{Ohms} = 64\text{W}$$

Technology has certainly come a long way since then, as is now apparent.

But Seriously, Folks

If, from the above, you have deduced that I am less than favourably impressed by such deceptions, you are correct. Indeed, the term "RMS" power is just as grating to an engineer, since there is no such thing.

'RMS' Power

Power is simply the product of RMS Volts and RMS Amps, and the resulting figure is 'power'. Not 'RMS Power' - or any of the insane derivatives described above - just 'power'.

The term RMS (Root Mean Squared) can only be applied to voltage or current. The RMS value is determined to be the Alternating Current (AC) equivalent of a Direct Current (DC) which creates the same amount of heat in a load.

For a sine wave, this is the peak value, divided by the square root of 2 - i.e. 1.414 (I shall not bore you with the exact reason for this, but it is a scientifically and mathematically accepted fact).

For a perfect square wave, it is the peak value alone, since if the positive and negative peaks were to be rectified (so as to be the same polarity), the result is DC. This condition (or at least close to it) is quite common with guitar amps (the distortion is part of the sound), but should never occur in Hi-Fi, even briefly.

Power should only ever be measured with no clipping. When an amp clips, there is more available power, but higher distortion. It is not uncommon to see amplifier powers rated at 10% distortion. This is quite unacceptable, as this indicates that there is severe clipping of the signal. A good quality amplifier will have less than 0.1% distortion just before clipping, somewhat higher for push-pull valve amps, and a lot higher for single ended triode valves.

When I refer to power in any of my articles, common usage shall prevail, and I (like many others in audio) will reluctantly accept the term RMS Power to mean power. All amplifier power ratings in the project pages (and elsewhere) are 'RMS' unless otherwise stated.

Music Power

The music power of an amp is real, and is generally higher than the continuous power. It is measured by using a tone-burst generator, and is the peak power than an amp can supply for (typically) about 10ms. This is quite reasonable, but not terribly useful when it is examined carefully. Since music is very dynamic, with the peak amplitude exceeding the average by 10 to 20dB (depending on the type of music), an amplifier is never called upon to provide full power all the time (at least if clipping is avoided, which should be all the time).

If the power supply is regulated or has considerable excess power capacity, the continuous and music power ratings will be almost identical. The difference was (at one

time) measured, and was called 'dynamic headroom'. Few amps have a dynamic headroom of better than 1 or 2dB, and the greater the headroom, usually the cheaper the power supply for the rated power.

An amplifier with a much greater music power than its 'RMS' power usually has a transformer and/or filter capacitor that is too small. In most cases, a 90W (RMS) / 100W (music power) amp will not sound louder than a 90W amp with a regulated supply (so RMS and music power are the same). The extra 10W represents a little under 0.5dB, which is barely audible in a comparative listening test.

C# - And on that note ....

1.0 Introduction

This article does not attempt to cover general household or commercial wiring practices - only the internal wiring needed for electrical safety and making your power supply work are covered. For detailed information on wiring practices, you must contact your local supply authority/ company, or obtain a copy of the wiring rules for your country or locality. I am unable to assist with this, as it is highly country specific, and in many countries is also heavily regulated and/or legislated.

Warning: Household electrical current is extremely dangerous, and it may be illegal for you to perform your own wiring, even for equipment that connects via a standard wall outlet. If you are unsure of the procedures, terminology or anything else that may cause a potentially fatal error due to oversight or lack of knowledge, you must seek assistance from a qualified electrician. Remember that if someone is killed or injured as a result of your work, you may be held liable and subject to severe criminal and financial penalties.

2.0 How to Wire a Power Supply

I have been asked many times about PCBs for power supplies for amplifiers. I do not recommend using a printed board for a number of reasons, and these are as follows ...

1. Limited range of capacitor values: When the constraints of a PCB are imposed, the capacitors you choose must be the same physical size as those the board can accommodate. This restriction is so great (IMO) that this precludes the use of a board for almost any DIY power amplifier project.

2. Electrical Characteristics: The normal copper thickness on a printed board is not really sufficient to ensure that there is minimal resistance, so there is a greater likelihood of hum (or buzz) and efficiency may be marginally reduced. In contrast, hard wiring can be as thick as the constructor likes (although it is still necessary to be able to solder to it and the capacitor terminals).

3. Physical layout: A printed board limits the flexibility to mount capacitors in the most convenient place. This is probably one of the most compelling reasons to use hard wiring, since multiple capacitors may be best arranged in a row or a block, depending on the internal construction of the chassis mounted components (e.g. transformer, heatsinks, PCBs, etc.).

4. Other components: A PCB is less than ideal (to put it mildly) for mounting a bridge rectifier, and doubly so if a 35A chassis mount bridge is used. These need to be on a metal panel to obtain heatsinking, and it is very hard to achieve this when a PCB is used.

2.1 Electrical Connections

So, what is the constructor to do? Hard wire the power supply is what. A basic configuration may look like that shown in Figure 1 - this is the schematic for a general purpose supply, suitable for a high end hi-fi power amplifier.

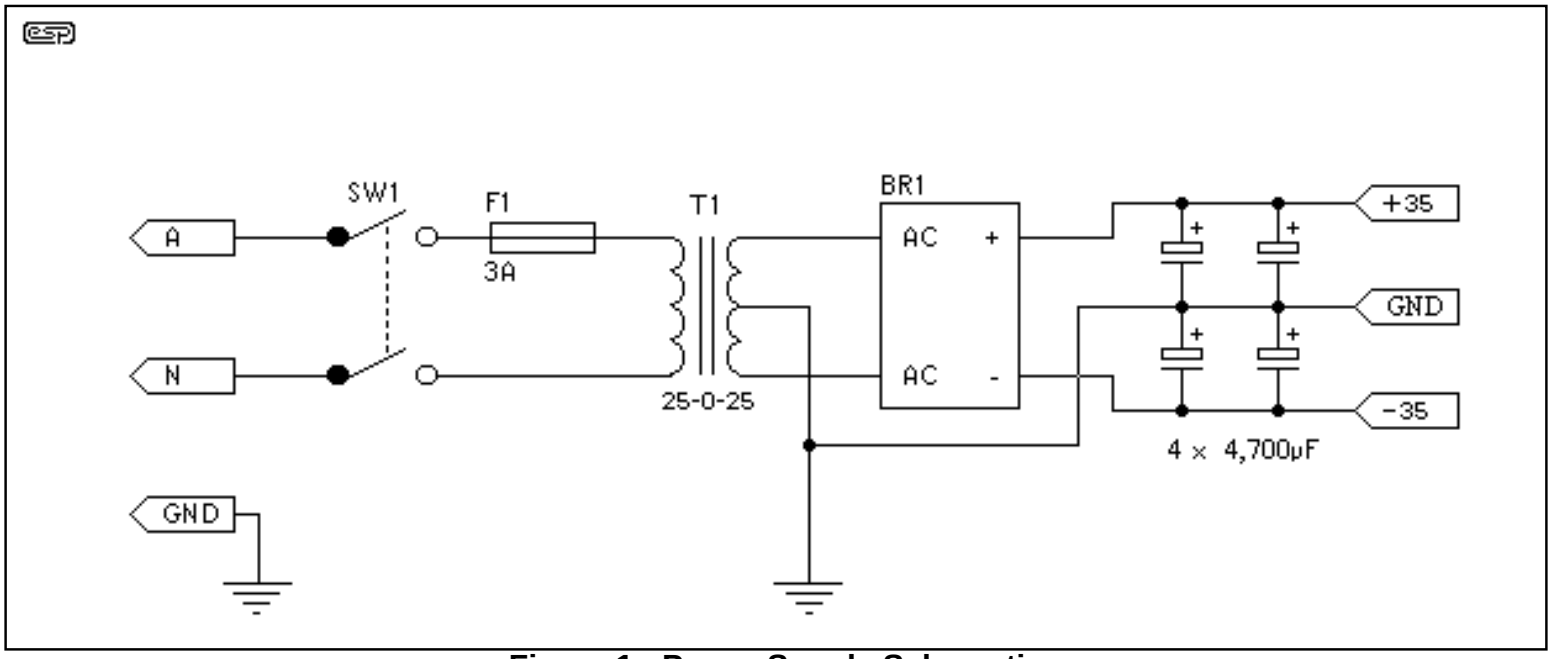

Figure 1 - Power Supply Schematic

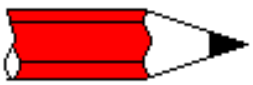
This is all well and good, but these are the electrical connections, and have no direct relationship to the physical connections needed. For the purposes of the exercise, we shall assume an IEC mains connector, chassis mounted mains fuse, and a power switch mounted on the front panel.

The diagram in Figure 2 shows one possible physical arrangement of the supply components. If you need to re-arrange the locations, it is a relatively simple matter to move things where you need them, while maintaining the required electrical connections. Some construction articles (and especially kits) will try to enforce a specific layout, but this will not always suit the constructor - especially if s/he happens to have a whole box of 2,200uF capacitors at their disposal (wishful thinking for most :-) where the bill of materials calls for 10,000uF.



It is extremely important that the DC is taken from the capacitors, and *not* the bridge rectifier. If DC is taken from the bridge, it will be noisy, and this can easily get into the amplifier, degrading the signal to noise ratio - particularly under load! The noise may not be heard directly, but will add unwanted signals to the music which may sound "hazy" or "clouded" as a result.

2.2 Physical Connections

The "stylised" drawing below shows how the various components should be connected together. From this, it is possible to extend the basic idea very easily. The diagram assumes that the constructor will use 4 filter caps in a series-parallel arrangement (2 for each supply rail), a 35A chassis mount bridge rectifier, and a toroidal transformer. The colour coded transformer leads are for indentification - they are ***not*** intended to be taken literally. Refer to the manufacturer's specifications to make sure that you get the correct colours! IEC (European)

mains colour coding has been used, and this is now almost a world standard, so should be painless for all. The older standards are also provided below.

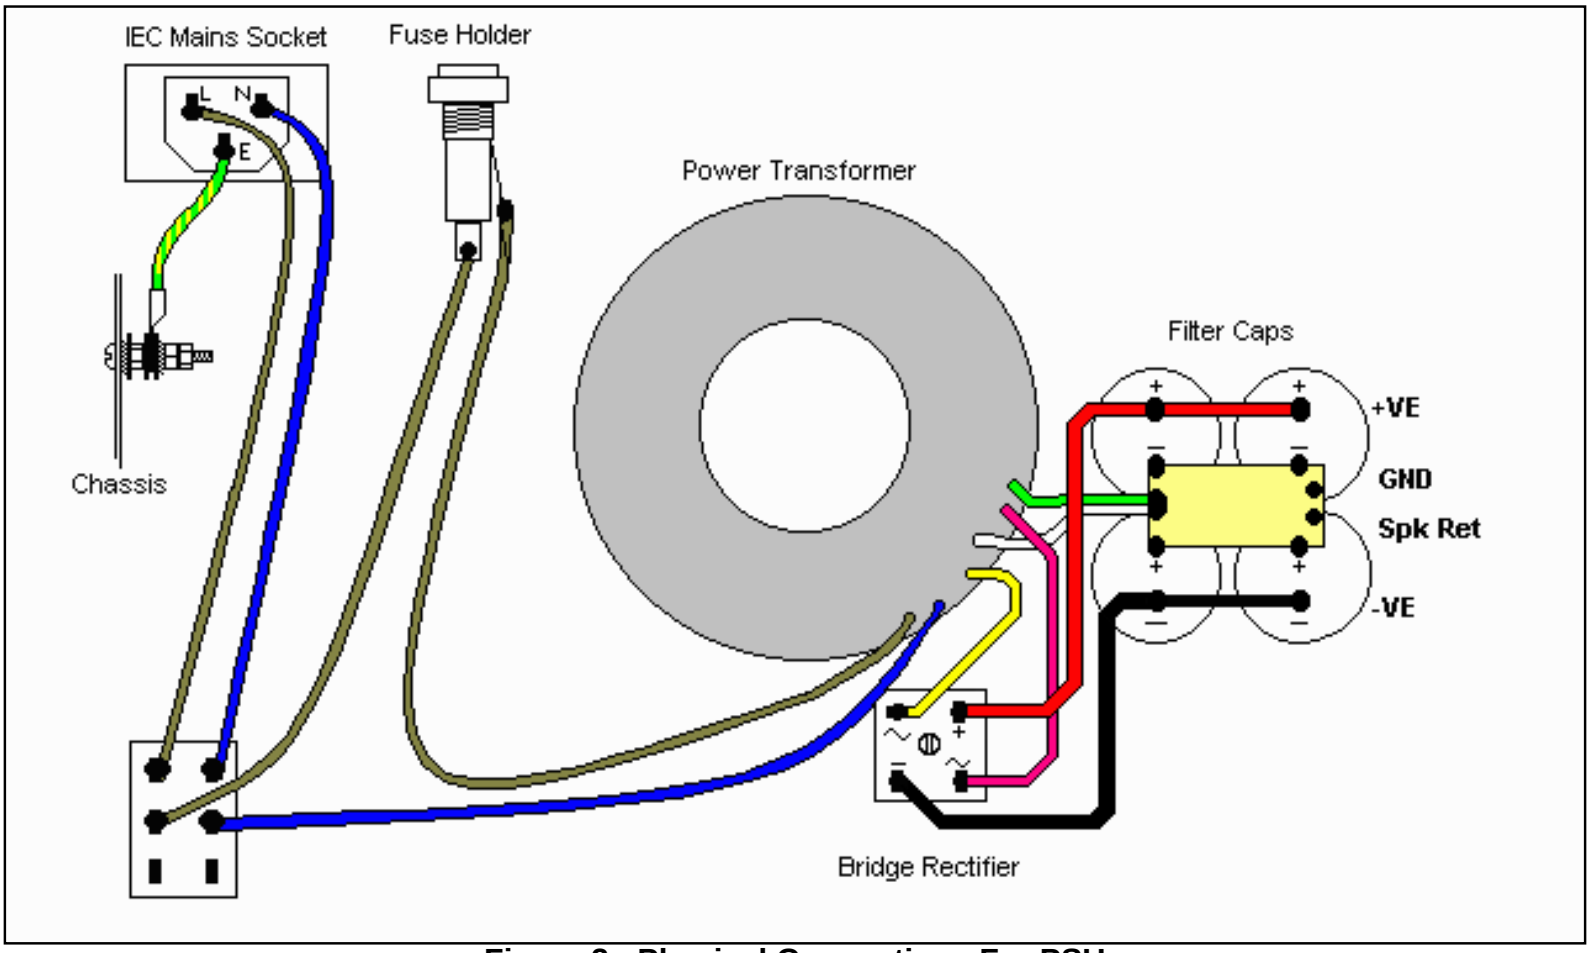


Figure 2 - Physical Connections For PSU

Note that I have not shown the required sleeving over all mains connections. This is essential for electrical safety, and usually just means the the required heatshrink tubing is placed over the wire(s) before attaching and soldering. Make sure that soldering does not heat the tubing, or it will shrink before it is properly located. To this end, make sure that the tubing can be located at least 25mm (1") and preferably more, back from the solder connection.

Rubber boots are available for IEC chassis mount connectors, and large heatshrink can be used to completely encase the fuseholder. Don't forget to feed the wires through the heatshrink or rubber boot before soldering!

As well as proper safeguards against accidental contact with the mains, it is also extremely important to keep mains and low voltage wiring well separated. This means either physical separation, or reinforced insulation between the two sets of wiring. If physical separation is used (and this is the most common and easily achieved), make sure that wherever possible, the minimum distance is 25mm. It should not be possible to squeeze or otherwise coerce the primary (mains) and secondary (low voltage) together under any circumstances. All wiring must be secured using cable ties, and suitable chassis anchors may be needed in some cases to

ensure that all wiring remains properly separated.

With most toroidals, all leads come out of the over-wrapping in (more or less) the same general area. Normally the insulation provided is sufficient to ensure safety, but some additional heatshrink tubing will not go astray if the leads are close together.

3.0 Additional Components

The diagrams above show only the basic parts needed. Other components are used routinely for lower noise, capacitor discharge, etc. A diagram of these extras is not needed, but a brief discussion of them is certainly warranted.

Low Value Capacitors

It is very common to use 100nF or so polyester, mylar or polypropylene capacitors in parallel with the filter capacitors. The use of these ensures that the impedance of the power supply remains low at all frequencies up to several megaHertz. While it will cause no problems to use these components at the power supply itself, most amplifier PCBs will have provision for them on the board. This also ensures that lead inductance between the supply and the amplifier is dealt with. Many power amplifiers also have on-board electrolytic caps - effectively in parallel with the main filter caps.

In addition, capacitors (typically 100nF) are often used across the bridge rectifier, effectively in parallel with each diode. These may help reduce noise, but normally, a properly designed and constructed supply will not require them. However, they do no harm, and may be used if you so desire. Note that if used with a choke input filter, fast diodes must be used - standard speed diodes will overheat. Choke input filters are very uncommon with semiconductor amplifiers, but are seen occasionally with valve amplifiers.

Capacitors may also be used in parallel with the secondary windings, again to reduce noise. Use of caps across the mains is covered below, and great care must be used if you decide to do this. Some common practices are extremely dangerous - especially with 220V or greater mains voltages.

It is very common with valve amplifiers to use a "bleeder" or discharge resistor across the power supply. Although not strictly necessary with low voltage solid state equipment, they don't cause any harm (apart from a small amount of heat). A typical value for supply voltages of +/-30V to +/-60V would be 1k 5W - just make sure they are not mounted too close to the filter capacitors (the heat may reduce the capacitor life).

4.0 Mains Connections

Before discussing the mains, there are several standards of colour coding and nomenclature that need to be covered first. If unsure of any detail, you should seek assistance from a suitably qualified electrical trades person - in some countries it may be illegal to perform any mains wiring unless you are qualified and/or licensed. Make sure that you understand the specific regulations that apply to you - this document is a guideline only, and it is not possible to account for the regulations of all countries.

	Colours			
IEC	**US**	**Old ***	**Lead**	**Also Called**
Brown	Black	Red	Active	Line, Hot
Blue	White	Black	Neutral	Return, Cold, Grounded conductor
Gr/Ye **	Green	Green	Earth	Ground, Safety Earth, Earth Ground, Grounding conductor ***

Table 1 - Wiring Colour Codes

* The "Old" standard was used in various countries (including Australia), and some wiring may still use these colours.

** Gr/Ye - Green with Yellow stripe - this is the standard world wide, although it is not common in the US or Canada at present.

*** There is an important distinction between "Grounding conductor" (safety earth) and "Grounded conductor" (Neutral). These are *US* terms for the conductors and they are ***not*** interchangable, despite the similarity of the names ***!***

The incoming household mains may be connected using a fixed lead, but it is far more convenient to use a connector. The European style IEC connector has world-wide approval, and is recommended. Ready made moulded connector style power leads are available from retail outlets, and are safe and durable. Other lead types may also be available in your area. Be careful that the lead you use is legal in your country - for example, many "specialist" or "high end" leads will be illegal in a great many countries outside the USA - note that this is not one of my attacks on such items, but is a simple fact of electrical safety. Indeed, unless they have UL or CSA approval, you may be at risk in the US and Canada as well, especially if there is an insurance claim in the balance.

If a fixed lead is used, it must be securely clamped at the entry point, and must also be insulated from the chassis with a rubber or plastic grommet. This prevents the lead from damage by metal edges of the entry hole. Cord clamping grommets are available, but be aware that the hole size is critical to the ability of the grommet to clamp the cable securely without damage, and ensure that the lead (replete with grommet) cannot be pulled out.

It is recommended (or required in some areas) that the earth (ground) wire of any fixed mains lead should be longer than the other leads inside the casing to ensure that it is the last to break should the lead clamp fail. This provides some degree of additional safety, but is not infallible.

Use of an approved mains connector is by far the safest and most flexible option.

5.0 Fuse Holder

The mains fuse holder should (must) be a safety type, again depending upon where you live. The safest is an IEC mains connector with integral fuse holder, as it is impossible to access the fuse while the lead is inserted. Where a separate chassis fuse holder is used, it should be connected so that it is not possible to contact the fuse until it is completely clear of internal connections. Most new fuse holders will be designed to meet this requirement, but many older ones will not.

Older style fuse holders allowed physical (finger) contact with a partially withdrawn fuse, which could easily contact an internal conducting part of the holder. The potential for serious injury is quite obvious if power is applied to the unit and the fuse is intact!

6.0 Mains Switch

The ideal mains switch is a double pole switch, to ensure that both active and neutral leads are disconnected when the power is off. This guards against internal components remaining live due to accidental reversal of the mains leads, either because 2 prong mains plugs are used (not recommended), or because of incorrectly wired power outlets or extension leads, for example. These are unfortunately quite common where inexperienced persons have wired the lead, and have not followed the correct colour code.

7.0 Earth Connection

The mains safety earth must be connected to a separate bolt, whose sole purpose is to provide a solid earth connection to the equipment chassis. Where there are separate removable panels, it may also be a requirement where you live that these have a wired connection to the main chassis. This prevents any possibility of the removable panel from becoming "live" should an electrical fault cause the mains to be in contact with the panel - regardless of whether the securing screws are installed or not.

8.0 Mains Capacitors

It is common for many amplifiers to use a capacitor connected between the active (live) lead and neutral. This can provide some useful attenuation of mains borne noise. The capacitor must always be rated for mains AC usage, and preferably for at least 400 VAC - a DC capacitor will fail sooner or later regardless of rated voltage.

In some cases, a capacitor may be used between live and earth (particularly in the US). This is especially common in some guitar amplifiers, and the capacitor is likely to fail - especially at 220 or 240 volts AC, since DC capacitors are commonly used. In some cases, a capacitor may be used from both active and neutral to earth. This is an extremely dangerous practice, and is illegal in many countries. Generally, I do not recommend or condone the use of capacitors from any mains connection to safety or chassis earth. Indeed, under some circumstances these caps can cause residual current devices (RCDs - safety switches) to trip. The use of any capacitor between mains and the chassis places the user at risk of electric shock if the chassis is not connected to safety earth.

Introduction

From the editor (Rod E) - I have inserted some of my own comments, which are identified by ***(rode)*** tacked onto the end. Otherwise the article is almost untouched. Many thanks Andy - A fine piece of work.

A Pursuit Indeed ...

Praise be to electronics. There can be no finer and more honourable pursuit for the man with time on his hands and at least some money to burn.

In theory it is an inexpensive, safe and absorbing hobby with at least the potential for learning what all the pretty little coloured tubes and cans of various shapes and sizes in the back of the television are. Beyond this, you can wow the men and woo the women with your worldly wise talk of linear power supplies, voltage and current amplifiers, pi filters, power transistors and heat sink efficiency. Such talk will eventually guarantee at least one, and possibly more, of the following –

- A seat in the pub when everyone else mysteriously disappears two minutes into the conversation.
- A slap round the side of the head.
- A workshop full of ageing and dilapidated electrical gear, most of which presents a really serious public health hazard, that you've promised to repair free of charge for your family and mates as soon as you find the time.

The gathering of broken electrical gear is a particular one to watch out for. It has been suggested that the recent unexplained disappearance of a number of electronics enthusiasts may have been caused by dimensional instability in their workshops. The theory is that the accumulation of such vast amounts of semi-deceased gear can force into existence a temporal doorway into a world with lead fumes for an atmosphere. This theory has yet to be proved and may be a load of old cobblers. However, it always pays to be wary.

---

1. It Helps to Have a Purpose

Adopting a (slightly) more serious note, the remainder of this article will address some of the issues that you will need to be aware of if you are coming into the field of electronics as an absolute beginner. As with any activity there are some dangers, but the risk of suffering any form of harm can be reduced to practically zero by adopting a few simple working practices and taking a careful and methodical approach to the work in hand.

On the upside, the rewards to be had when you have learned enough to consider yourself a competent amateur are many and varied. Its impossible to make an exhaustive list as everyone gets something different out of their hobby. However, there are some general benefits and these include ...

- A deeper understanding and appreciation of the technology that is a constant in modern life.

- The ability to diagnose and repair simple faults in your own equipment which would otherwise have to be professionally repaired or replaced completely. As an example, an ageing hi-fi amp of mine died recently whilst in use. Five minutes with the multimeter

helped me to confirm that the bridge rectifier in the power supply unit had failed. In this case the repair cost me nothing as I had an equivalent bridge in my parts drawer. Even if I'd had to buy one, it would have cost me no more than two or three pounds sterling. Not bad if you consider that binning the entire amp and replacing it with a new one of a similar quality would have set me back about a hundred times the cost of the new rectifier.

- The satisfaction of correctly constructing kits and designing and building your own circuitry.

- The scope to acquire faulty electrical items at little or no cost and restore the unit to working order in your own time. I'm quite a fan of old audio/video equipment and you'd be amazed if I were to tell you about all the lovely pieces of gear that I have seen destined for the skip when the fault was nothing more serious than a tired transistor or even a blown fuse. A good example of this is my own record deck – a 1974 Bang and Olufsen Beogram 4000 which was going to be binned after three "professional" repairers had failed to bring it back to life. I picked the unit up for ten pounds sterling, spent half an hour replacing the mains supply fuses in the case, and grinned broadly when I plugged it in and watched it come to life. Its been used every day for three years now and has worked reliably on all occasions. What's more, it gives every indication of being quite happy about the prospect of running perfectly for another 26 years, so long as it gets the occasional bit of TLC. As an added bonus, when I want back and talked to the guy in the shop where Id bought it, he was so pleased to hear the record deck working that he gave me amplifier that went with it for nothing.

In the next section, we abandon our traditionally light-hearted approach and discuss the very serious issue of electrical safety. If you read nothing else at all in your life then this read this.

---

2. Avoiding Evaporation Trauma

In the last section, I aimed to convince you of the fun that you can have being an amateur sparky. If you find that you don't fancy it at all then I suggest that you quit now before you start buying loads of relatively expensive gear which will be of no use whatsoever to you.

Electronics is usually a lot of fun, and I try to reflect this in the light-hearted nature of these articles. However, for this part of the series I'm afraid that I have to get very, very, very serious about something.

Yep, you've guessed it – ***electricity***.

In very basic terms, electricity is the flow of electrons along a conductive material such as copper. In order to use electricity in anger, this flow of electrons must be impeded by some sort of resistive or capacitive load. This can be an electrical circuit of varying complexity, a coil such as found in an electric motor, or a filament such as found in a normal lightbulb. I accept that this is verging on a gross over-simplification of the truth, but it will more than adequately serve our purpose at present.

One of the characteristics of this flow of electrons is that it will always follow the path of least resistance to the point of lowest potential. Since the human body is around 98% water, and given that water suitable saturated with mineral salts (that's us!) is an excellent conductor of electricity, the potential for you to involuntarily and unexpectedly become the conductor of a great deal of electricity is considerable. For the amateur electronics enthusiast, this risk is increased a hundredfold since your chosen hobby will inevitably bring you into potentially intimate contact with electricity on a regular basis.

It seems to be an article of faith amongst many that the lower the electrical voltage, the less potential danger exists when working close to it. This is complete nonsense when you consider that the static electricity shock that you can get by touching the body of a car on a hot, dry day can be in the order of 30 – 50,000 volts. Whilst such shocks can be irritating, it is extremely unlikely that you will be inconvenienced beyond this due to the very, very low electrical currents involved, and the instantaneous nature of the discharge from the car body to your own. However, when working with direct current (DC) or alternating current (AC) sources at much lower voltages, the result of physical contact with a live wire can be almost instantaneous death.

Indeed, a current of 50mA (barely enough to make a low wattage lamp even glow) is sufficient to send your heart into a state called "ventricular fibrillation", where the heart muscles are all working out of synchronisation with each other. Little or no blood is pumped, and you will die within about 3 minutes unless help is immediately at hand.

Sometimes (but less often), your heart will simply stop. If this happens, it is possible that with external heart massage that it might re-start, and occasionally it might even re-start by itself - rare, but it can happen.

However, worry not. As I have said, this risk can be reduced considerably with the application of a few simple working practices, a careful and methodical approach to the job, and a large helping of simple common sense. The list below is intended to give some pointers to what the correct working standards should be. What it is not is the de facto standard for electrical safety. It is expected that you will use the recommendations below in conjunction with the absolutely basic principles such as not overloading plug points, not mixing electricity with water, and not leaving live bare wires dangling within reach of anybody.

If you are still in the dark after reading the list then I strongly suggest that you do not even consider proceeding with electronics as a hobby until you have located and attended an approved course on all aspects of electrical safety, and you are more than satisfied that your understanding of the subject is correct and thorough. Many educational institutions such as colleges and universities run such courses during the evening. They are generally quite cheap to enrol on, and usually run for one or two evenings a week for a period of five to six weeks.

- Treat DC and AC electricity at **ALL** voltages with the utmost respect and caution. This includes all household and battery supplies, no matter how small the battery may be. Statistics suggest that the survival rate for people with gunshot wounds is far higher than for those who have suffered serious electrocution.

- Unless you are **ABSOLUTELY** sure of what you are doing, **NEVER** work on a live chassis under any circumstances. Even experienced engineers are loathe to work on live equipment unless it is absolutely necessary. Prior to working on any form of equipment, ensure that it is isolated from the mains by physically disconnecting the plug from the mains socket. If the mains socket is switched then also ensure that you have switched the socket off. If you must work in close proximity to any form of electrical socket then stick insulating tape across the front of the socket to prevent electrocution due to tools or fingers coming into inadvertent contact. In addition, take careful note of what I say in all sections here before you even *think* about breaking out the screwdrivers.

- **Never** under any circumstances be tempted to "jerry rig" your latest creation to the mains using bare wires and matchsticks (or similar) shoved into a plug socket. You may laugh but I've seen such suicidal stupidity perpetrated on many occasions. **This is an incredibly stupid thing to do !** When connecting any device to the mains, use a good quality plug from a reputable manufacturer, and ensure that the plug is correctly assembled and that all connections and covers are secure and tight prior to connection. For plugs with integral fuses, such as those supplied in the U.K., ensure that the fuse is of the correct rating for the device.

- Of course, there are rare situations where it is necessary to work on a live chassis – setting the bias current on a power amplifier is one example. Prior to commencing work of this type, it is **IMPERATIVE** to satisfy yourself that **ALL** electrical connections are correctly insulated in order to prevent accidental contact. This is particularly important in equipment that you have built yourself, though I have seen wiring in quite expensive commercial products which is nothing short of reprehensible. When making insulated connections I have three sizes of heatshrink sleeving. After ensuring that the connection is well made and has no sharp edges which may puncture the sleeving, I alternately apply and shrink each size of sleeving, finishing with the largest. In this way,

I am satisfied that there can be no accidental contact.

- In addition to the other points raised above, **NEVER** wear a watch, ring, necklace or any other form of conductive jewellery whilst working on electrical devices, whether they are live or not.

- If, like me, you have switched mains sockets mounted on your workbench, **NEVER** assume that the appliance that you are working on is completely isolated from the mains when you switch the socket off. To be safe, always completely remove the mains plug from the socket and lay it well away from any live contacts in a place on the bench where it cannot be knocked. In addition, give serious consideration to having a qualified electrician install a residual current device (RCD*) on the mains supply to your work room. These devices work on the principle that if more current is flowing on one supply pole than the other, then some must be going where it is not intended to. Under these circumstances, the device will cut out the supply of electricity extremely quickly. I have witnessed a situation where someone came into accidental contact with a mains cable immediately after inadvertently slicing it in two with a pair of hedge trimmers. Luckily, the cable was connected to the distribution board via an RCD which cut out immediately, and the unlucky gardener suffered no ill effects whatsoever. Had the circuit been protected with a more traditional cartridge fuse, the situation may have been far different. Even if a fuse does blow in a situation where someone is being electrocuted (and this is not at all guaranteed), this can take up to three seconds, which is more than long enough for the unfortunate person to be killed outright.

- Be aware of the fact that any equipment which utilises power reservoirs such as capacitors in its design may well be live for many hours or days after it has last been powered up. A excellent example here is the power supply for any form of amplifier. Nearly all power supplies for these devices utilise capacitance smoothing after the rectifier, and in some cases the capacitors used can store a great deal of power for a considerable length of time after the device has been switched off and disconnected from the mains supply. When working with equipment of this type, if you are in any doubt at all then it is far safer to assume that there is power stored in the capacitors, and proceed accordingly.

- In addition to the points raised above, be aware of the fact that **ALL** Cathode Ray Tubes in televisions, computer monitors and oscilloscopes can store lethal levels of charge at many, many thousands of volts for weeks after they have been switched off and disconnected from the mains. The design, construction, repair and servicing of any device incorporating CRTs is a very specialised and dangerous task unless you know exactly what you are doing. Indeed, I know of many extremely competent electronics

enthusiasts who will not even consider touching devices incorporating these components. To be safe, I suggest that you don't either.

- Microwave ovens have probably killed more technicians than any other electronic device. The capacitor can store a huge electrical charge, and this charge can remain poised to pounce on any unsuspecting technician for weeks. These animals are seriously dangerous, and must be treated with the utmost respect - or avoided altogether. ***(rode)***

* RCDs are also known as earth (ground) leakage circuit breakers ***(rode)***

This may seem to be an extensive list, but I am loathe to make an apology even if you feel that I may have overstressed the point. Whilst I do find that the majority of people behave sensibly and apply common sense when working with electricity, I have seen some inexcusable examples of sheer stupidity in my time, and these have generally been as a result of people not thinking about what they are doing. Mistakes with electricity are at the best costly, and at the worst fatal.

In the next section, we make a thankful return to slightly more light-hearted matters and discuss how to assemble a decent toolkit without having to remortgage the kids.

---

3. Tools, and Their Place in the World

Its always said that a bad workman always blames his tools. A corollary of this is a good workman can only be as good as the tools he is using. In this section, we'll look at the toolkit you will need to assemble in order to get started as an electronics hobbyist.

Firstly, a word on the buying of tools in general.

I'm sure everyone who is reading this has strolled around the odd Sunday market in the course of their lives and encountered the mythical 50,000-piece toolkit of dubious geographical origin that cost little more than a decent set of screwdrivers, and which seems to meet all your needs in one fell swoop without breaking the bank. Whilst these kits may seem to be excellent value on the face of it, and the tools that they contain may look to be little different to their far more expensive counterparts stocked by well-established retailers, they are generally not up to the reasonably hard daily use to which you will put them in the pursuit of your hobby.

In the case of tools such as hammers, spanners, screwdrivers and drill bits, the very cheap ones are not only a waste of money as they won't last two minutes, they are downright dangerous. Even when undertaking very light duties in the workshop, you'd be surprised at the

stresses and strains on a tool as simple as the humble spanner or screwdriver. In order to perform correctly under these conditions, good quality tools are well designed for the job in hand, and the metal from which they are made is correctly tempered and heat treated so that the tool will give many years of trouble free service before a replacement is required. Cheaper tools are generally poorer quality copies of the better designs, and there is no guarantee that the metal has been correctly treated at all. At the very least, such a tool may slip whilst in use and damage the workpiece. At the worst the tool may bend, snap or even shatter whilst in use, causing personal injury.

As a general rule of thumb, when buying tools you should go to a well established retailer and only buy tools made by reputable manufacturers. It is far better to spend some time saving up to buy the best tools you can afford, rather than to compromise on cheaper ones which will not last as long, and which may not be as satisfying to use. This is particularly the case with tools that will be put to heavy use such as hammers, spanners, pliers, screwdrivers, cutters and strippers.

When it comes to power tools, what I have said about buying quality items is especially pertinent. It is important that tools such as power drills, jigsaws, circular saws, routers and planers are of good quality, and this extends not only to the tool itself, but to any accessories or blades which are fitted to it. Be especially wary of ultra-cheap power tools that seem to offer the world for little money. They will not last long, they most certainly won't be up to the job in hand, and you may end up completely spoiling what you are working on for the want of something decent.

Before we start with our wish list, it's worthwhile mentioning that there are very, very few injuries suffered when a well designed tool of good quality is used correctly for its intended purpose. The well known banged heads, scuffed elbows, skinned knuckles and puncture wounds that give us the walking wounded of the DIY wars are only caused when the right tool is used for the wrong job or a tool is forced beyond its designed limits. Using the correct tool generally means that you'll get the job finished quicker, you won't injure yourself, and you won't break or spoil anything else whilst working.

- **Screwdrivers -** The better quality screwdrivers have tempered shafts and hardened tips so that they won't slip on the screw head and damage the screw, the workpiece, or most importantly, you. Try to aim to have at least four sizes of flat head screwdriver, and four sizes of posidrive screwdriver, along with a decent set of flat headed and posidrive jeweller's screwdrivers for dismantling or assembling smaller components. For ease of use, those with the softer contoured handles are far better than those with the traditionally shaped plastic or wooden handles, and they generally provide far better insulation – this is a must when working with electrical gear. You'll be surprised at just how much use your screwdrivers will be put to, and how much it will hurt if one slips, so buy the best that you can possibly afford.

In use, it is important to remember that a screwdriver is only for the fixing and removal of screws. It is not a chisel, a hammer, a crowbar, a counterweight, a hook, or any of the other things that the many improvised uses I have seen may suggest. Years of experience has taught me that screwdrivers are sentient beings in their own right. If you misuse them they WILL bite back. Some day I'll get round to publishing my extensive collection of scars to reinforce this point – there's no teacher like pain :-)

- **Spanners -** You won't need anything in the monkey wrench league for electronics work. A good quality set of open ended and ring spanners which go from 3mm to 13mm in 1mm increments will be ideal for your purpose. If you're going to be restoring old equipment then it may be an idea to get hold of similar-sized set of imperial spanners as well, though these needn't be anywhere near the top of your list otherwise. As usual, make sure that what you're buying is the best you can afford. The drop forged chrome vanadium spanners from well-known manufacturers such as Draper (in the U.K.) or Snap On (worldwide) are made to exacting standards out of high quality materials. Whilst the initial outlay from buying a set may have you sitting in a cool room for a while to recover, they really will provide you with a lifetime of unfailing service. In the U.K., cheap and nasty spanners are known as ‘knuckle f*****s’ - nobody wants hands like an ageing prize fighter when you're trying to fiddle that 2mm nut on in a space it's taken you the best part of two months to get into.

- **Pliers and Cutters -** Again, there's no need for a pair of water pump pliers with 40 inch knurled vice grips. Try to aim for a good quality set of pliers which consists of two or three sizes of needle nosed pliers, a couple of sizes of flat nosed pliers, and a couple of different configurations of wire cutter. As usual, look for good quality well made examples with comfortable moulded grips that provide high electrical resistance – this is very important. Cheap and nasty pliers are particularly prone to shattering when being used with enthusiasm. When they do give way, bits of razor sharp metal fly everywhere at incredible speeds, so you're not even safe when standing behind someone who's using a pair of bargain basement specials.

- **Knives -** Frowned down upon by some enthusiasts, but invaluable in my view. I have a set of scalpels for fine work, a pair of Swiss Army knives for general use, and a couple of large lock knives for stripping the insulation from heavy duty cables that won't fit in my wire strippers. Do not even think about using something other than a good quality lock knife when you're going to be applying some pressure to the workpiece in order to cut through it – pen knife blades can simply close against your fingers whilst in use. No further description necessary I fancy.

The ubiquitous Stanley™ knife is a good investment - avoid the many cheap copies, as they often have a less than perfect locking mechanism. Searching the workshop floor for the missing bit (prior to rushing off for microsurgery) is not the ideal way to spend one's Sunday afternoon. ***(rode)***

- **Hammers -** There's nothing to be ashamed of – even the most refined of us occasionally need to resort to the rough stuff in order to finish the job. To be fair, it's rare that you'll ever need a hammer when working with electronics, the two just don't go together. However, having a small toffee hammer tucked away in the corner of your toolkit can be invaluable, for example when working on racking or equipment mounts. To be honest, it's so long since I bought a hammer that I have no idea how to go about selecting the correct one. They used to be sold by the weight of the head and I have two in my toolkit stamped at six ounces and one pound respectively (roughly 170 and 220 grams). If possible, try and get hold of a ball peen hammer with a head weight of about 150 grams and a good quality wooden handle. For the use that I suspect it will get, going broke buying it is not essential, but remember to steer away from the really cheap and nasty stuff.

  On the subject of hitting things, a set of centre punches is essential if you intend drilling holes (which is hard to avoid most of the time). A centre punch allows you to carefully mark a small indentation on the workpiece before you start drilling, and it will stop the drill bit from wandering all over the place until it finally decides to make a hole in the wrong place. "Automatic" centre punches are also available - these do the same thing, but you only need to press down on the tool - a spring provides the tension, and a pressure sensitive release "lets go" at the preset pressure and makes a nice little indent for you. ***(rode)***

- **Reading Lamp -** What ? Nothing for nipping, gripping, bending or knocking ? Nope, just a plain old reading lamp. Nowadays reading lamps come in all shapes and sizes ranging from the standard old anglepoise to space-aged low voltage halogen designs with the transformers hidden inside an art-deco base. I would avoid the really expensive models as I suspect you're paying a lot of money for design and styling which will never be appreciated in the workshop. A simple flexible necked reading lamp with a nice heavy base and a 40-60 watt bulb fitted to it will be more than adequate for your needs.

  While you are at it (especially for fine work, and more so if you are getting old, like me :-) a good magnifying lamp or headband magnifier is worth its weight in ruined circuit boards. ***(rode)***

- **Drill and Drill Bits -** Its a good idea to have a large mains-powered drill for heavier work such as drilling metal casework, and a smaller battery powered drill for lighter duty tasks

such as working with plastic, or drilling very small holes using bits which would be prone to snapping if used in a power drill. In the case of both the battery drill and the mains powered unit, if you can buy those that have electro-mechanical devices which sense the pressure on the drill trigger and vary the motor speed accordingly then all the better. This is an especially useful feature on the battery-powered drill and means that you can work with very delicate items at extremely low speed to minimise the risk of damage to the workpiece. As usual, buy the best unit that you can afford from a reputable manufacturer.

This is also true for the drill bits. It is often more economical to buy these in a set and you should aim for good quality items made from high speed steel. If you can buy a set of drill bits which also includes one or two hand or power reamer bits then this is ideal. Whilst all drill bits will eventually go blunt and need replacing, the better quality ones do give much longer service than the cheaper ones. When drilling any material, considerable friction is generated between the drill bit and the workpiece. It is important that you don't allow the bit to become too hot, as this can sometimes cause it to soften and become ineffective.

During drilling, do not apply too much pressure to the drill as you will almost certainly snap the bit. Over time, you will develop a ‘feel’ for when the bit has nearly penetrated the bottom of the hole, and you will know when to ease pressure on the drill in order to avoid the jaws of the chuck coming into contact with the workpiece and damaging the surface.

To extend the usefulness of your mains power drill, you will also want to invest in a good quality drill stand and press. Its probably a good idea to buy one made by the manufacturer of your drill as you can then be sure that everything will fit together correctly. If the drill press comes with an optional vice that attaches to the bed of unit and allows workpieces to be held rigidly whilst drilling then all the better.

- **Taps and Dies -** Nope, not the ones on your bath, mate. Once a suitably sized hole has been drilled in a piece of metal, a tap is used to cut threads into the edges of the hole to admit and hold a threaded fixing. A die is the exact opposite of a tap in that it is screwed onto a shaft of metal (usually referred to as a ‘blank’) to cut threads and make a bolt. There is a dizzying number of standards in the world for specifying and cutting threads of different pitches in different sized holes or blanks, and whole volumes have been written on the subject. I don't propose to go into these at all here (though the insomniac may find an excellent cure for his affliction within their pages). In response to this multitude of standards, many tool suppliers sell a kit of taps and dies covering the thread sizes and pitches that will be most commonly encountered when working with mainstream equipment.

Taps come in a number of types but we're only really interested in tapered taps which are normally used for cutting threads in panels, and so-called ‘blind’ taps which are used for cutting threads in holes which do not pass through the whole depth of the material. A good example of the latter would be holes bored in one side of a heatsink for transistor mounting bolts. When buying your kit, ensure that it contains all the necessary sizes of tapered and blind taps. Using taps and dies is nowhere near as easy as it first looks.

A detailed discussion is really beyond the scope of this document, and it would be far better to find someone who is skilled in their use and ask them to show you. Once you are satisfied that you have mastered the basics, practise on some scrap metal until you are sure of what you are doing. During the course of this learning process, don't be at all discouraged if you turn out some dreadful examples. As I have hinted, there is a definite knack to using these tools and time is the best teacher.

- **Wire Strippers -** These will separate the professional amateurs from the amateur professionals every time. Unless you're working with thick armoured cable, or very heavy duty solid core cable, you're showing yourself up if you try and remove the insulation from the wire with your thumb and the blade of a knife. Not only is it guaranteed that you'll eventually slice a chunk of yourself off, but it requires an incredibly light touch and almost a lifetime of practise to feel when the blade has passed through the insulation and is about to damage the conductors. In multi-cored cable such as mains cable, you can cut through the outer insulator and damage the inner cable sheaths in one smooth movement. Assuming that you even notice this potentially dangerous mistake, the only thing to do is cut the whole lot off and start again. I'm sure that if all the cable that this splapdash approach wastes each year were to be put end to end then we'd be well on the way to the moon in no time.

  If you're doing it right, you're going to be using your wire strippers a hell of a lot in electronics. If you don't splash out on any other tool in your kit, you'll be thanking yourself for years if you show a little extravagance when buying this one. The very best wire strippers are nicely balanced with padded handles, well machined spring loaded mechanisms and replaceable blades. The standard for wire sizes is called (not surprisingly) the Standard Wire Gauge (SWG). All good wire strippers are marked in some way to indicate how the tool should be set in order to strip the insulation from wire of a certain SWG. If the tool is set to an SWG which is too high for the wire you are working with, it will just damage and stretch the insulation without removing it. If set too low, then both the insulation and some or all of the conductors (assuming stranded wire) will be removed. If you are working with solid core cable, the conductor may seem to be undamaged until you try to solder it to the fitting, at which point it will snap. In all cases,

the damaged section of wire must be cut from the length, the tool correctly set, and the operation repeated. If you have a serious amount of disposable income to blow on a pair of wire strippers (and I suggest that if you have then you should), you can buy some with an "intelligent" spring loaded mechanism that "senses" when the blades have cut through the insulation, and stops them before they reach the conductors. The blades then move backwards in the jaw to break the newly cut insulation away, all in one smooth movement. Its not necessary to set the SWG for the wire that you're using, and they'll strip anything first time, every time. Years ago, I went without beer for a whole month to buy a pair of those – it was (damned) difficult at the time but I appreciate my strength of will every time I use them.

- **Soldering Iron and Desolder Tool -** You'll be using your soldering iron almost as much as your wire strippers so it's worthwhile getting a good one. Go to a shop where the assistant will let you pick up a number of similar irons and chose the one that feels comfortable and well-balanced. The heating element should be ceramic cored and the iron should be designed in such a way as you can change the tips as and when necessary. If you can select a model with low tip leakage current then all the better. As well as the iron itself, you'll need a good heavy stand, ideally with an integral sponge. Its also a good idea to buy a number of different tips of varying sizes for different types of work. The more advanced (and expensive) temperature controlled soldering irons and soldering stations are overkill for the beginner, though you may want to think about one if you're doing a lot of work, or if you become very serious about your hobby.

  Desolder tools come in a dizzying array of shapes and sizes. For the hobbyist, the spring-loaded plunger design is more than adequate. Be aware that these tools do need to be dismantled and cleaned, practically after each session, and the tips and ‘O’ rings do need to be replaced periodically. If you can buy a supply of ‘O’ rings and tips along with the desolder tool itself then all the better.

  With regard to the solder itself, buy a decent quality 60/40 solder, and **NEVER EVER** use plumber's flux when working with electronics. Its not necessary, makes a hell of a mess, and is highly corrosive.

- **Files -** Buy a good quality set of needle files for close work, and a set of larger files for general metal working. The now familiar caveat of buying good quality is still relevant even for files. Cheap and nasty files have uncomfortable handles which will do nothing but give you blisters and snap when you're using them. The teeth are poorly machined and they'll just make a mess out of all your hard work. A piece of metal worked properly with a good quality file can sometimes not be distinguished from one which has been machined. A couple of flat (preferably "bastard" cut), round and square files in different sizes will allow you to make odd shaped holes for connectors and switches.

- **Hacksaw(s) -** A good quality full size hacksaw and a "baby" version - but not the plastic bodied types - they are useless. Cutting pot and switch shafts, reducing screws to a sensible length and a multitude of other essential cutting tasks will be a lot harder if you have to chew through them with your teeth. ***(rode)***

- **Steel Rule -** Absolutely invaluable this. Buy a good one with both metric and imperial divisions. A couple of cheap plastic rules will also come in handy. For marking out panels before drilling, an accurate 90 degree square is a good investment.

- **Vice -** Loose women ? Gambling ? Drinking to excess ? If you're already good at any of these then you don't need me to tell you how to do them better, and if you've already got such a wild life then when will you find time for electronics ? :-)

  What I do mean is the humble old bench vice. You don't need a huge engineer's vice for normal electronics work, a small woodworker's vice will do just nicely. If you can get one that comes equipped with a quick release mechanism so that you can move it to whichever corner of the workbench takes your fancy then this is excellent. One which will allow you to fashion and fit jaw covers made of wood or plastic is also a good idea, as the standard cast or wrought iron jaws will almost certainly damage a lot of the components that you will be working with, no matter how careful you are.

  On the subject of holding things in place, I also find that a collection of artery forceps and a number of different sizes of ‘G’ cramp are often just what you're looking when there just aren't enough fingers or hands to go round. (Also see miscellaneous, below.)

  Finally, for just a few of your hard-earned dollars (pounds, shekels ….) you can get hold a tool with a heavy base, infinitely flexible arms about six to ten inches in length ending in a pair of crocodile clips, and with an integral magnifying glass attached. What's more, they don't complain and drop the wire when it starts getting hot. I don't know what they're called elsewhere, but they're commonly known as ‘helping hands’ in the U.K., and they're the best thing since sliced bread when it comes to connecting cables to small plugs or sockets. You can arrange the cable and the socket just how you want and then apply the soldering iron without fear of anything flying off into the distant corners of the workbench. For example, if you chose to do a lot of work with older hi-fi equipment as I do, you'll often encounter the old five and seven pin DIN plugs and sockets. Don't even try to solder one of these without a pair of helping hands.

- **Pop Rivet Gun -** Whilst one of these isn't vital for a beginner, they are useful. When actually installing the rivet in the workpiece, you're asking a lot of the gun so buy a decent one, and don't forget to maintain your stock of rivets and washers. The times that I've gone to the rivet drawer to discover that I've used up the size that I need are without number, and this always seems to happen on a Sunday afternoon when everywhere is shut.

  I can't resist a further word on the Sunday afternoon phenomenon at this point. Whilst I have no proof of this (what would you expect ?), I've a feeling that the forces of physics and the natural vindictiveness of small inanimate objects are in a particular state of harmony after about 2.00 PM on a Sunday afternoon. If it's a wet and cold Sunday afternoon then this harmony is a particularly good one. If it's snowing and you have a desperate need for the thing that you are working on the next day then the harmony is practically angelic. Expensive and difficult to obtain components that you could attach a spanner to and happily swing from (on any other day of the week) will readily snap, bend, run away after being dropped and magically metamorphose into something the wrong size after 2.00 PM on a Sunday afternoon, and there's not a bloody thing that you can do about it as everywhere is shut. To add insult to injury, you just **know** that you haven't got a spare – you don't have to even both looking, you just **know**. I've talked to a lot of hobbyists and mechanics who have built an entire belief system of uncanny internal consistency around this phenomenon, to the point where they will get very drunk on a Saturday night for the **sole** purpose of averting the temptation to do **anything** on a Sunday afternoon – it's nothing to do with riotous quaffing or having a good time, it's all about avoiding the Sunday afternoon sinking feeling - honest :-)

  The above is slightly different in other countries where a somewhat more liberal approach to regulated shopping hours is common - the effect will simply perform an appropriate time shift to ensure maximum annoyance and/or frustration. ***(rode)***

- **Miscellaneous *(rode)* -** Gripping "things" - spring clamps, clothes pegs, G-cramps and a tiny (as in *really* small) bench vice will be used once in a blue moon, or every day. It is almost guaranteed that if you don't have a good selection of these essentials, their immediate requirement to allow you to complete the job will increase tenfold. Also include masking tape and rubber bands (the former holds anything in place temporarily, and the latter are great for keeping a pair of pliers closed on the workpiece :-)

  Consider raiding your local medical supply outlet for a pair (or two) of artery forceps. These used to be considered “unusual”, but they are now available from many electronics retailers who have finally realised the usefulness of these little devices. They may be used as tiny pliers, clamped onto sensitive component leads to act as a heatsink, or used to retrieve that (blessed) small screw from the nether regions of a

chassis where it has taken root. These are probably my most used small “gripping tool” of all.

A large plastic kitchen cutting board can also be very useful for cutting paper labels (to be stuck to front panels and covered with clear plastic), plus other uses which will dawn on you when you see all the knife marks on your workbench. Even slicing open plastic packets of resistors or capacitors is made easier and safer if you have a proper surface to do it on. Oh yes, add a couple of pairs of scissors to the list while you are at it.

An array of pencils, a steel scriber, and a few permanent and non-permanent felt tip pens will always be used, as well as a notepad. I know I'm stating the obvious, but you'd be surprised how often these basic essentials are nowhere to be seen.

Andy has made a good point with all his suggestions about good quality tools, but sometimes the 50,000 piece set for $29.99 actually makes good sense. Some of the tools will break, but in the meantime, you have a huge array of things you can use until you find out what you really need - you then replace the broken cheapie with a good quality equivalent, knowing in advance that you will use it (you must, otherwise you wouldn't have broken it, right?). Don't trust any of the cheapie sets for anything other than "light duties" - and sometimes some of the other bits of the kit can be modified into something you really need, even for a single use job - a blowtorch, angle grinder and hammer can modify almost any tool, and if you mess it up, you haven't blown any serious money. This is a technique I have used many times, and as a result have a very wide range of "interesting" tools (the original purpose of which is now lost in time in many cases :-)

Earthed wrist strap and earthed mat for working on static sensitive devices (e.g. MOSFETs and CMOS logic).

Insulating safety gloves for working on valve amps and mains supplies. - Not to everyone's taste, but useful if you are sufficiently paranoid (not a bad trait when electricity is involved).

Wirewool and fine emery paper for cleaning component leads etc.

A first aid kit, especially if the workshop is away from the house.

A self-contained smoke detector in case accidents with the soldering iron etc.

A suitable brick wall (head-hitting for the use of) for when things don't go quite right :-)

(With some additional input from Geoff Moss, my unpaid, but very appreciated editor)

---

4. ‘Big’ Tools - Nice to Have Vs. Have to Have

We've now exhausted the list of smaller tools that you'll need to make a start in electronics. As you progress, you'll undoubtedly gather unto yourself a wide and varied selection of useful tools above and beyond what I've mentioned in this section, and you'll be amazed at just what you can buy. For example, I recently saw a tool that you can fit to the end of your power drill that will make a four inch deep perfectly square cutout of any size in any material short of solid steel ! No more belting the hell out of a cold chisel just to fit a socket in the wall I fancy !

Before we move onto setting up a workshop, it's worthwhile briefly mentioning a number of tools which may not have an immediate application to electronics, but which are often worth their weight in gold when carrying out related work. Please remember to always wear the correct protective equipment when using power tools. At the very least, always have a pair of safety specs handy as a matter of course.

- **Drill Press -** A small cheap drill press will be more accurate than an expensive hand held drill, no matter how good you are with the latter. For drilling heatsinks and even PCBs, they have no equal. Most are now made in China and are a tad dubious, but if set up with care will be more than adequate for most jobs where small or perfectly vertical holes are essential. This is especially true if you are drilling holes that are to be tapped. ***(rode)***

- **High-Speed Rotary Engraver -** These are made by various manufacturers, and are invaluable for making small modifications to cases, PCBs, and just about anything else that is not the shape you want it to be. For a small tool, they are expensive, but add a few sanding drums and disks to the basic set, and you have a tool that has a multiplicity of uses for fine work. ***(rode)***

- **Angle Grinder -** Go anywhere, do anything, sharpen anything and cut anything. Watch out for sparks and dust and ALWAYS wear good safety specs. I've had the odd grinding disc explode on me and it's NOT funny !

- **Circular Saw -** Adds infinite macho appeal but wear safety specs and please keep your fingers out of the way

- **Electric Plane -** I can't imagine anything better when wood refuses to fit !

- **Jig Saw -** Just remember that they make different saw bits for wood and metal. When cutting aluminium, always ensure that the workpiece is well lubricated with light machine

oil

- **Heat Gun -** Great for mess-free paint stripping and there's nothing better for heat shrink sleeving. Do try to remember that these are not to be used as hair dryers :-)

- **Power Sander -** For those times when you've got better things to do than spend forever rubbing things down by hand. Orbital sanders are excellent for fine finishing. Belt sanders are particularly effective (and evil).

- **Band Saw -** Excellent for case work, and a far better alternative to a jig saw when making long cuts in sheet metal

- **Router** - Can be used to cut perfect (including recessed) holes for speaker mounting, and odd shaped cutouts for terminal panels and the like. Rounding bits allow you to make all the sharp edges go away on a speaker box, which is great for reducing refraction and protecting small people from injury when they crash headlong into your cabinets. Other router bits can make fancy trims or just simple slots for shelving or reinforced cabinet assembly. ***(rode)***

- **Sheet Metal Punches -** Whilst not cheap, a set of these useful little things will guarantee that you'll never bend or break anything again whilst trying to force a 12mm HSS drill bit through it at suicidal speed.

- **Welder -** Of all electric arc welders, nothing beats a MIG (Metal Inert Gas) set to my way of thinking. They're versatile, easy to use, cheap to run, and you can get some excellent results with one after a bit of practise. If you're really going for it then think about acquiring a small oxygen and acetylene welding set for metal cutting, brazing and really fine welding work. When working with electric arc welders, ALWAYS use an approved welding mask (there are NO exceptions to this), and remember that a recently welded workpiece is guaranteed to make you sizzle if you touch it, even when the bright red glow has gone away!

  With oxyacetylene equipment, bear in mind that both gasses are HIGHLY explosive if incorrectly (or even correctly) fiddled with. You won't just take out yourself and your workshop, you'll very likely also take out the entire street (I'm not kidding here).

- **Lathe -** Using one of these properly takes a lot of mastering, but once you've got there,

you can make practically anything you need. Many hobbyists and home mechanics believe that the lathe has almost totemic powers against the Sunday afternoon syndrome referred to above.

- **Air Compressor -** A tool of little use by itself, unless you just want an unusual source of noise and heat. With the right attachments, you can spray paint, blow swarf and dust out of the hardest to reach places, and operate a whole array of air tools. Not specifically something for the average home hobbyist, but one of these really has some posing value.

---

4. The Workshop

Okay, you're skint as a flint (i.e. completely broke!) but replete with tools, and you're itching to get going. All that you need now is the workshop.

In this section, I'll provide some guidelines on how to establish a workshop, how to build a workbench, and how to store components and tools so that what you need is always to hand without too much searching and turning over of rocks. I'll also make a brief mention of how to maintain your tools once they are installed and racked up in the workshop, and how to approach your work correctly once the workshop is in place and being used for its intended purpose.

- **The Right Place at the Right Time -** The first challenge is to select the place in your house, garage, outbuilding, shed, shack or cave that will become your workshop. I know that your choice will be limited by available buildings, space not dedicated to other uses, and the overall size of your house and outbuildings, so consider the following solely as guidelines.

    - Try to establish your workshop in a space no smaller than 20 feet by 40 feet (around 6 metres by 12 metres give or take).

      Naturally, your personal situation (or s/he who must be obeyed) will dictate the feasibility of this - subtle force may be required in extreme cases (i.e. every time). ***(rode)***

    - Ideally, the space should be one that can be permanently dedicated as a workshop. There's nothing worse than having to clear all your tools and gear away in the middle of a half finished job. In addition, the best way to avoid becoming cheesed off with the job in hand is to know that you can walk away, close the door on it, and return whenever you wish. Always remember that this

will be your hobby, and that it should always be fun and a form of relaxation and recreation, not a chore. In some cases I've finished projects in a weekend when I've been in the right mood. In other cases it's taken me six months to a year to complete a piece of work, and I still have projects ongoing now that I started years ago. Having a dedicated workshop allows me to do pursue my hobby in this way.

- The ideal floor covering for this space will be smooth concrete with a coating of floor paint, or floorboards covered with hardboard and linoleum, depending on the type of building. Carpet will inevitably get stained, etched, burnt and dirty and dropped components have a knack of disappearing into it forever.

- Ensure that the space has an adequate source of ambient lighting, ideally both natural and artificial, which you can then supplement with your desk lamp for close work.

- Ensure that there is a safe and reliable mains supply to the workshop. I strongly suggest that where practical you take a fused spur directly from the distribution board into the workshop board, and feed each workshop socket from a separate RCD. There are different types of RCD, some will tolerate a little more leakage or surge current and take a little longer to trip, others are extremely sensitive and will trip at the first sign of any form of current imbalance on the active and neutral poles. Given the use to which the workshop will be put, always go for the second type of RCD. Okay, this may seem a little over-cautious, and will almost certainly not be cheap, but we're talking about a room in which electricity will be played with on an almost continuous basis.
  In comparison with the cost of a human life, a bit of mains wiring and couple of RCDs is an infinitesimally small price to pay. My own workshop is wired in exactly this way. I have of course had the odd mishap over the years, and the majority were due to unexpected component failure, and one or two have been due to working too late into the night and getting tired, or just being bloody stupid. In all cases my RCDs have protected me from any harm by tripping instantly, and I've lived to tell the tale.

  Where you must have a temporary work space, portable "in-line" RCDs are available, and one of these should be used as a matter of course. Also make sure that you use the test facility that is provided on these units regularly, to make sure that it is working properly - a false sense of security can get you killed. Do try not to become a statistic! ***(rode)***

  On a final note, as is the case with all electrical installations, if you're not **absolutely certain** of what you're doing then for God's sake get the work carried

out by a competent and correctly qualified electrician. You can have all the safety devices in the world, but if the wiring itself is a health hazard then you may as well replace your RCDs and fuses with cut off lengths of six inch nails for the good that they'll do you. Even if like me you're a relatively competent amateur, have a correctly qualified electrician at least look over all your wiring before you throw the switch for the first time. If nothing else, at least you've then got peace of mind.

- If the workshop will be in an outbuilding such as a shed or detached garage, bear in mind that there will eventually be a fair amount of expensive equipment stored in it, and secure the premises accordingly. Your local police crime prevention unit can generally advise you about how to go about securing your workshop, but common sense and a little low-grade paranoia are just as good. It goes without saying that if there is a window into the workshop then it should be covered by a net curtain, and valuable items should not be left on display.

- If you live in the U.K., or a country with a similar climate (hard to imagine but there you go), you will need to think about keeping the workshop dry and warm. If the workshop is in your house then this isn't much of a problem. If you are working in an outbuilding then ensure that it is free of leaks and draughts, and that condensation is kept to a minimum all year round. Electricity and damp conditions are not particularly good bedfellows, and keeping all your tools and components in a damp and cold environment will do nothing at all to prolong their life. As a secondary concern to the well-being of your tools, it's a good idea if you can also be warm and comfortable whilst working, and suitable heating should be arranged to ensure this.

- **The Workbench -** The place where it will all happen. I've spent many, many happy hours in front of my workbench and I attribute a lot of these to the thought that I put in when building it. A good way to start is to take your chosen workshop chair, sit down in it and decide the height at which you will be comfortable working. Ensure that your chosen height will allow you to keep your back and neck relatively straight, and to work with your forearms at an angle of about ninety degrees relative to your upper arms. Assuming the rough room dimensions referred to in section 1, and the presence of a window in your chosen space, try to run the workbench down the full length of one of the long walls as close to the window as possible, and make it between a meter and a half and two meters in width to give you plenty of space for your tools, your test equipment and the project currently in hand. Where practical, support the workbench on sturdy brackets anchored to a load-bearing wall with rawlplugs, or to the wall frame rather than the cladding if the workshop is to be in a timber framed building.

  Supplement the brackets with a number of legs along the front of the bench which should be securely anchored to the floor. The top of the bench can be covered with thin

aluminium sheet or heat-resistant Formica, or you can do the whole job in one fell swoop by getting hold of a suitably sized lump of kitchen worktop. This is an excellent option if you don't want to mess around with Formica and evo-stick, or if aluminium sheeting wouldn't exactly blend in with the room's existing décor. Tools which will be permanently attached to the bench, such as your band saw or drill press should be fitted within easy reach, but away from the section that is to be your permanent working area. Its a good idea to attach about eight mains sockets with double pole switches and integral neon tell-tales to the top of the bench, and to feed these from the RCD board that you can attach to the wall beside your bench.

Since you are now completely broke (as we established earlier :-), good workbench tops are expensive! An alternative that I have used (am still using, actually) is the "hollow core" interior door. These are usually inexpensive, and are surprisingly strong because of the cardboard matrix inside. Minimal bracing is needed (or none at all), and they will happily support 1kW power amplifiers without a complaint. Surface treatment is optional, since most are pre-painted with an undercoat and they look quite good as well as being the cheapest worktop you will ever get. Just don't drop heavy things on them, or the hardboard surface *will* break. Not normally a problem - mine has moved premises several times and has been in constant use for well over 15 years with no protective covering at all ! They are not suitable for heavy bench mounted tools such as drill presses, grinders or a vice, so don't even think about it. ***(rode)***

Storing tools is a fairly simple job, and you can make an excellent rack with a decent sized sheet of MDF and a pot of assorted self-tapping screws. There's the added bonus here that you can lay everything out just as you want it without having to compromise as you would with a shop-bought tool rack. Once you've decided what will go where, use a pencil to trace the outline of the tool onto the MDF backboard. It may all seem obvious when the tools are in the rack, but when they're all out on the bench and it comes time to put them away, all you'll see is an irregular matrix of random-sized self-tapping screws. If you think this is the voice of experience speaking here then you'd be absolutely right :-)

- **Storing Components -** I've tried the lot – margarine cartons, empty syrup tins, home made boxes, carefully sub-divided desk drawers, cardboard boxes. You name it. In the end I had to bite the bullet and buy a big metal rack containing many, many, many small clear plastic drawers. I eventually expanded this installation to include a couple of rails and about ten parts bins for the bigger items such as motors, trannies and large capacitors. The whole lot cost me about forty quid so it wasn't cheap, but now everything is correctly labelled and I can find what I want when I want it. If you can find a cheaper and more efficient way of storing components then by all means go ahead and do it – this one works for me.

- **Looking After Your Tools and Yourself -** This is nowhere near as difficult as it may sound. Ensure that the things such as knives and wire cutters which should be sharp stay sharp, and replace items such as drill bits, files and screwdrivers as and when they become blunt. Always use the right tool for the right job and remember that if you are forcing a tool whilst grunting and sweating profusely with effort then you're using the wrong tool, or the right tool in the wrong way. Stop what you are doing immediately, take stock of the situation, and decide on an alternative approach before either you or the workpiece are damaged.

  The moving parts of tools such as pliers and wire strippers do need to be lubricated from time to time. Use only a small amount of light machine oil and lubricate only the linkages, not the business end of the tool.

  A good mental attitude in the workshop can make the difference between a successfully completed project of which you are rightfully proud, and an expensive piece of junk which you will have to bin. If you watch a competent amateur or a trained profession at work, you'll see a composed individual working calmly and methodically towards completion of the task in hand. His work area will be well laid out and tidy, and all tools will be carefully selected and correctly used. Only commence work on your projects when you want to. Never rush to finish a project and don't drive yourself unnecessarily. Remember that this is a hobby – it should make you happy and enable you to relax and derive reward from what you do. Before starting work, make sure that external distractions are at a minimum, that the lighting is correct, and that you are warm and comfortable.

  Never work beyond your capabilities. If you don't know what you are doing then stop immediately and use a suitable source of information to learn what you need to know. You have to be very lucky indeed for all your guesses to be correct ones when working with electronics. More often than not the end result of an uninformed guess is sparks, blown fuses, smoke, a nasty smell and a steep retrospective learning curve.

  Though the temptation when you're on a roll is to keep working until you finish, don't become over tired as you will make mistakes and you may end up ruining an expensive piece of equipment in the process. Its far better to do a bit and then have a break than to go for an all night bender in the hope that everything will go well and the coffee won't unexpectedly dry up.

  As a final note, if you like a couple of beers as I do, don't attempt to do any work after imbibing. I once wired up a guitar amp PSU whilst a little intoxicated, and I thought the standard of my work was excellent. It was fortunate that I decided not to throw the switch as a quick inspection the next morning showed badly routed wires, missing or

badly positioned insulation sleeving, and a pair of incorrectly wired bridges – this is just why so many countries now have strict drink driving laws. After a couple of beers you think you're doing fine when what you're actually doing is making a right pig's ear out of the whole thing.

And finally, why not go back and re-read section 2 on electrical safety ?

In the next instalment, we'll look at correct soldering technique, and the right way to assemble circuits in general, I'll then complete the series (for now) with a short article on casing up your new masterpiece safely and attractively.

Preface

One thing that obviously confuses many people is the idea of flux density within the transformer core. While this is covered in more detail in Section 2, it is important that this section's information

is remembered at every stage of your reading through this article. For any power transformer, the maximum flux density in the core is obtained when the transformer is idle. I will reiterate this, as it is very important ...

For any power transformer, the maximum flux density is obtained when the transformer is idle.

The idea is counter-intuitive, it even verges on not making sense. Be that as it may, it's a fact, and missing it will ruin your understanding of transformers. At idle, the transformer back-EMF almost exactly cancels out the applied voltage. The small current that flows maintains the flux density at the maximum allowed value, and represents iron loss (see Section 2). As current is drawn from the secondary, the flux falls slightly, and allows more primary current to flow to provide the output current.

It is not important that you understand the reasons for this right from the beginning, but it *is* important that you remember that *for any power transformer, the maximum flux density is obtained when the transformer is idle*. Please don't forget this

---

Introduction

As you look through this article, you may be excused for exclaiming "This is for beginners? - the man's mad. Mad, I tell you!" This is probably fair comment, but transformers are not simple, and there is no simple way to provide all the information you need to understand them properly. There are sections here that probably go a little bit deeper than I originally intended, but were just too interesting to leave out.

There are parts of this article you may want to skip over, but I suggest that you do read all of it if you can. A full understanding to the extent where you can design your own transformer is not the aim, but the majority of the information is at the very least interesting, and will further your general electronics knowledge.

For those who wish to delve deeper, Section 2 does just that. It is recommended reading, even for beginners, as there is a great deal to be learned about transformers, despite their apparent simplicity.

The principles that allow us to make use of electro-magnetism were only discovered in 1824, when Danish physicist Hans Oersted found that a current flowing through a wire would deflect a compass needle. A few years after this, it was found that a moving magnetic field induced a current into a wire. From this seemingly basic concept, the field of electromagnetism has grown to the point that society as we know it would not exist without the many machines that make use of these discoveries.

Transformers are essential for all modern electronics equipment, and there are very few devices

that do not use them. Each transformer type has a specific use, and it is uncommon that a transformer made for one application can be used for another (quite different) purpose.

Before embarking on a description of the different types, the basic theory must be understood. All transformers use the same basic principle, and only the finer points ever change. A transformer works on the principle of magnetic coupling to transfer the energy from one side (winding) to the other.

Transformers are bi-directional, and will work regardless of where the input is connected. They may not work as well as they otherwise might, but basic functionality is unchanged. An ideal transformer imposes no load on the supply (feeding the primary) unless there is a load across the secondary - real life components have losses, so this is not strictly true, but the assumption can be used as a basis of understanding.

Power transformers are rated in Volt-Amps (VA). Using Watts is of no use, since a load that is completely reactive dissipates no power, but there are still Volts and Amps. It is the product of "real" voltage and current that is important - a wattmeter may indicate that there is little or no real power in the load, but the transformer is still supplying a voltage and a current, and will get hot due to internal losses regardless of the power.

Transformer cores have a quoted permeability, which is a measure of how well they "conduct" a magnetic field. Magnetism will keep to the path of least resistance, and will remain in a high permeability core with little leakage. The lower the permeability, the greater is the flux leakage from the core (this is of course a gross simplification, but serves well enough to provide an initial explanation of the term).

A transformer may be made with various materials as the core (the magnetic path). These include

- Air - provides the least coupling, but is ideal for high frequencies (especially RF). Permeability is 1.
- Iron - A misnomer, since all "iron" cored transformers are steel, with various additives to improve the magnetic properties. Permeability is typically about 500 and upwards.
- Powdered Iron - Steel magnetic particles formed into a core and held together with a bonding agent, and fired at high temperature to create a ceramic-like material with very good properties at medium to high frequencies (over 1 MHz). Especially suited to applications where there is a significant DC component in the winding or for very high power. Permeability is typically 40-90.
- Ferrite - A magnetic ceramic, usually using exotic magnetic materials to obtain extremely high permeability and excellent high frequency performance (from 50kHz to over 1MHz). An astonishing range of different formulations is available for different applications. Permeability is from about 500 up to 9,000 or more.

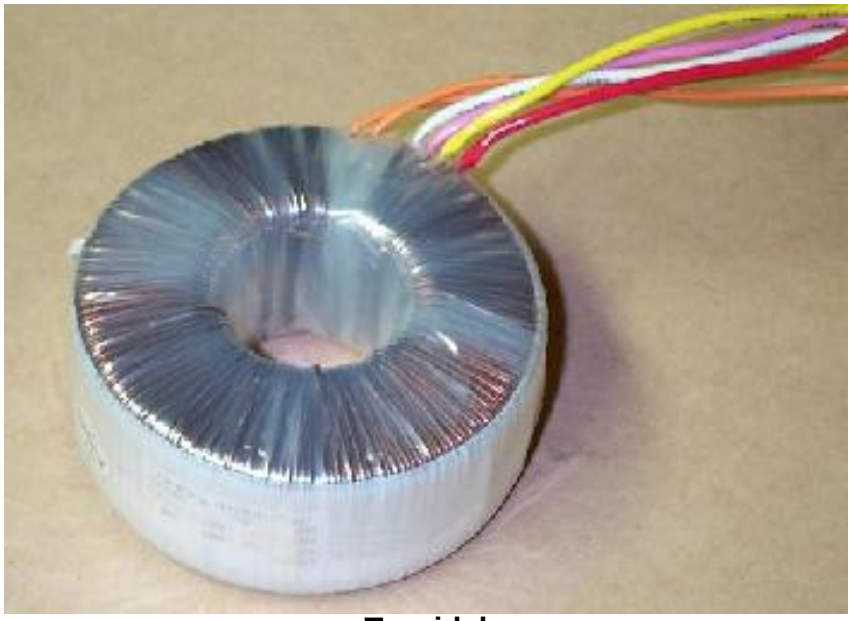
Technically, powdered iron and ferrites are both classified as soft (see below) ferrites, but they have very different characteristics, even within the same "family". They are generally unsuitable for low frequency operation, except at low levels. Ferrites are often used as signal transformers (such

as isolation transformers for telecommunications or other small signal applications), where the high permeability makes them an ideal choice for small size and high inductance.

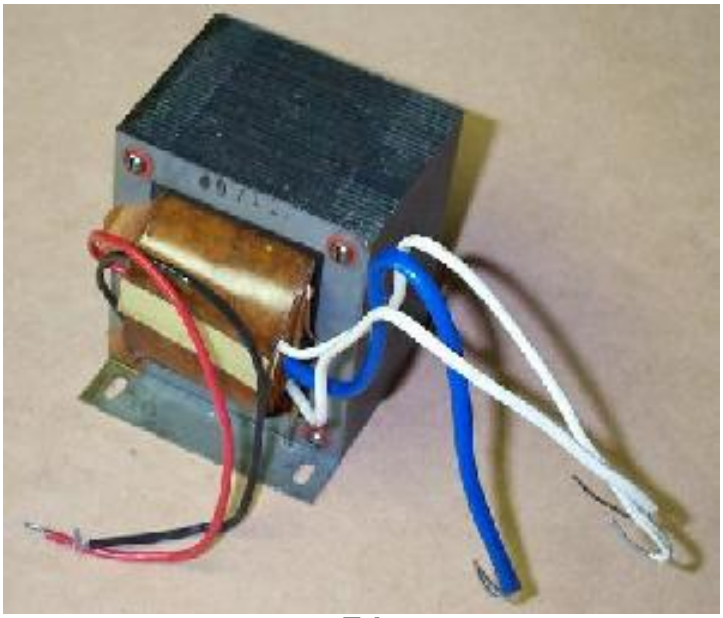
Core materials are generally classified as "soft" - this has nothing to do with their physical properties (they are all hard to very hard), but is a reference to their ability to retain magnetism (remanence). Hard magnetic materials are used for magnets, and they have a very high remanence, which is to say they retain a very large proportion of the original magnetic field that was induced into them during manufacture.

All switchmode power supplies use ferrite transformers, since conventional laminations cannot be made thin enough to prevent huge losses in the core.

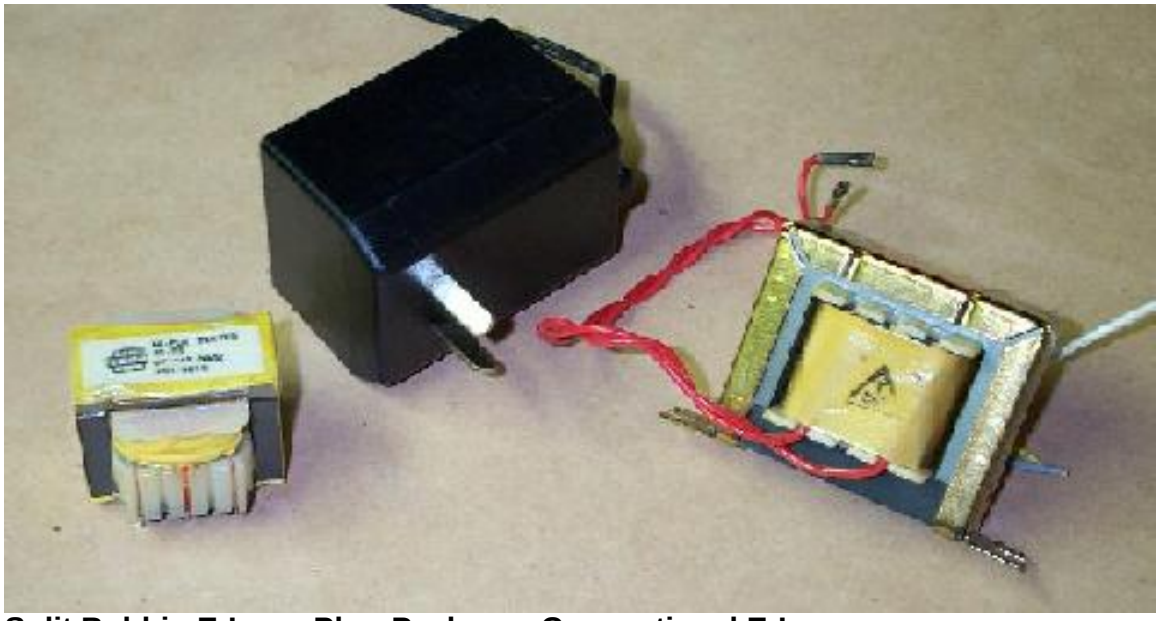
Many limitations exist in any core material. For low frequency power applications, grain-oriented silicon steel (about 4% silicon) is by far the most common, as it has a very high flux density before saturation. Almost all other materials are inferior in this respect, one of the main reasons this material is still so common.



Toroidal



E-I



Split Bobbin E-I Plug-Pack Conventional E-I

A small sample of some transformers is shown above (not to scale). The toroidal and E-I transformers are the same power rating, and a small selection of little transformers and a plug-pack (wall transformer, wall-wart, etc) are shown as well.

---

1. Magnetism and Inductors

The transformer is essentially just two (or more) inductors, sharing a common magnetic path. Any two inductors placed reasonably close to each other will work as a transformer, and the more closely they are coupled magnetically, the more efficient they become.

When a changing magnetic field is in the vicinity of a coil of wire (an inductor), a voltage is induced into the coil which is in sympathy with the applied magnetic field. A static magnetic field has no effect, and generates no output. Many of the same principles apply to generators, alternators, electric motors and loudspeakers, although this would be a very long article indeed if I were to cover all the magnetic field devices that exist.

When an electric current is passed through a coil of wire, a magnetic field is created - this works with AC or DC, but with DC, the magnetic field is obviously static. For this reason, transformers cannot be used directly with DC, for although a magnetic field exists, it must be changing to induce a voltage into the other coil.

Try this experiment. Take a coil of wire (a loudspeaker crossover coil will do nicely for this), and a magnet. Connect a multimeter - preferably analogue) to the coil, and set the range to the most sensitive current range on the meter. As you move the magnet towards or away from the coil, you will see a current, shown by the deflection of the meter pointer. As the magnet is swung one way, the current will be positive, the other way - negative. The higher the coil's inductance and the stronger the magnet (and/ or the closer it is to the coil), the greater will be the induced current.

Move the magnet slowly, and the current will be less than if it is moved quickly. Leave it still, and there is no current at all, regardless of how close the magnet may be. This is the principle of magnetic induction, and it applies to all coils (indeed to all pieces of wire, although the coil makes the effect much greater).

If you now take a handful of nails and place them through the centre of the coil, you will see that the current is increased many times - the magnetic field is now more concentrated because the steel nails make a better magnetic path than air.

The ability of a substance to carry a magnetic field is called permeability, and different materials have differing permeabilities. Some are optimised in specific ways for a particular requirement - for example the cores used for a switching transformer are very different from those used for normal 50/60Hz mains transformers.

The permeability of transformer cores varies widely, depending on the material and any treatment that may be used. The permeability of air is 1, and most traditional cores have a much higher (i.e. > 1) permeability. A couple of notable exceptions are aluminium and brass, which are sometimes used to reduce the inductance of air cored coils in radio frequency (RF) work. This is much less common than a ferrite "slug" core, which increases the inductance and is used to tune some RF transformers.

As well as permeability, magnetic cores (with the exception of air) have a maximum magnetic flux they can handle without saturation. In this context, saturation means the same as in most others - when a towel is saturated, it can hold no more water, and when a magnetic core is saturated, it can carry no more magnetic flux. At this point, the magnetic field is no longer changing, so current is not induced into the winding.

You will be unable to saturate your nails with the magnet, as there is a very large air gap between the two pole pieces. This means that the core will always be able to support the magnetic flux, but the efficiency is also very much lower because the magnetic circuit is open. Nearly all the transformers you will see have a completely closed magnetic circuit, to ensure that as much of the magnetism induced into the core as possible will pass through the winding(s).

There are some cases where a tiny air gap will be left deliberately, and this is done routinely when a transformer or coil must sustain a significant DC component as well as the AC. This is covered briefly below, but there is more on this subject in the second section of the article.

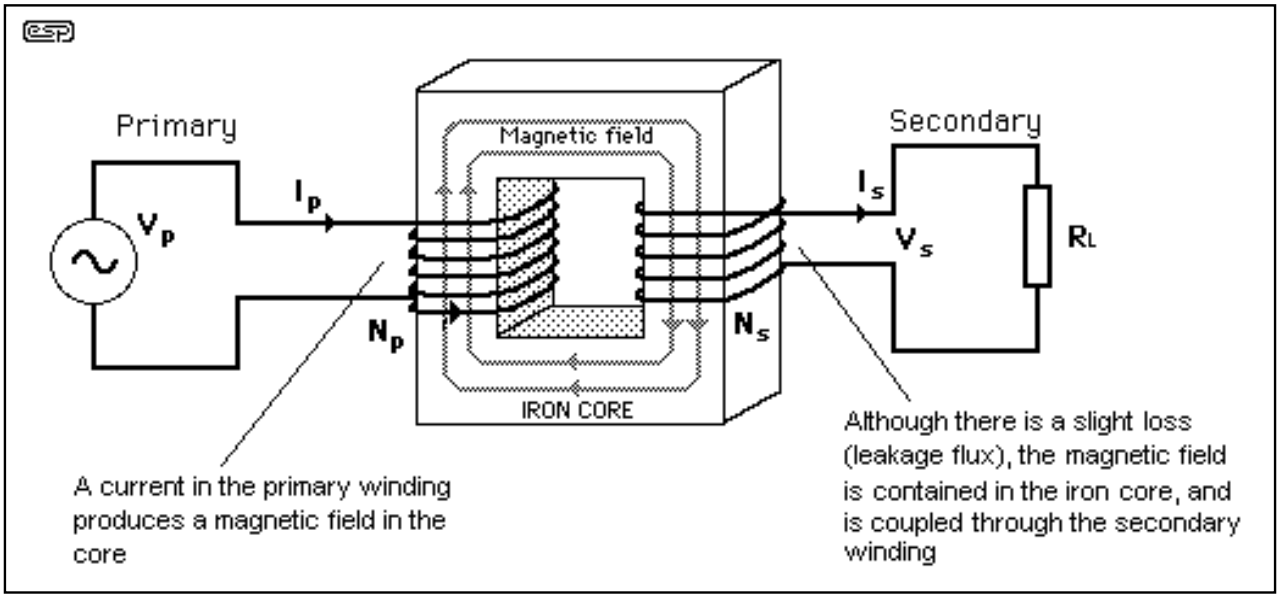


Figure 1.1 - Essential Workings of a Transformer

Figure 1.1 shows the basics of all transformers. A coil (the primary) is connected to an AC voltage source - typically the mains for power transformers. The flux induced into the core is coupled through to the secondary, a voltage is induced into the winding, and a current is produced through the load.

The diagram also shows the various parts of a transformer. This is a simple transformer, with two windings. The primary (denoted as such during the design) will induce a magnetic field into the core in sympathy with the current produced by the applied AC voltage. The magnetic field is concentrated by the core, and nearly all of it will pass through the windings of the secondary as well, where a voltage is induced. The core in this case is typical of the construction of a "C-Core" transformer, where the primary and secondary are separated. More common is the "traditional" EI (ee-eye) type, which although somewhat out of favour these days is still used extensively. This is shown below.

The magnitude of the voltage in the secondary is determined by a very simple formula, which determines the "turns ratio" (N) of the component - this is traditionally calculated by dividing the secondary turns by the primary turns ...

1.1.1 **N = Ts / Tp**

Tp is simply the number of turns of wire that make up the primary winding, and Ts is the number of turns of the secondary. A transformer with 500 turns on the primary and 50 turns on the secondary has a turns ratio of 1:10 (i.e. 1/10 or 0.1)

1.1.2 **Vs = Vp * N**

Mostly, you will never know the number of turns, but of course we can simply reverse the formula so that the turns ratio can be deduced from the primary and secondary voltages ...

1.1.3 **N = Vs / Vp**

If a voltage of 240V (AC, naturally) is applied to the primary, we would expect 24V on the secondary, and this is indeed what will be measured. The transformer has an additional useful function - not only is the voltage "transformed", but so is the current.

1.1.4 **Is = Ip / N**

If a current of 1A were drawn by the primary in the above example, then logically a current of 10A would be available at the secondary - the voltage is reduced, but current is increased. This would be the case if the transformer were 100% efficient, but even this - the most efficient "machine" we have - will sadly never be perfect. With large transformers used for the national supply grid, the efficiency of the transformers will generally exceed 95%, and some will be as high as 98% (or even more).

Smaller transformers will always have a lower efficiency, but the units commonly used in power amplifiers can have efficiencies of up to 90% for larger sizes. The reasons for the lost power will become clear (I hope) as we progress. For the time being, we shall consider the transformer to be "ideal" (i.e. having no losses) for simplicity.

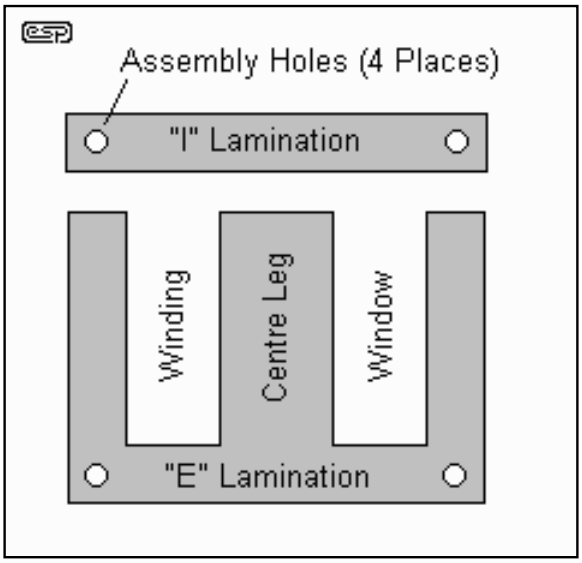

Figure 1.2 - E-I Laminations

The conventional E-I lamination set is still extensively used, and a few pertinent points are worth mentioning. The centre leg is always double the width of the outer legs to maintain the cross-sectional area. Likewise, the "I" lamination and the "back" of the E are the same width as (or sometimes slightly larger than) the outer legs. The winding window is where the copper windings live, and in a well designed transformer will be almost completely full. This maximises the amount of copper and reduces resistive losses because the windings are as thick as they possibly can be.

---

2. Magnetic Core Terminology

This list is far from complete, but will be sufficient to either get you started or scare you away. I have included the symbols and units of only three of the entries below, since most are of no real interest.

Coercivity -is the field strength which must be applied to reduce (or *coerce*) the remanent flux to zero. Materials with high coercivity (e.g. those used for permanent magnets) are called *hard*. Materials with low coercivity (those used for transformers) are called *soft*.

Effective Area - of a core is the cross sectional area of the centre limb for E-I laminations, or the total area for a toroid. Usually this corresponds to the physical dimensions of the core but because flux may not be distributed evenly the manufacturer may specify a value which reflects this.

Effective length - of a core is the distance which the magnetic flux travels in making a complete circuit. Usually this corresponds closely to the average of the physical dimensions of the core, but because flux has a tendency to concentrate on the inside corners of the path the manufacturer may specify a value for the effective length.

Flux Density - (symbol; B, unit; Teslas (T)) is simply the total flux divided by the effective area of the magnetic circuit through which it flows.

Flux linkage - in an ideal inductor the flux generated by one turn would be contained within all the other turns. Real coils come close to this ideal when the other dimensions of the coil are small compared with its diameter, or if a suitable core guides the flux through the windings.

Magnetomotive Force - MMF can be thought of as the magnetic equivalent of electromotive force. It is the product of the current flowing in a coil and the number of turns that make up the coil.

Magnetic Field Strength - (symbol: H, unit; ampere metres ($A\ m^{-1}$)) when current flows in a conductor, it is always accompanied by a magnetic field. The strength, or intensity, of this field is proportional to the amount of current and inversely proportional to the distance from the conductor (hence the -1 superscript).

Magnetic Flux - (symbol: Φ; unit: Webers (Wb)) we refer to magnetism in terms of lines of force or flux, which is a measure of the total amount of magnetism.

Permeability - (symbol; μ, units: henrys per metre (Hm^{-1}) is defined as the ratio of flux density to field strength, and is determined by the type of material within the magnetic field - i.e. the core material itself. Most references to permeability are actually to "relative permeability", as the permeability of nearly all materials changes depending upon field strength (and in most cases with temperature as well).

Remanence - (or remnance) is the flux density which remains in a magnetic material when the externally applied field is removed. Transformers require the lowest possible remanence, while permanent magnets need a high value of remanence.

I mention these here for the sake of completeness, but their real importance is not discussed further in Section 1. Section 2 of this article will revisit the terms, and their importance is somewhat enhanced in context.

---

3. How a Transformer Works

At no load, an ideal transformer draws virtually no current from the mains, since it is simply a large inductance. The whole principle of operation is based on induced magnetic flux, which not only creates a voltage (and current) in the secondary, but the primary as well! It is this characteristic that allows any inductor to function as expected, and the voltage generated in the primary is called a "back EMF" (electromotive force). The magnitude of this voltage is such that it almost equals (and is effectively in the same phase as) the applied EMF.

No simple calculation can be made to determine the internally generated voltage. As described in Part 1 of this series, for a sinusoidal waveform, the current through an inductor lags the voltage by 90 degrees. Since the induced current is lagging by 90 degrees, so too is the induced voltage (back EMF). For the sake of simplicity, imagine an inductor or transformer (no load) with an applied voltage of 100V. For the effective back EMF to equal the applied AC voltage (as it must), the actual magnitude of the induced voltage (back EMF) is 141V. If this is all to confusing, don't worry about it. Unless you intend to devote your career to transformer design, the information is actually of little use to you, since you are restrained by the "real world" characteristics of the components you buy - the internals are of little consequence. Even if you do devote your life to the design of transformers, this info is still merely a curiosity for the most part, since there is little you can do about it.

When you apply a load to the output (secondary) winding, a current is drawn by the load, and this is reflected through the transformer to the primary. As a result, the primary must now draw more current from the mains. Somewhat intriguingly perhaps, the more current that is drawn from the secondary, the original 90 degree phase shift becomes less and less as the transformer approaches full power. The power factor of an unloaded transformer is very low, meaning that although there are volts and amps, there is relatively little power. The power factor improves as loading increases, and at full load will be close to unity (the ideal).

Now, another interesting fact about transformers can now be examined.

We will use the same example as above. A 240V primary draws 1A, and the 24V secondary supplies 10A to the load. Using Ohm's law, the load resistance (impedance) is therefore 24/10 = 2.4 Ohms. The primary impedance must be 240/1 = 240 Ohms. This is a ratio of 100:1, yet the turns ratio is only 10:1 - what is going on?

The impedance ratio of a transformer is equal to the square of the turns ratio ...

3.1.1 **$Z = N^2$**

Transformers are usually designed based on the power required, and this determines the core size for a given core material. From this, the required "turns per volt" figure can be determined, based on the maximum flux density that the core material can support. Again, this varies widely with core materials.

A rule of thumb can be applied, that states that the core area for "standard" (if indeed there is such a thing) steel laminations (in square centimetres) is equal to the square root of the power. Thus a 625VA transformer would need a core of (at least) 25 sq cm, assuming that the permeability of the core were about 500, which is fairly typical of standard transformer laminations. This also assumes that the core material will not saturate with the flux density required to obtain this power.

The next step is to calculate the number of turns per volt for the primary winding. This varies with frequency, but for a 50Hz transformer, the turns per volt is (approximately) 45 divided by the core area (in square centimetres). Fewer turns are needed for a 60Hz transformer, and the turns per volt will be about 38 / core area. Higher performance core materials may permit higher flux densities, so fewer turns per volt might be possible, thus increasing the overall efficiency and regulation. These calculations must be made with care, or the transformer will overheat at no load.

For a 625VA transformer, it follows that you will need about 432 turns for a 240V primary, although in practice it may be less than this. The grain-oriented silicon steels used in better quality transformers will often tolerate much higher total flux per unit area, and fewer turns will be needed.

You can determine the turns per volt of any transformer (for reasons that will become clearer as we progress) by adding exactly 10 turns of thin "bell wire" or similar insulated wire to an existing transformer, wound over the existing windings. When powered from the correct nominal supply voltage, measure the voltage on the extra winding you created, and divide by 10 to obtain the turns per volt rating for that transformer.

Now, what earthly use is this to you? Well, you might be surprised at what you can do with this knowledge. Assume for a moment that you have a transformer for a fair sized power amplifier. The secondary voltage is 35-0-35V which is much too high to power the preamp circuit or even its power supply - but you will be able to do that with a single 16V winding. Another transformer would normally be used, but you can also add the extra winding yourself. This is almost too easy with toroidal transformers, but with others it may not be possible at all. If the transformer uses (say) 2 turns per volt, a mere 32 extra turns of bell wire (or similar) will provide 16V at the typical 100mA or so you will need. Add a 10% margin, and you still have only 36 turns to add, and this can be done in a few minutes. Make sure that the extra winding is securely taped down with a good quality tape (Kapton is highly recommended if you can get it). Do ***not*** use ordinary electricians' tape - it is not designed for the temperature that transformers may operate at under consistent load.

NOTE: Ensure that there is no possibility whatsoever of the added winding shorting between turns - this will cause the smoke to escape from the insulation in a spectacular fashion, and you may ruin the transformer itself.

---

4. Interesting Things About Transformers

As discussed above, the impedance ratio is the square of the turns ratio, but this is only one of many interesting things about transformers (well, *I* think they are interesting, anyway :-)

For example, one would think that increasing the number of turns would increase the flux density, since there are more turns contributing to the magnetic field. In fact, the opposite is true, and for the same input voltage, an increase in the number of turns will decrease the flux density and vice versa. This is counter-intuitive until you realise that an increase in the number of turns increases the inductance, and therefore reduces the current through each coil.

I have already mentioned that the power factor (and phase shift) varies according to load, and this (although mildly interesting) is not of any real consequence to most of us.

A very interesting phenomenon exists when we draw current from the secondary. Since the primary current increases to supply the load, we would expect that the magnetic flux in the core would also increase (more amps, same number of turns, more flux). In fact, the flux density decreases! In a perfect transformer with no copper loss, the flux would remain the same - the extra current supplies the secondary only. In a real transformer, as the current is increased, the losses increase proportionally, and there is slightly less flux at full power than at no load.

---

5. Examples of Transformer Uses

This is only a brief discussion of the many uses of transformers. I have avoided switchmode supplies in this section, and will only present the most common linear applications. Power supply applications are covered more fully in Section 2, and also in the article on Linear Power Supply Design.

It would be impossible to cover all aspects of transformers and their uses, since they are so diverse and are used in so many different things. Computer network interface cards, modems, through to power amplifiers and microwave ovens, car and marine ignition systems, Tesla coils and moving coil phono preamps are a very small sampling of the diversity of the humble transformer (well, maybe it is not so humble after all :-)

5.1 - Push-Pull Valve Output Stage

Apart from the obvious uses in power supplies, transformers are used in other areas as well. Valve power amplifiers nearly all use a transformer for the output stage, and this converts the high impedance of the anodes to the loudspeaker impedance, as well as providing the voltage feed to the output valves. No biasing or other support components have been shown here - for more information on this, have a look at How Amplifiers Work. <

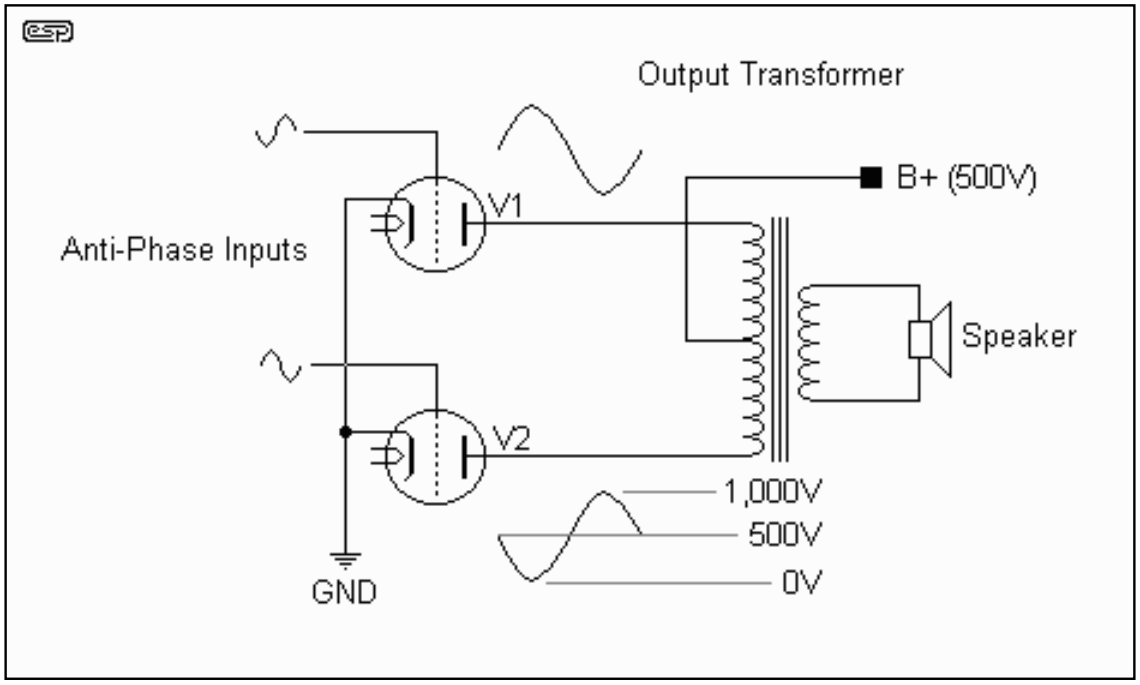

Figure 5.1 - Push-Pull Valve Output Stage

Figure 5.1 shows how this works. The primary winding acts in a manner that may surprise you at first, but it is quite in accordance with all the theory. The supply voltage shown is 500V, and we will assume that the valve can turn on hard enough to reduce this to zero alternately at each end of the winding. This is never the case, because valves do not have a low enough internal impedance, but it makes the explanation simpler :-)

Neither valve will draw appreciable current with no signal, and the amount drawn does not magnetise the core. The reason is simple - an equal amount of current is drawn through each section of the primary winding, but effectively in opposite directions. The magnetic field created by one half of the winding is cancelled by that from the second half, leaving a nett steady state magnetic field of zero.

When valve V1 turns on completely, the voltage at its end of the winding is reduced to zero, and the voltage at the anode of V2 is 1,000 volts. This must be the case, or the transformer theory is in tatters. The primary is operating as an "auto-transformer". Likewise, when V1 turns off and V2 turns on, the situation is reversed. You may well ask why 2 valves are needed at all? The voltage from one valve is quite capable of swinging the voltage from one extreme to the other, it would seem.

This is not the case. Since the valve can only turn on, it will only be able to supply current for 1/2 of the waveform. A Class-A push-pull design will normally have each valve carrying 1/2 of the maximum peak current required. In the case of a push-pull design, there is no core saturation because of the DC current (which cancels out as before), so although two valves are needed, the transformer will be smaller and will have very much better performance. Single-ended Class-A amps require a very large core with an air-gap to prevent saturation. This reduces the performance of the transformer dramatically, and increases distortion and gives a poorer low frequency response because of the lower inductance. High frequencies can also be adversely affected,

because the air-gap causes some of the magnetic flux to "leak" out of the core. This is the cause of leakage inductance (covered in more detail in Section 2).

It is worth noting that the effective peak to peak swing across the entire transformer primary is 2,000V. When V1 is turned on completely, it has zero volts (for our example only) at the plate, and V2 turns on it has a plate voltage of 1,000V. V2 has exactly the same voltage peaks, but they are 180 degrees out of phase. The total voltage across the transformer is therefore the sum of the two voltages. From an AC perspective, the B+ supply line can be considered the same as zero volts (remember it will be bypassed with a large capacitance).

The RMS voltage is easily calculated from the standard formula ...

5.1.1 **$V_p = V_{p-p} / 2$**

To obtain the peak value from peak to peak, then ...

5.1.2 **$V_{rms} = V_p / \sqrt{2}$**

To find the RMS value.

In this case, the peak to peak voltage is 2,000V, so peak is 1000V. The RMS value is 707V.

5.2 Single Ended Triode (SET) Output

Figure 5.2 shows the basic arrangement of a SET amplifier output stage. The full DC current must flow through the transformer primary, and as discussed above, an air-gap must be introduced into the core to prevent saturation. Because an air gap reduces the efficacy of the magnetic path, the core needs to be considerably larger than would otherwise be the case.

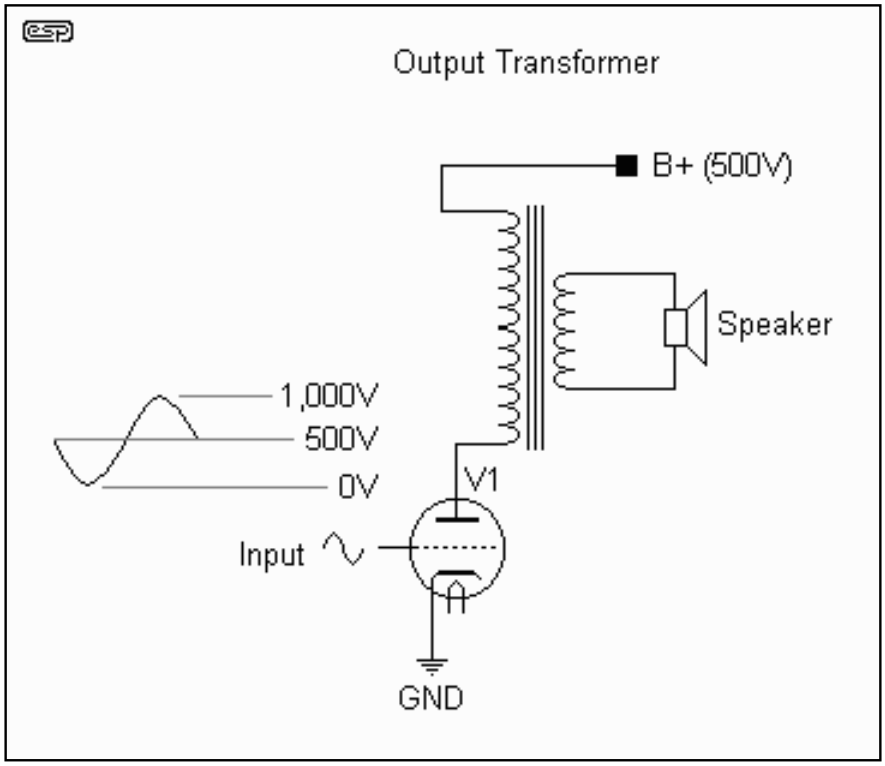

Figure 5.2 - Single Ended Triode Output Stage

The core operates with only one polarity of flux, which varies with the signal. One might think that this alone would reduce distortion, since the flux never crosses the zero point, but this is not the case. It is still necessary for the flux to change, and the characteristics of magnetic materials indicate that the resistance to change (rather than the absolute polarity of the magnetic field) is the dominant factor. The valve (and transformer primary) must now carry a current equal to the peak AC current demanded by the load - subject to the transformation ratio, of course. Maximum negative swing (valve turned on) will double this current, and it will be reduced to nearly zero as the valve turns off (positive swing). As the current is reduced below the average standing (quiescent) current, the voltage across the transformer increases in the opposite polarity - hence the fact that the plate voltage exceeds the supply voltage.

For the same power output, the valve in a single ended circuit must be considerably larger than that required for a push-pull circuit, because of the higher dissipation needed for the extra current. There are also many other issues with this arrangement, and they will be covered in more detail in Section 2.

Not the least of these is that the (probable) advantage of the additional voltage swing when using a centre tapped transformer is now gone, so the maximum RMS voltage that can be developed is 353V - a significant drop in primary AC voltage.

5.3 Line Level Applications

Transformers are also used for "line-level" low power applications, typically balanced microphone inputs and line output stages. A transformer is unsurpassed for real-world balanced circuits, as the input or output is truly floating, and requires no connection to earth. This means that common mode signals (i.e. any signal that is common to both signal leads) are almost completely rejected.

Figure 5.3 shows a transformer balanced input, converting to unbalanced. The signal is amplified, and sent to the output transformer for distribution as a balanced signal again. The "amplifier" will typically be a mixing console, and will take mic or line level signals as the input (having run from the stage to the mixing area), and the final mixed output is sent back to the stage for the main (Front of House) public address amplifiers and speakers. There may be in excess of 100 metres of cable from the microphone to the mixer and back to the main amps, and barely any noise will be picked up in the process.

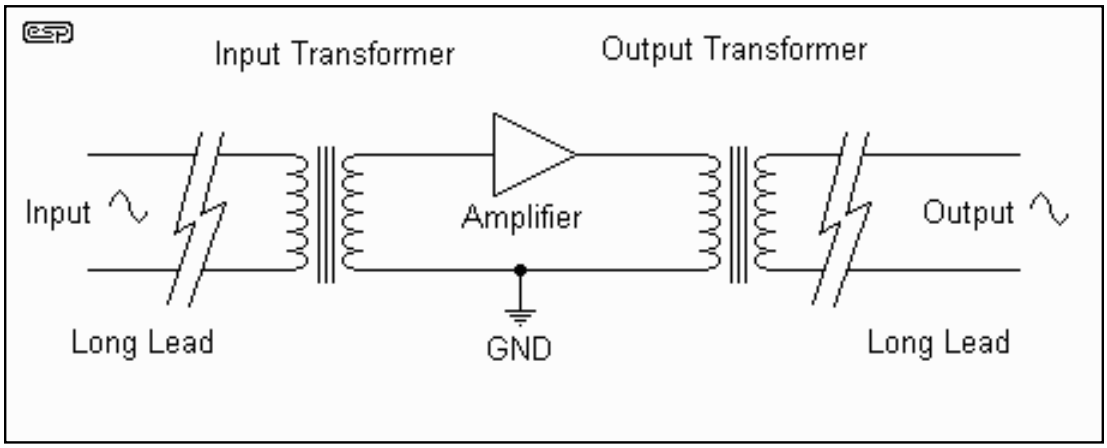

Figure 5.3 - Balanced Microphone and Line Outputs

The telephone system used to be completely dependent on transformers to feed the signal from the exchange (or Central Office in the US) to the customer premises equipment (CPE). The phone switch used in offices, (PABX - Private Automatic Branch Exchange, or PBX for the US) equipment still uses transformers for nearly all incoming circuits whether analogue or digital. The principle is exactly the same as for the audio application shown above, except that for telephone circuits there is usually a DC voltage present to power the CPE (in the case of a home telephone) and to provide some basic signalling. All modern PABX circuits use ferrite cored transformers, with DC isolation circuitry to ensure that no DC flows in the transformer windings, as this degrades the performance in the same way as with the output transformer for a SET power amplifier.

Audio applications for transformers in balanced circuits came from the telecommunications industry where the concepts were first thought of. A telephone line may be 4km or more in length, and is not shielded, so a method of eliminating hum and noise was essential.

---

6. Safety

Safety is a major consideration for any power transformer (and in the case of telecommunications, the isolating transformers), and electrical contact between primary and secondary must not be allowed under ***any*** realistic fault condition. All countries have safety standards that apply to transformers where electrical isolation is important, and if in any doubt about the safety of a transformer for a particular purpose, make sure that you verify that the transformer complies with the relevant standard(s). It is well beyond the scope of this article to cover all the possibilities of standards and compliance issues, so I shall leave that to you.

Many power transformers are fitted with an internal "once only" thermal fuse that will become open circuit in the event that a preset temperature is exceeded. This temperature is chosen to be the maximum safe temperature of the windings before the insulation melts or breaks down, so in the event of a fault, the thermal fuse will open before the insulation is damaged and the component becomes potentially dangerous. It also helps to prevent the risk of fire (and no, this is not intended to be humorous - a friend of mine had his house burned to the ground because of a faulty power transformer in a video recorder - as determined by the fire investigators. True story!). See Figure 6.1 (below) as an example of how bad things can get if the transformer is not protected.

Once the thermal fuse opens, the transformer must be discarded, as it is usually not possible to gain access to the fuse for replacement. This is not as silly as it may sound, since the thermal effects on the insulation cannot be predicted, and the transformer may be unsafe if it were still able to be used.

There are transformers that are designed to be "intrinsically safe", and these usually have the windings on separate sections of the core, not in physical contact with each other. If the core is connected to the electrical safety earth (which is usually a requirement), no method of failure (including a complete meltdown) in the primary will allow mains voltage to appear at the secondary. Side by side windings are the next safest, and although primary and secondary are on the same bobbin, the material used is selected to withstand high temperatures and will maintain separation of the windings. Toroidal cores and other concentrically wound transformers are the least safe, since the only separation between primary and secondary is a rather thin layer of insulation. This is one of the reasons that thermal fuses are often used with toroids.

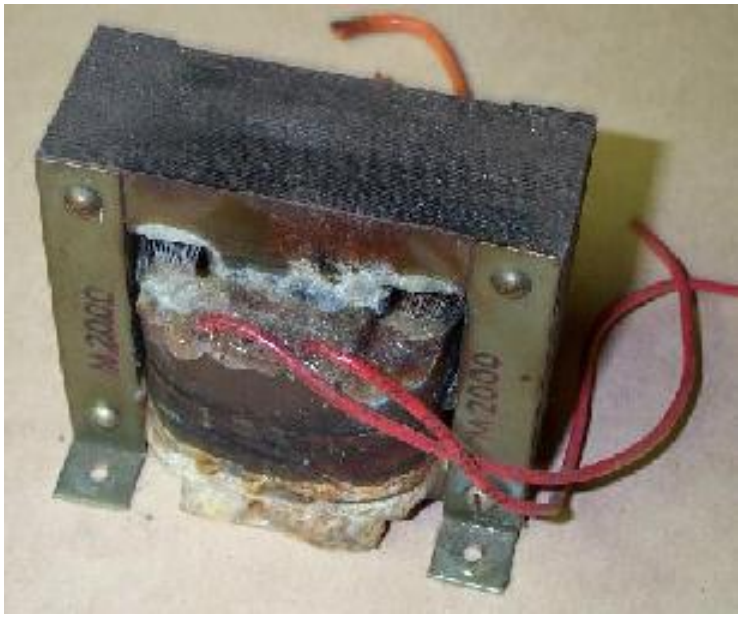

Figure 6.1 - Transformer Meltdown

Figure 6.1 shows a transformer I removed from a repair job. It is a complete meltdown, and the remains of the plastic bobbin can be seen quite clearly. In any circuit, it is extremely important to protect the user from coming into contact with the mains should this happen. In this case, the bobbin had melted away from the windings, dribbled on the base of the equipment, and generally

made a big mess. Despite all this, there was no electrical connection between primary and secondary or the laminations. This was a well made transformer (it failed due to gross continuous overload, not any failure in the transformer itself).

Proper safety earthing is the only real way to ensure that a transformer that fails catastrophically (such as that shown) does not cause the chassis to become live - not all transformers are created equal when safety is concerned. Correct fusing will ensure that the fuse blows - hopefully *before* the electrical safety is compromised. A thermal fuse would have prevented the situation from becoming as bad as shown, but the transformer would have been just as dead.

---

7. Noise

Transformers make noise. This is not only the electrical noise that is created by the nasty current waveform through the windings, diodes and into the filter capacitors, but actual audible noise. One source is winding vibration, due to the wire moving because of the magnetic field and the current flowing through the conductors. This is to be avoided at all costs, since constant vibration will eventually wear away the insulation, the windings will short circuit, and the transformer is ruined. Fortunately, this is rather unusual, but it can (and does) happen on occasion.

Most of the noise is from the laminations or other core material, which contract when subjected to an intense magnetic field. This is called magnetostriction, and happens to a greater or lesser degree with all magnetic materials. A stethoscope will verify the source of the noise, and there is little or nothing that will stop it. A resilient mounting will stop most of the noise from being acoustically amplified by the chassis, and generally the noise will be worse at no load. In some cases, a transformer may have been designed for 60Hz, but is used at 50Hz. In this case, the flux density will probably exceed the maximum allowable for the core, and the transformer will get much hotter than it should, and will almost certainly be a lot noisier as well. Toroidal transformers will generally be much quieter than EI laminated (i.e. conventional) types.

Most (all?) transformers designed specifically for 60Hz will eventually fail with 50Hz mains, due to overheating. The reverse is not true, and 50Hz transformers can be operated quite safely on 60Hz.

Another problem with E-I laminations is that they may not have been fastened together well enough, and this allows the outer laminations in particular to vibrate. Better quality conventional transformers will commonly be impregnated with varnish (sometimes under vacuum) and baked in a moderate oven until tender .... oops, I mean until the varnish is completely dry. This binds the laminations and windings together, preventing noise, and also making the transformer more resistant to damage by water or other contaminants, and/ or under conditions of high humidity (such as in the tropics).

Section 2

Click here to view the second part of the article. As I am sure you have noticed, transformers are

not so simple after all.

References

These references are common to both sections of the article, although most only apply to Section 2. Countless different Web pages were researched during the compilation of these articles, and although some were interesting, the majority were of minimal use. Of those who I actually remember (a daunting task in itself, considering the sheer amount of searching I had to do), I must "thank" the following Web pages (in alphabetical order) ...

The following (slightly edited) definitions are from Units of Measurement

Units of Measurement site copyright by Russ Rowlett and University of North Carolina at Chapel Hill.
Definitions used by permission.

Tesla (T) - flux density (or field intensity) for magnetic fields (also called the magnetic induction). The intensity of a magnetic field can be measured by placing a current-carrying conductor in the field. The magnetic field exerts a force on the conductor which depends on the amount of the current and the length of the conductor. One Tesla is defined as the field intensity generating one newton of force per ampere of current per meter of conductor. Equivalently, one Tesla represents a magnetic flux density of one Weber per square meter of area. A field of one Tesla is quite strong: the strongest fields available in laboratories are about 20 Teslas, and the Earth's magnetic flux density at its surface, is about 50 microteslas (μT). One Tesla equals 10,000 gauss. The Tesla, defined in 1958, is named after Nikola Tesla (1856-1943), whose work in electromagnetic induction led to the first practical generators and motors using alternating current (much to the annoyance of Edison, who claimed DC was "safer").

Weber (Wb) - magnetic flux. "Flux" is the rate (per unit of time) in which something crosses a surface perpendicular to the flow. In the case of a magnetic field, then the magnetic flux across a perpendicular surface is the product of the magnetic flux density, in Teslas, and the surface area, in square metres. If a varying magnetic field passes perpendicularly through a circular loop of conducting material (one turn), the variation in the field

induces a electric potential in the loop. If the flux is changing at a uniform rate of one Weber per second, the induced potential is one volt. This means that numerically the flux in webers is equal to the potential, in volts, that would be created by collapsing the field uniformly to zero in one second. One Weber is the flux induced in this way by a current varying at the uniform rate of one ampere per second. The unit honours the German physicist Wilhelm Eduard Weber (1804-1891), one of the early researchers of magnetism.

Introduction

For those brave souls who have ploughed their way through the first section - I commend you! As you have discovered, transformers are not simple after all, but they are probably far more versatile than you ever imagined. They are, however, real world devices, and as such are prey to the failings of all real components - they are imperfect.

This section will concentrate a little more on the losses and calculations involved in transformer design, as well as explain in more detail where different core styles are to be preferred over others. Again, it is impossible to cover all the possibilities, but the information here will get you well on your way to a full understanding of the subject.

The first topic may seem obvious, but based on the e-mails I get, this is not the case. Transformers can have multiple windings, and these can be on the primary or secondary. Windings can be interconnected to do exciting and different things, but from a safety perspective it is ***imperative*** that primary and secondary windings are kept segregated.

There are several references to "shorted turns" within this article. If any two turns of a winding short to each other, the current flow is limited only by the DC resistance of the shorted section of the winding. The current flow is enormous, and with even one shorted turn, the transformer is no longer serviceable and must be discarded or rewound. No shield or other conductive material may be wrapped around a core and joined, as this creates a shorted turn capable of possibly hundreds of amperes. The exception to this is the magnetic shield sometimes used with E-I laminated transformers, but this is wrapped around the entire transformer, and is not considered as a "turn" as it is not in the winding window with the primary and secondary.

It is also worth noting that a transformer behaves quite differently depending upon whether it is driven from a voltage source (i.e. very low impedance, such as a transistor amp or the mains) or a current source or intermediate impedance. This will be covered in a little more detail further on in this article.

---

8. Windings in Series and Parallel

Many transformers are supplied with two (or more) secondaries. In many cases, the data sheet will indicate that the windings may be connected in parallel or series. For example, a toroidal transformer may be rated at 2 x 25V at 5A (250VA). With the windings in parallel, the available current is 10A, but only for a single voltage of 25V AC. Connect the windings in series, and you get 50V at 5A, or by referencing the centre tap to earth, the familiar 25-0-25 designation.

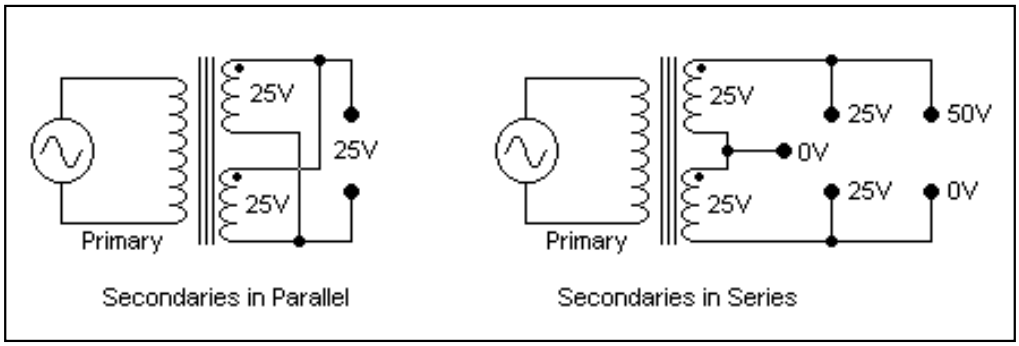

Figure 8.1 - Windings in Series and Parallel

There are some rules that apply to winding interconnections - if you break them, you may break your transformer as well. Note the dots on the windings - this is the traditional way to identify the start of a winding, so that the phase may be determined.

Antiphase wiring will not harm a transformer when wired in series (although the zero volts output for equal windings is somewhat limited in usefulness). Parallel antiphase connection will destroy the transformer unless the fuse blows - which it will do mightily. Always use a fuse when testing, as a simple mistake can be rather costly without some form of protection for the transformer and house wiring!

8.1 Series Connections

Windings may be connected in series regardless of voltage. The maximum current available is the rating specified for the ***lowest*** current winding. Windings may be connected so as to increase or decrease the final voltage. For example, dual 25V windings may be connected so as to produce 50V or zero volts - although the latter is not generally useful :-)

When windings are connected in phase the voltages add together, and if connected out of phase, they subtract. A 50V, 1 amp winding and a 10V 5 amp winding may therefore be connected to provide any of the following ...

- 10V @ 5A - The 10V winding by itself
- 50V @ 1A - The 50V winding by itself
- 60V @ 1A - Both 50V and 10V windings, connected in series and in phase
- 40V @ 1A - Both 50V and 10V windings, connected in series and out of phase

The above example was used purely for the sake of example (such a transformer would not be useful for most of us), but the principle applies for all voltages and currents. Series connections are sometimes used in the primaries as well, mainly for equipment destined for the world market. There are several common mains supply voltages, and primary windings are connected in various combinations of series and parallel to accommodate all the variants.

8.2 Parallel Connections

Parallel connection of transformer windings is permitted in one case only - the windings must have exactly the same voltage output, and must be connected in phase. Different current capacities are not a problem, but it is rare to find a transformer with two windings of the same voltage but different current ratings.

Even a 1V difference between winding voltages will cause ***big*** problems. A typical winding resistance for a 5A winding might be 0.25 ohm. Should two such windings be connected in parallel, having a voltage difference of 1V, there will be a circulating current limited only by the resistances of the windings. For our example, the total winding resistance is 0.5 ohm, so a circulating current of 2A will flow between the windings, and this is completely wasted power. The transformer will get unexpectedly hot, and the maximum current available is reduced by the value of the circulating current.

Should the windings be connected out of phase, the circulating current will be possibly 100A or more, until the transformer melts or the fuse blows. The latter is generally to be preferred.

The transformer manufacturer's specifications will indicate if parallel operation is permitted. If you are unsure, measure the voltages carefully, and avoid parallel connection if the voltages differ by more than a couple of hundred millivolts. There will always be a difference, and only the manufacturer's winding tolerances can predict what it will be. With toroidal transformers, the windings are often bifilar, meaning that the two windings are wound onto the transformer core simultaneously. The tolerance of such windings is normally very good, and should cause no problems.

---

9. Valve Output Transformer Example Calculation

In Section 1, I described a very basic push-pull valve output stage. Now it is time to examine this a little more closely. We shall use the same voltages as were obtained in the basic description of Section 1 - an RMS voltage of 707V. It must be said that the following is not intended to be an accurate representation of valves, as the losses in real life are somewhat higher than indicated here. This is for example only. We shall also take the (typical) losses as 10%, and adjust the secondary impedance accordingly.

A valve (tube) amplifier is required to drive an 8 ohm loudspeaker. The primary impedance (called the Plate-Plate impedance for a push-pull amplifier) is 6,000 Ohms, and the supply voltage is 600V. Allowing for losses of 100V across each valve, the maximum voltage swing on the plates (anodes) of the valves is 1kV p-p (or effectively 2kV peak to peak on the transformer primary). What is the output power?

Secondary impedance will be 7.2 ohms, based on the 10% loss ...

Zs = 8 / 1.1 = 7.2 ohms

The impedance ratio is calculated first ...

Z = 6,000 / 7.2 = 833

The turns ratio may now be determined

N = √833 = 28.8 (29:1)

The voltage ratio is the same as the turns ratio, so the peak to peak voltage to the speaker is

Vs (p-p) = Vp / N = 2,000 / 29 = 69V

To convert this to RMS ...

Vp = 1/2 Vp-p = 34.5V
RMS = peak * 0.707 = 24V
Power is therefore 24^2 / 8 = 72W

Notice that at each calculation, the figures were rounded to the closest (or next lowest) whole number.

This was for convenience, but the way I did it also gives a conservative rating that is more likely to be met in practice.

Ouch! Sorry, that *was* a bit nasty for this time of day :-)

A bit nasty or not, it is a reasonable representation of the reality of an output transformer design, but naturally real (as opposed to my "invented" figures) will be substituted. Typically the losses across the output valves will often be far greater than indicated here. but that depends on the valves used (and the topology - triodes behave very differently from pentodes or tetrodes).

Just to complete this section and to put the above into perspective, I have included a few figures (taken from the 1972 Miniwatt Technical Data manual) for the EL34/ 6CA7 power pentode - quite possibly my all-time favourite output valve.

Class	Mode *	Plate Volts	Plate Current	Screen Volts	Screen Current	Grid Bias	Load Impedance	Power Output	Comments
Class-A	S-E	250	100	265	15	-13V	2,000	11W	Plate supply = 265V, THD** 10%
Class-AB	P-P	375	2 x 75 ## 2 x 95	365	2 x 11.5 2 x 22.5	-19V	3,400 (p-p) #	35W	Cathode bias resistor 130 ohms, common screen resistor, 470 ohms, THD 5%
Class-B	P-P	775	2 x 25 2 x 91	400	2 x 3.0 2 x 19	-39V	11,000 (p-p)	100W	Plate supply, 800V, THD 5%
Class-A (Triode)	S-E	375	70	-	-	-25V	3,000	6W	Cathode bias resistor 370 ohms, Screen tied to plate, 400V plate supply, THD 8%
Class-AB (Triode)	P-P	400	2 x 65 2 x 71	-	-	-28V	5,000 (p-p)	16W	Screen tied to plate, Cathode bias resistor 220 ohms, THD 3%

Table 9.1 - Abbreviated Data For EL34 Power Pentode

*	S-E: Single Ended, P-P: Push-Pull
**	THD - Total Harmonic Distortion (this is for the valves only, and does not include transformer distortion)
#	p-p: Plate to Plate impedance
##	First figure is no load, second figure is full power

As can be seen quite readily, the distortion of the S-E configurations is much worse than the push-pull versions. Not only that, but (to maintain relevance :-) the transformers are larger and harder to design, and even then will be worse than their push-pull counterparts. In the maximum efficiency configuration, power output is 100W, and distortion is still lower than for either of the single ended configurations. The losses across the output valve in this mode are about 58V, but are considerably higher for any of the cathode biased versions - as one might expect.

This will be revisited in another article on the design of valve amplifiers.

---

10. Compromises

It is very important that the core does not saturate (see below), since there will be no variation of flux, no back EMF, and excessive current will be drawn - especially at no load. The final design of any

transformer is a huge compromise, and there is a fine line between a transformer that will give acceptable regulation and one that gets too hot to touch at no load.

Somewhat surprisingly, the flux density in the core actually decreases with increased load current drawn from the secondary. Even though the primary is drawing more current, this is transferred to the secondary and thence the load - it does not cause the flux density to increase. The flux density decreases largely due to primary resistance, which causes the effective primary voltage to decrease. Any voltage lost to resistance (remember Ohm's law?) is voltage that is "lost" to the transformer, and serves no function in the transformation process. It does cause the transformer to get hot (or hotter) than at no load.

Also, the normal variation of mains voltage must be allowed for. A transformer running at the very limit of saturation at nominal supply voltage will overheat if the mains is at the upper (normal) limit. A transformer that is designed to run at the limit will have superior regulation compared to a more conservative design, but this is of little consequence if it fails in normal use.

For audio transformers, there are even more compromises.

---

11. Losses

As discussed earlier, a transformer is a real component, and therefore has losses. These are divided into two primary types, but there are other "hidden" losses as well. All losses reduce efficiency, and affect frequency response. The low frequency limit is determined by the primary inductance, and this is proportional to the area (and consequent mass) of the transformer core. High frequency losses are caused by eddy currents in the core (see below), and by leakage inductance and winding capacitances.

None of these can be eliminated, but by careful selection of core material, winding style and operational limits, they can be reduced to the point where the transformer is capable of doing the job required of it.

11.1 Iron (Core) Losses

Core losses are partly the result of the magnetising current, which must keep forcing the magnetic field in the core to reverse in sympathy with the applied signal. Because the direction of flux is constantly changing, the transformer core is subject to a phenomenon called hysteresis, shown in Figure 11.1

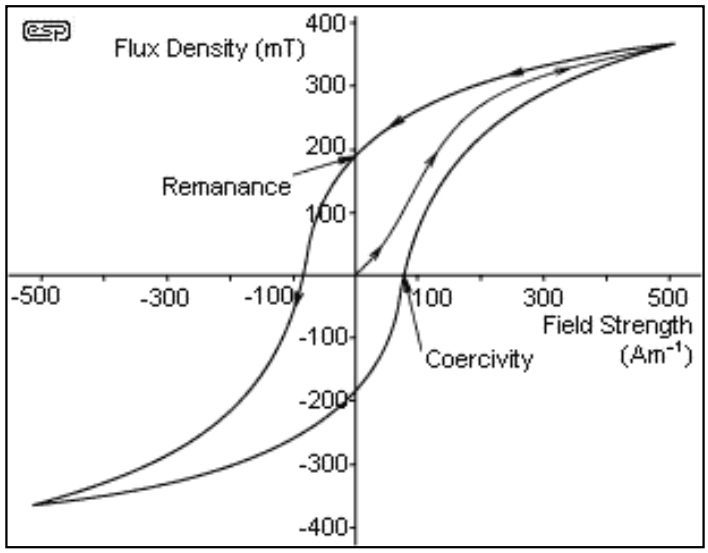

Figure 11.1 - The Hysteresis Loop

When the magnetomotive force is reversed in a magnetic material, the residual magnetism (remanence - also known as remnance) in the core tries to remain in its previous state until the applied flux is too great (coercivity). It will then reverse, and the same situation will occur twice for each cycle of applied AC. The power required to force the flux to change direction is the hysteresis loss, which although usually small, is still significant. I am not about to go into great detail on this, but a Web search will no doubt reveal more information than you will ever need.

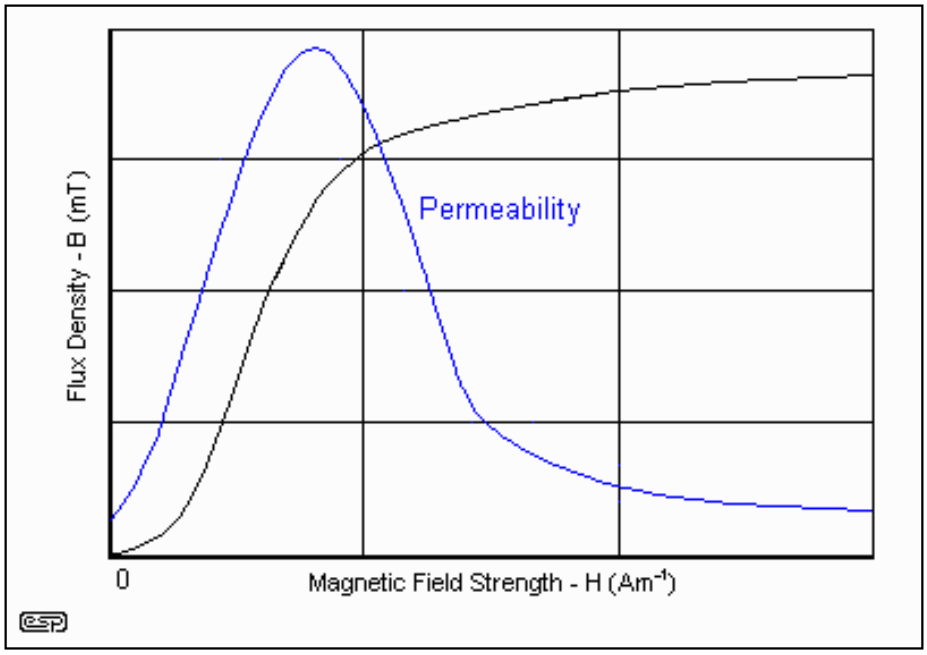

Figure 11.2 - B-H Curve

As can be seen from the two magnetic field drawings, the flux density (B) is dependent upon the applied magnetic field strength (H). For the example shown, the "knee" of the curve coincides with the point where permeability starts to fall. Above this, a progressively larger change in the magnetic field is required to increase the flux density. This is saturation, and most transformers will be designed to operate at or below the knee. Above the knee is dangerous, as a small increase in applied voltage will not produce the required increase in back EMF, and the primary current will increase disproportionately to the rise in voltage. In other words, the transformer will be too sensitive to applied voltage, and will

possibly self destruct if the mains voltage were even slightly higher than normal.

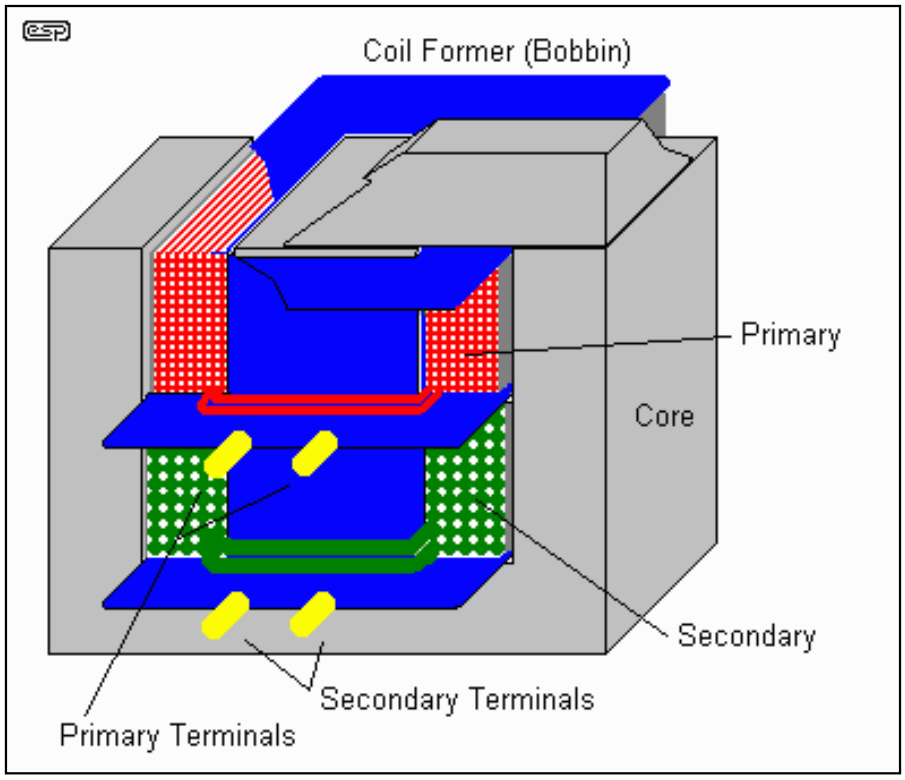

Figure 11.3 - Cutaway View of a Transformer

The transformer shown is a "split bobbin" type, having separate sections on the former for the primary and secondary windings. This reduces the capacitance between windings, and also provides a safety barrier between the primary and secondary. For some applications, this is the only winding method that meets safety standards. It is also very simple to add an electrostatic shield between the windings - a flat plate of thin metal is cut so that it can be slipped over the bobbin, and the ends are insulated so that it does not create a shorted turn. This is connected to earth, and prevents noise from being capacitively coupled between windings. The shield would logically be placed on the secondary side of the bobbin divider for safety.

In addition, there are so-called "eddy current" losses. These are small circulating currents within the magnetic core, as shown (exaggerated) in Figure 11.4, and these cause the core material itself to get hot. Each of these eddy current loops acts as a tiny shorted turn to the transformer, and to reduce the effect, the core is laminated - i.e. made from thin sheets of steel, insulated from each other. The thinner the laminations, the smaller are the eddy current losses, but they will never be eliminated. Eddy current losses increase with frequency, requiring different techniques for high frequency operation, and are the major contributor to the iron losses in any transformer.

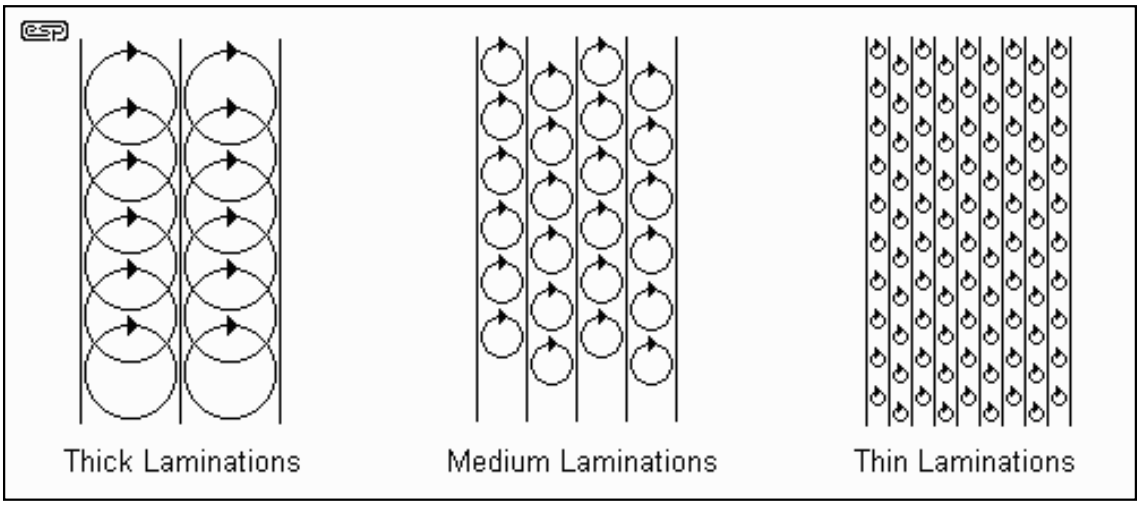

Figure 11.4 - Eddy Currents in Laminations

The eddy currents are shown for three lamination thicknesses. Although not shown (for the sake of clarity), the current loops are constantly overlapping, and are effectively infinite in number. The thick laminations allow the loops to be larger, and therefore the lamination section is cut by more magnetic "lines" of force, so the currents (and losses) are larger. For high frequencies (above 10kHz), it is generally not possible to make laminations thin enough to prevent the losses from becoming excessive, and ferrite materials are preferred. These effectively have a huge number of incredibly small magnetic particles, all insulated from each other, and eddy current loops are very small indeed. Even so, ferrite materials are normally specified up to a few hundred kilo-Hertz for power applications, before the losses become too great again.

Iron losses of both types are the primary source of losses in any transformer that is operating at no load or only light loading. At no load, the core flux density is at its maximum value for any given applied voltage / frequency combination. Power transformers are usually designed to operate below the knee of the saturation curve (this is essential with toroidal types), with sufficient safety margin to ensure that the core can never saturate.

Saturation involves a dramatic loss of permeability (and therefore inductance), and causes the primary current to rise disproportionally to an increase of voltage. Significant waveform distortion occurs once the core starts to saturate.

As a load is drawn from the secondary, the primary must supply more current, and this means that the resistance of the primary winding becomes significant. Any voltage 'lost' to winding resistance is effectively no longer part of the applied voltage, so core flux is reduced.

11.2 Copper Losses

Following on from the previous point, the voltage lost to winding resistance is copper loss, and all such losses must be dissipated as heat. Consider a transformer at idle, with 240V on the primary. The primary resistance may be in the order of 5 ohms, and the idle current perhaps 20mA. The loss is determined by the normal power formula, and in this case is ...

$$\mathbf{P = I^2 * R} = 0.02^2 * 5 = 2\text{mW}$$

V = R * I = 5 * 0.02 = 100mV

For all intents and purposes, the full 240V is applied to the primary. When the transformer is loaded, this changes. Let's assume 1A primary current and look at the figures again ...

P = I² * R = 1.00²* 5 = 5W
V = R * I = 5 * 1.00 = 5V

Now, the effective primary voltage is only 235V, because 5V is 'lost' due to winding resistance. Naturally, if the voltage is lower, the flux density must also be lower.

Minimising copper loss in both primary and secondary is essential, but there are limits to what can be achieved. These are imposed by the available space for the winding, and just how much copper the manufacturer can get into that space. Allowance must still be made for insulation and manufacturing tolerances.

You will see that in Figure 11.3 the windings are shown stacked directly on top of each other. Surely a more efficient winding can be made by making use of the "valleys", minimising the winding height and allowing heavier windings. Ah, if only life were that simple! The windings are traditionally made from left to right, then right to left, so the turns in each layer are at a slight angle relative to the layer below or above. It is therefore not possible to interleave the windings properly, and if you were to design a transformer based on the erroneous assumption that interleaving would work, the winding would not fit into the window.

For the normal layered construction (i.e. primary closest to the core, and secondary over the top), we also have to allow for insulation between primary and secondary, and in some cases additional insulation is used between layers of larger transformers because of the large voltage difference between the outer limits of each winding. These are another set of compromises that must be made, all of which mean that the windings must be thinner than we might like, and thus the losses are increased.

Because any length of wire has resistance, there will always be winding resistance. The greater the resistance for a given current, the more power is dissipated as heat - this is a complete loss. At no load, there is virtually no loss, since the currents are low, but as secondary current increases, so too do the copper losses.

Copper loss is the primary source of loss at any appreciable power from a transformer. Conventional rectifiers as used in semiconductor amplifier power supplies cause the resistance to be more significant than would otherwise be the case. See Linear Power Supply Design for more details on these losses.

Ultimately, copper losses limit the power available from a transformer. Since all copper loss results in heat, this becomes a limiting factor, so once you reach the point where the temperature rise cannot be limited to a safe value, the size of the core must be increased. This allows the manufacturer to use fewer turns per Volt, and the larger core has more space for the windings. The wire size can therefore be increased, so copper losses are brought back to the point where overheating is no longer a problem. This process continues from the smallest transformers to the largest - each size is determined by the VA rating and allowable temperature rise.

11.3 Regulation

Copper loss is responsible for a transformer's regulation - the ratio of voltage at no load versus full load. Regulation is almost always specified into a resistive load, which considering the way nearly everyone uses transformers, is virtually useless. It is rare that any transformer is operated into a purely resistive load - the vast majority will be used with a rectifier and filter capacitors, and the manufacturer's figure is worthless. Actually, it is worse than worthless, as it misleads the uninitiated to expect more voltage than they will obtain under load, and causes people grief as they try to work out why their amplifier (for example) gives less power than expected.

Naturally, there are some to whom any measurement is sacrilege, so none of this applies to them

The output voltage is (nearly) always specified at full load into a resistance. So a 50V, 5A transformer will give an output of 50V at a sinewave output current of 5A. If the regulation of this transformer were 4%, what is the no-load voltage?

The answer is 52V. Regulation is determined quite simply from the formula ...

$$\mathbf{Reg\% = (V_N - V_L) / V_L * 100 / 1}$$

Where $\mathbf{V_N}$ is no-load volts, and $\mathbf{V_L}$ is loaded volts.

As determined earlier, this assumes a sinusoidal output current, and this just does not happen with a rectifier / filter load. It may be found that this same transformer has an apparent regulation of 8 to 10% when supplying such a load. See Linear Power Supply Design for more information on this topic (there is little point in doing the article twice :-)

The regulation with rectifier loads is a complex topic, but you will need to know the ramifications before you start construction of your latest masterpiece, rather than find out later that all your work has resulted in much lower output power than you expected. Not that you can change it for any given transformer, but at least you will know what to expect.

11.4 Other Losses

Since the transformer is not an ideal device, it has unwanted properties apart from the losses described so far. The other losses are relatively insignificant for a power transformer, but become difficult to manage for transformers intended for wide bandwidth, such as microphone transformers and valve output transformers.

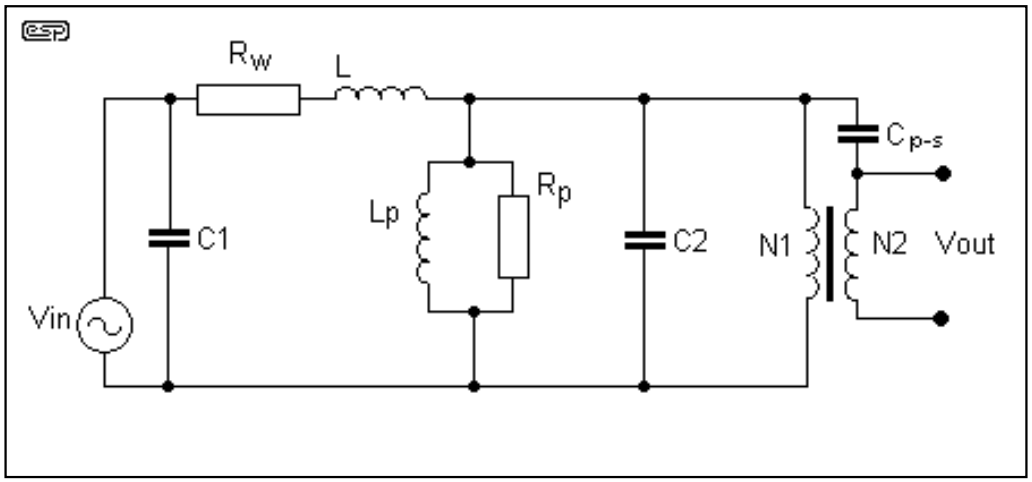

Figure 11.5 - Transformer Simplified Equivalent Circuit

The equivalent circuit shown in Figure 11.5 is greatly simplified, but serves to illustrate the points. Since the windings are usually layered, there must be capacitance (C1 and C2) between each layer and indeed, each turn. This causes phase shifts at high frequencies, and at some frequency, the transformer will be "self resonant". This is not a problem with power transformers, but does cause grief when a wide bandwidth audio transformer is needed.

In addition, there is some amount of the magnetic field that fails to remain in the core itself. This creates a "leakage" inductance (L) that is effectively in series with the transformer. Although small, it tends to affect the high frequencies in particular, and is especially troublesome for audio output transformers. This is typically measured with an inductance meter, with the output winding short circuited. Any inductance that appears is the direct result of leakage flux.

Lp is the primary inductance, and as you can see, there is a resistor in parallel (Rp). This represents the actual impedance (at no load) presented to the input voltage source, and simulates the iron losses. The series resistance (Rw) is simply the winding resistance, and is representative of the copper losses.

C_{p-s} is the inter-winding capacitance, and for power transformers can be a major contributor to noise at the output. This is especially irksome when the transformer is supplying a hi-fi system, and mains borne noise gets through and makes horrid clicks, electronic "farts", electric motor whine, and various other undesirable noises in the music. Toroidal transformers are very much worse than conventional (E-I) transformers in this respect, because of the large area of each winding. An electrostatic shield will all but eliminate such noises, but these are expensive and uncommon with toroids (pity).

The capacitance between the primary and secondary can become troublesome with this technique, and although possible, an electrostatic shield (actually, a number of electrostatic shields are needed) adds considerably to the cost, but creates a minimal overall benefit. This winding method is not used (or needed) with low frequency power transformers, and would lead to greatly reduced electrical safety because of the difficulty of insulating each section from the next. This latter problem also exists with an output transformer, but is easier to control because one side of the secondary is earthed.

Another problem exists when the capacitance between primary and secondary is high - electrical noise on the primary is coupled through the capacitance to the secondary. This can lead to mains noise getting through the entire power supply and into the amplifier in extreme cases. To combat this problem, an

electrostatic shield is sometimes used, and this is connected to earth. Note that the shield cannot be joined in a complete circle around the winding, as this would create a shorted turn that would draw a tremendous current and burn out the transformer.

There is a technique that is used for valve output transformers, shown in Figure 11.6 - you will not find this method used in power transformers, as it is completely unnecessary.

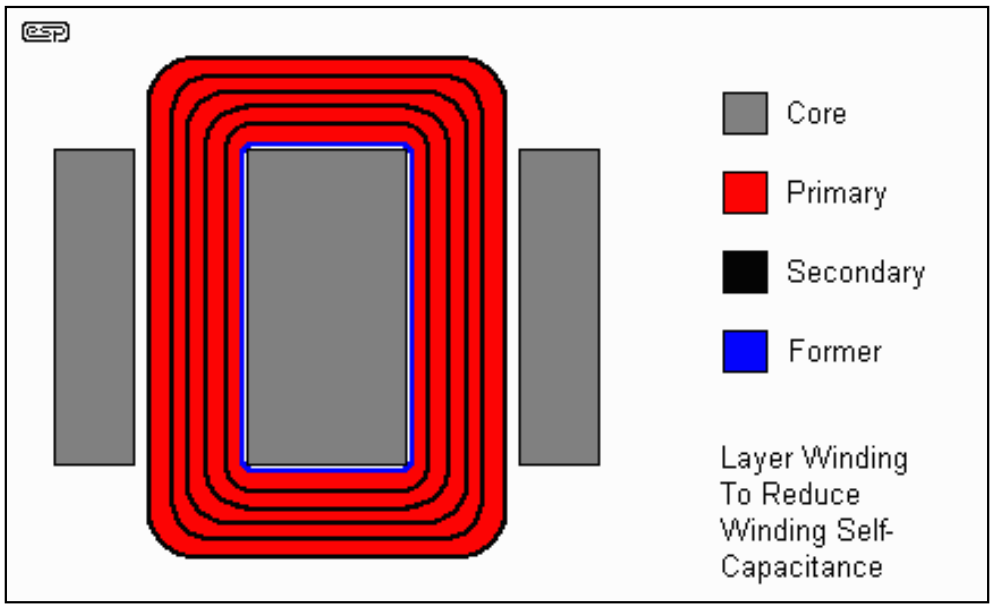

Figure 11.6 - Interleaved Winding for Extended HF Response

The trick to winding transformers to minimise the winding leakage inductance and self capacitance is called "interleaving", but this results in much greater inter-winding capacitance (between primary and secondary). The most common way this is done is to use a multi-segmented winding, as shown in the sectional drawing of Figure 11.6. This type of winding is (or was) quite common for high quality valve output transformers, and the extension of frequency on the top end of the audio spectrum is very noticeable.

---

12. Some Measurements

I measured the characteristics of a small selection of transformers to give some comparative data. I excluded regulation from this, as it is difficult to make a suitable load at short notice, and loads tend to get rather hot even with short usage. Most manufacturers will provide this information in their specifications, but be warned that this refers to a resistive load, and regulation will be *much* worse when supplying a conventional rectifier and filter capacitor (see above, and the Power Supply Design article for more details). It is also worth noting that an inductance meter is often of little use with large iron cored transformers, unless it operates with a sinusoidal waveform at (or near) the design frequency of the transformer. The inductances shown are calculated, since the measured values with my meter were a long way off.

Type	Rating	Inductance	Resistance	Turns/Volt	Magnetising	Core Loss	Reactance	Mass (kg)
Toroidal	500VA	34.7 H	2R4	2	22mA	5.28W	10.91k ohms	5.0
Toroidal	200VA	63 H	5R1	3	12mA	2.88W	20k ohms	2.7

E-I	200VA	4.36 H	6R6	2	175mA	42W	1.37k ohms	3.2

Table 7.1 - Measured Characteristics of Some Transformers

The toroidals are clear winners in terms of core loss in particular, but it must be said that the E-I transformer tested is not really representative of the majority. This is one of a few left that I had specially made, and they were deliberately designed to push the saturation limits of the core. These transformers run quite hot at no load, but give much better regulation than a more conservative design - the vast majority of such transformers. They were actually designed to run just above the "knee" of the B-H curve for the laminations used, and although somewhat risky, none has failed (to my knowledge) since they were made about 20 years ago. I use a pair of them in my hi-fi system, which has been in daily use for 10 years now.

It is also worth noting that the mass is lower than for a more "traditional" transformer design - a conventional design of the same power rating would be expected to weigh in at about 5kg.

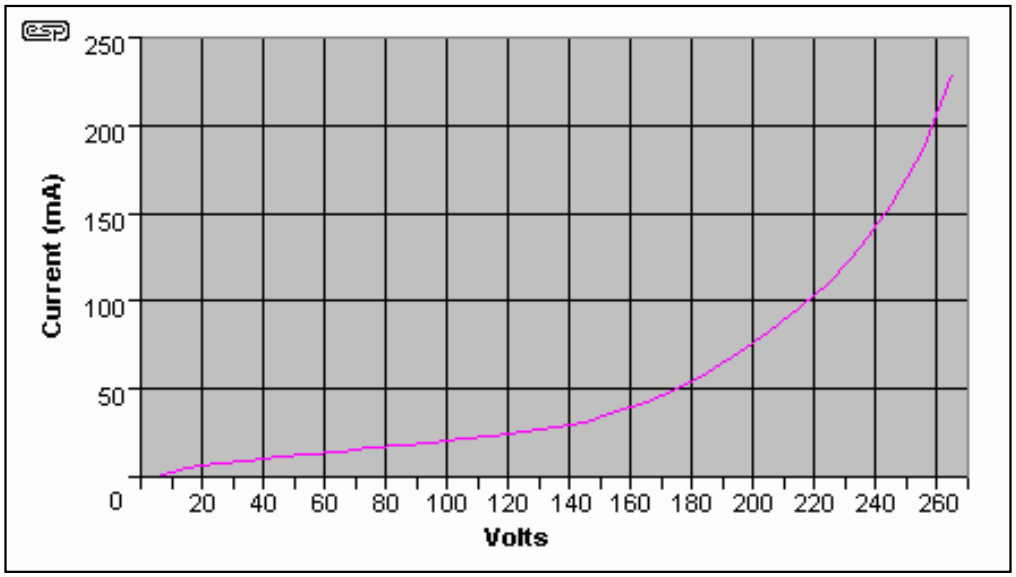

Figure 12.1 - Current vs. Voltage for the E-I Transformer

To take my measurements to the logical limit, I measured the magnetising current of my sample E-I transformer. Look closely at the graph in Figure 12.1, and you will see a typical BH curve (as shown in Figure 11.2 but with the axes reversed). As you can see, at 240V input, the transformer is operating at the knee of the curve, and is well on the way to saturation. There was no point doing this for the toroidals, as they are operated well below saturation level and I would be unable to (conveniently) measure them.

Toroids usually have a more pronounced knee, and a correspondingly steeper rise in current once the saturation limit has been reached. This is primarily because of the fully enclosed magnetic path, which has no air gaps at all (E-I laminated transformers have a small but significant gap where the laminations are joined. This is unavoidable in any practical transformer, but has little affect on performance in real life.

---

13. Core Styles

There is a huge array of different core shapes, and each has its own advantages and disadvantages. The two most common for commercial and DIY audio equipment are the E-I "shell" core and the toroidal core, but there are many others.

Ferrites in particular are moulded, and therefore have many specialised shapes to suit various applications, as well as the more traditional shapes shown below.

Toroidal cores are made from a continuous strip grain oriented silicon steel, and are bonded to prevent vibration and maximise the "packing density". It is important that there are no gaps between the individual layers, which will lower the performance of the core. The sharp corners are rounded off, and they are usually coated with a suitable insulating material to prevent the primary (which is always wound on first) from contacting the core itself.

I don't propose to even attempt them all, but one iron core that warrants special mention is the "C" core. These were once very popular, but have lost favour since suitable winding machines became available for toroids. They are still a very good core design, and are especially suited where an intrinsically safe transformer is required (i.e. where the primary and secondary windings are physically separated), and this technique also ensures that the inter-winding capacitance is minimal. C-cores are made by rolling a continuous strip into the desired shape, and after bonding, it is cut in half. To ensure the best possible magnetic coupling (i.e. no air gap), the cut ends are machined and polished as a pair - it is very important to ensure that the two are properly mated or unacceptable losses will occur. The core halves are commonly held together with steel banding, similar to that used for large transport boxes.

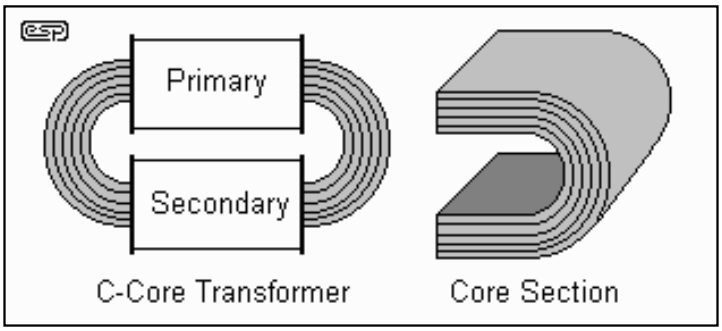

Figure 13.1 - C-Core Transformer

The main disadvantage of the single c-core arrangement shown above is that its leakage inductance is rather high. Although both windings could be placed onto a single bobbin with a pair of cores, it is more common to use four 'C' sections as shown below. This provides more iron (twice as much) and allows fewer turns for a given voltage. Naturally, the double c-core as shown below is not intrinsically safe, because both windings are wound together in the same way as for an equivalent E-I transformer.

C-cores are not as efficient as toroidal cores, but are easier to wind with conventional coil winding machines. The overall efficiency lies between the E-I core and the toroidal.

Figure 13.1A - Double C-Core Transformer

A sample of ferrite cores is shown in Figure 13.2 - this is but a small indication of the selections available, and most styles are also available in many different grades to suit specific applications.

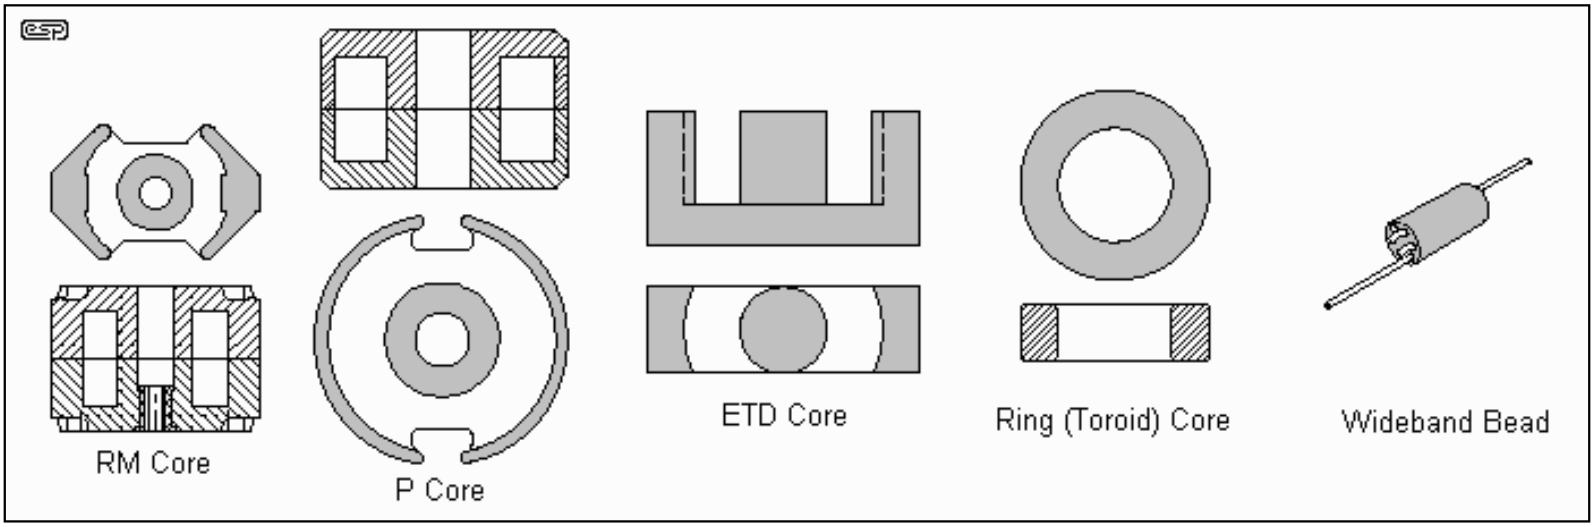

Figure 13.2 - Some Ferrite Core Styles

The diagram in Figure 13.3 shows the correct way to stack an E-I transformer. Sometimes manufacturers will use 2 or 3 laminations in the same direction, then the same in the other. This cuts costs, but the transformer performance will never be as good. Alternate laminations minimise the air gap created between the E and I sections due to imperfect mating of the two. It is essential that the laminations are packed as tightly as possible so that the effects of the air gaps are minimal.

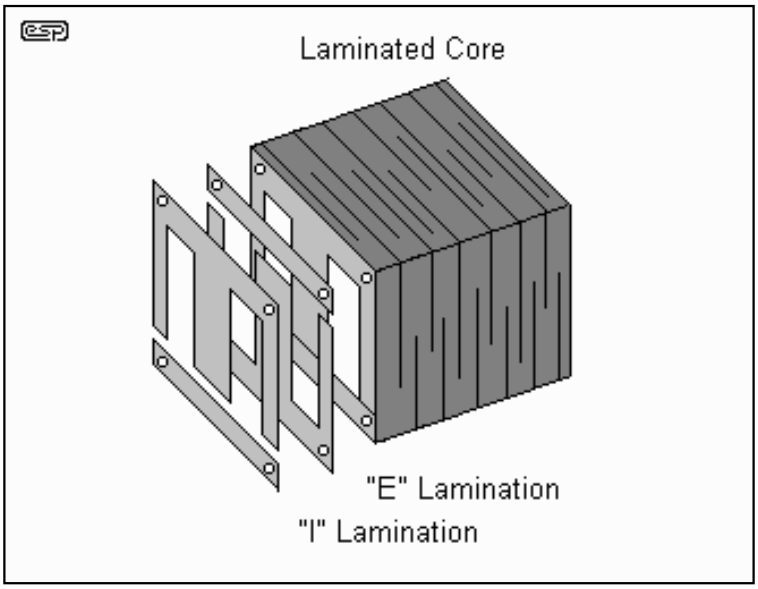

Figure 13.3 - E-I Lamination Stacking

When a transformer using E-I laminations is bolted together, it is important that the bolts are insulated from the core. If not, this would allow large eddy currents to circulate through the end laminations and the bolts, reducing performance dramatically. For safety, the core should always be bonded to mains earth unless the transformer is rated as "double insulated".

"Yes, but what good is that? The laminations are insulated from each other anyway." The inter-lamination insulation is sufficient to prevent eddy currents, but cannot withstand the mains voltage, so in case of electrical breakdown, the core may become "live" if not earthed.

In order to reduce the radiated flux from an E-I transformer core, you will sometimes see a copper or

brass band* wrapped around the winding and the *outside* of the core, as shown in Figure 13.4. This acts as a shorted turn *to the leakage flux only*, and greatly reduces magnetic interference to adjacent equipment. Such measures are not needed with toroidal transformers, as leakage flux is very much lower, and the core is completely enclosed by the windings.

(* While I am sure that many people would love to see their local brass band wrapped around a transformer, this is not what I had in mind. It does create an interesting mental picture though :-)

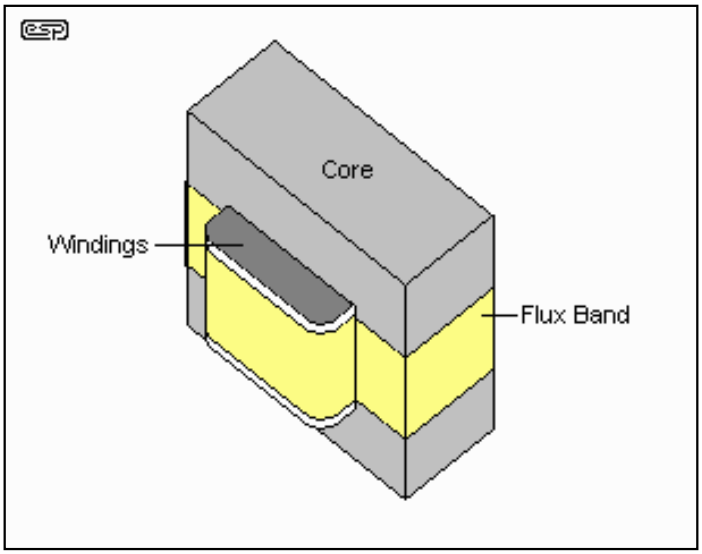

Figure 13.4 - Flux Banded Transformer

Just in case you were wondering, the dimensions of E-I laminations are worked out so that the laminations can be created with no material waste (other than the holes). The relative dimensions are shown below, and are just a ratio of the real dimensions, which will naturally be in millimetres or inches.

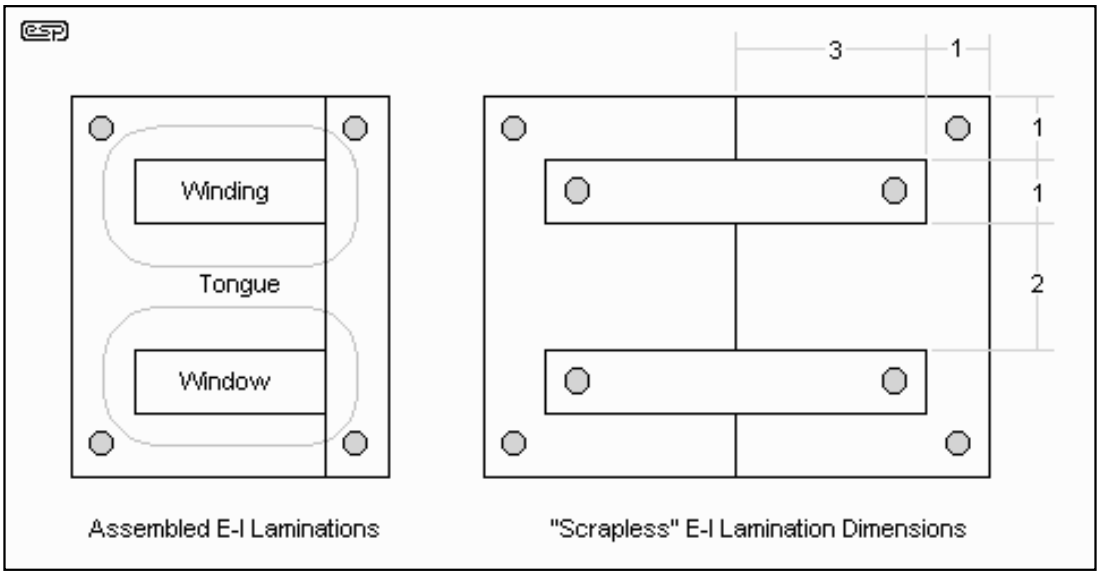

Figure 13.5 - Assembled Laminations and Punching Dimensions

The magnetic path length is the average for the dual path shown in the assembled lamination drawing, and is generally assumed to be 12 (units). This may be thought a little pessimistic, but is the commonly accepted figure. The winding window size is restricted by the punching dimensions, and it is critical that the maximum usage is made of the limited area available. Should the winding wire be too thin, there will

be plenty of room, but copper losses will be excessive. Make the winding wire too thick, and the completed winding will not fit into the available space. Additional space must be allowed for the winding bobbin, and for inter-winding insulation and the final insulation layer.

13.1 Air Gaps

DC flows in the windings for any transformer that is used for "flyback" switching supplies or SET power amplifiers, to name but two. The effect is that the DC creates a magnetomotive force that is unidirectional, and this reduces the maximum AC signal that can be carried before saturation in one direction. Indeed, the DC component may cause saturation by itself, so the transformer would be rendered useless as a means of passing the AC signal without *severe* degradation. Even the use of a half wave rectifier will introduce an effective DC component into the windings, and these should be avoided at any significant power level (i.e. more than a few milliamps).

To combat this, transformers that are subject to DC in the windings use an air gap in the core, so it is no longer a complete magnetic circuit, but is broken by the gap. This lowers the inductance, and means that a larger core must be used because of the reduced permeability of the core material due to the gap. An air gap also increases leakage inductance because of the flux "fringing" around the gap, and resistive (copper) losses are increased as well, because more turns will be needed.

It is beyond the scope of this article to cover this in great detail, but it does impose some severe restrictions on the design of transformers where DC is present. This is (IMO) one of the biggest disadvantages of the SET amplifier so popular with audiophiles, as it almost invariably leads to unacceptable compromises and equally unacceptable distortion (both harmonic and frequency).

In some designs, it is possible to eliminate the DC component by using a tertiary winding that carries ... DC. If the additional winding can be made to induce a flux that is equal and opposite that of the bias current, then the quiescent flux in the transformer can be reduced to zero (where it belongs). The disadvantage with this is that it requires an extra winding, and ***that*** takes up valuable winding space on the core. It is also a difficult technique to get right, and is not often seen these days. It was a popular technique in telecommunications equipment at one time, and meant that smaller transformers could be used for the same (or better) performance.

E-I transformers all have a minuscule "air gap" because of the way the laminations are assembled. With care, this can be almost be considered negligible, but it cannot be eliminated. C-cores will have their cut ends machined to minimise the effect, but again, it cannot be eliminated entirely. The toroidal core has no air gap at all, and is therefore more efficient (magnetically speaking) - they are utterly intolerant of DC in the windings.

---

14. Materials

There is an enormous range of core materials, even within the same basic class, so I will mention only a few of the most common. All materials have some basic requirements if they are to be used with AC (for transformers, rather than solenoids or relays, which can operate with DC). The core cannot be solid and electrically conductive, or excessive eddy current will flow, heating the core and causing very high

losses. Therefore, all cores use either thin metal laminations, each electrically insulated from the next, or powdered magnetic material in an insulating filler. The list below is far from exhaustive - there are a great many variations of alloys, and I have mentioned only a few of those that are in common use.

Silicon Steel (General Information)
Typically, soft (i.e. low remanence) magnetic steel will contain about 4% to 4.5% silicon, which lowers the remanence of the steel and reduces hysteresis losses. Normal mild steel, carbon steel or pure iron has quite a high remanence, and this is easily demonstrated by stroking a nail (or screwdriver) with a magnet. The nail will become magnetised, and will retain enough magnetism to enable it to pick up other nails. The addition of silicon reduces this effect, and it is very difficult to magnetise a transformer lamination strongly enough so it can pick things up.

This is not to say that the remanence is zero - far from it. When a transformer is turned off, there will often be residual magnetism in the core, and when next powered on, it is common for the transformer to make noise - both toroids and E-I transformers can sometimes make a "boing" noise when power is applied. That this phenomenon is intermittent is a combination of several factors ...

- What was the polarity and magnitude of the mains at switch off
- What is the polarity and magnitude of the mains at switch on
- To what extent has the core de-magnetised itself between events

The longer a transformer is left unpowered, the lower the remanent flux, and the less likelihood there is of an excessively high inrush current. If the mains is applied when at it's peak value, inrush current is at it's lowest. Conversely, if the mains is applied at the zero crossing point, inrush current will be maximum - this is exactly the reverse of what you would logically expect. The inrush current lasts for several cycles, and is made much worse with a rectifier and filter capacitor on the output. The capacitor is a short circuit when discharged, and large capacitors will take longer to charge.

Silicon steel and other metal (as opposed to ferrite) materials are normally annealed by heating and then cooling slowly after stamping and forming. This removes most of the internal mechanical stresses caused by the stamping or rolling operation(s) - these stresses reduce the magnetic properties of the material, sometimes very dramatically.

CRGO - Cold Rolled Grain Oriented Silicon Steel
Like many steels, this version is cold-rolled to obtain the required thickness and flatness needed for a transformer core. The magnetic "grain" of the steel is aligned in one direction, allowing a higher permeability than would otherwise be possible. This material is ideal for toroids and C-cores, since the grain can be aligned in the direction of magnetic flux (i.e. in a circular pattern around the core). It is less suited to E-I laminations, because the flux must travel *across* the "grain" at the ends of the lamination, reducing permeability.

CRNGO - Cold Rolled Non Grain Oriented Silicon Steel
Generally more suited to E-I laminations, this is essentially the same process as the CRGO, but the magnetic grain is left random, with no alignment of the magnetic domains. Although this reduces overall permeability, the effective permeability will be better with stamped laminations (as opposed to rolled, as with toroids and C-cores).

Powdered Iron
A soft ferrite ceramic material, used where there is significant DC in the winding. Powdered iron cores have relatively low permeability (about 90, maximum), and are designed for high frequency operation. These cores are most commonly used with no air-gap, and will not saturate easily. Typically used as filter chokes in switching power supplies, and as EMI (Electro-Magnetic Interference) filters - the toroid is the most common shape.

Ferrite
Soft ferrites are the mainstay of switching power supplies, and low level high speed transformers (such as might be used for network interface cards and small switching transformers. Ferrites are available with outstanding permeability, which allows small cores with very high power capability. Flyback (a type of switchmode operation) transformers in particular are usually gapped because of the DC component in the primary current.

High permeability ferrites are also very common in telecommunications and for other small audio frequency transformers where very high inductance and small size is required.

MuMetal
Named after the symbol for permeability, as one might expect, this material has an extraordinarily high permeability - typically in the order of 30,000. It is commonly used as magnetic shielding for cathode ray tubes in high quality oscilloscopes, screening cans for microphone transformers, and as laminations for low level transformers. The maximum flux density is quite low compared to other metallic materials. Apart from being relatively soft, if dropped, the magnetic properties may be adversely affected (MuMetal requires careful annealing to ensure that its magnetic properties are optimised).

---

15. Transformer Distortion

An ideal transformer has zero distortion, but there are zero ideal transformers. Therefore, it can be deduced that transformers do have distortion, but how much?

The answer depends entirely on how the transformer is used. When supplied from a voltage source of zero ohms impedance, the real life transformer has no distortion, but again, there is no such thing as zero ohms (actually, it *can* be done, but yields little real benefit).

Any transformer operating at low flux density, and with a low impedance source, will contribute very little distortion to the signal. As frequency decreases, and/ or operating level increases, the limits of saturation will eventually be reached in any transformer, and distortion will become a problem. This is not really an issue with mains power transformers, but is very important for valve output transformers, particularly at low frequencies.

The distortion characteristics of transformers used as valve output devices is a complex subject, and will not be covered here. Suffice to say that the normal methods of determining the turns per volt, based on the bare minimum lowest frequency response will give unacceptably high distortion levels at low frequencies.

Although interesting, the relationships are complex and will be of little real use to the majority of

hobbyists. If there is sufficient interest, I may cover this in a later article.

References

Countless different books and Web pages were researched during the compilation of this article, and although some were interesting, the majority were of minimal use. Of those who I actually remember (a daunting task in itself, considering the sheer amount of searching I had to do), I must "thank" the following Web pages (in alphabetical order) ...

- Amidon
- ATDL School (US Army)

Tesla (T) - flux density (or field intensity) for magnetic fields (also called the magnetic induction). The intensity of a magnetic field can be measured by placing a current-carrying conductor in the field. The magnetic field exerts a force on the conductor which depends on the amount of the current and the length of the conductor. One Tesla is defined as the field intensity generating one newton of force per ampere of current per meter of conductor. Equivalently, one Tesla represents a magnetic flux density of one Weber per square meter of area. A field of one Tesla is quite strong: the strongest fields available in laboratories are about 20 Teslas, and the Earth's magnetic flux density at its surface, is about 50 microteslas (μT). One Tesla equals 10,000 gauss. The Tesla, defined in 1958, is named after Nikola Tesla (1856-1943), whose work in electromagnetic induction led to the first practical generators and motors using alternating current (much to the annoyance of Edison, who claimed DC was "safer").

Weber (Wb) - magnetic flux. "Flux" is the rate (per unit of time) in which something crosses a surface perpendicular to the flow. In the case of a magnetic field, then the magnetic flux across a perpendicular surface is the product of the magnetic flux density, in Teslas, and the surface area, in square metres. If a varying magnetic field passes perpendicularly through a circular loop of conducting material (one turn), the variation in the field induces a electric potential in the loop. If the flux is changing at a uniform rate of one Weber per second, the induced potential is one volt. This means that numerically the flux in webers is equal to the potential, in volts, that would be created by collapsing the field uniformly to zero in one second. One Weber is the flux induced in this way by a current varying at the uniform rate of one ampere per second. The unit honours the German physicist Wilhelm Eduard Weber (1804-1891), one of the early researchers of magnetism.

Magnetic Terminology

This list is far from complete, but will be sufficient to either get you started or scare you away. I have included the symbols and units of only three of the entries below, since most are of no real interest.

Coercivity - is the field strength which must be applied to reduce (or *coerce*) the remanent flux to zero. Materials with high coercivity (e.g. those used for permanent magnets) are called *hard*. Materials with low coercivity (those used for transformers) are called *soft*. Coercivity is the "reverse" of remanence.

Effective Area - of a core is the cross sectional area of the centre limb for E-I laminations, or the total area for a toroid. Usually this corresponds to the physical dimensions of the core but because flux may not be distributed evenly the manufacturer may specify a value which reflects this.

Effective Length - of a core is the distance which the magnetic flux travels in making a complete circuit. Usually this corresponds closely to the average of the physical dimensions of the core, but because flux has a tendency to concentrate on the inside corners of the path the manufacturer may specify a value for the effective length.

Flux Density - (symbol; B, unit; Teslas (T)) is simply the total flux divided by the effective area of the magnetic circuit through which it flows.

Flux Linkage - in an ideal inductor the flux generated by one turn would be contained within all the other turns. Real coils come close to this ideal when the other dimensions of the coil are small compared with its diameter, or if a suitable core guides the flux through the windings.

Magnetomotive Force - MMF can be thought of as the magnetic equivalent of electromotive force. It is the product of the current flowing in a coil and the number of turns that make up the coil.

Magnetic Field Strength - (symbol: H, unit; ampere metres (A m^{-1})) when current flows in a conductor, it is always accompanied by a magnetic field. The strength, or intensity, of this field is proportional to the amount of current and inversely proportional to the distance from the conductor (hence the -1 superscript).

Magnetic Flux - (symbol: Φ; unit: Webers (Wb)) we refer to magnetism in terms of lines of force or flux, which is a measure of the total amount of magnetism.

Permeability - (symbol; μ, units: henrys per metre (Hm^{-1}) is defined as the ratio of flux density to field strength, and is determined by the type of material within the magnetic field - i.e. the core material itself. Most references to permeability are actually to "relative permeability", as the permeability of nearly all materials changes depending upon field strength (and in most cases - especially in ferrites - with temperature as well).

Remanence - (or remnance) is the flux density which remains in a magnetic material when the externally applied field is removed. Transformers require the lowest possible remanence, while permanent magnets need a high value of remanence. Remanence is the "reverse" of coercivity .

1.0 - Introduction

In this section, we will look at taking measurements from existing transformers to assess their ability to be re-used, some basic calculations usable for transformer design (thanks to Geoff Sevart) and look more closely at power supply analysis (thanks to Martin Czech). In all, there are three different programs that you can download and use presented here. It is also highly recommended that you use a good simulator to verify the final design - as always, I suggest SIMetrix. Before simulating, you will need to know the parameters to build the equivalent circuit - see section 2 for more information on this

topic.

2.0 - Transformer Analysis

Transformer analysis largely involves determining if a given transformer will provide a level of performance that meets your design goals. Three completely different approaches are provided here - one is an executable program that provides a fairly accurate assessment of the transformer's performance based on a few measurements that you perform.

The other is a Microsoft Excel spreadsheet that does much the same thing. The main difference is that the spreadsheet does not have an on-line help facility, so all instructions are provided here (as well as in a 'readme' file included in the compress archive).

Finally, the third program can be used to reverse engineer a transformer, or to design one that meets your needs. Only the basics are covered, and you need to be well versed in the requirements for insulation (both inter-winding and intra-winding). You may also need to know the details of the steel used - assumptions are not always valid. Remember that in all cases, it is your responsibility to ensure that the design is safe (or remains safe if you modify an existing transformer).

There are some differences in the way the three analysis processes work, and it is up to you to decide which one is most suitable. None is intended for beginners or those with an aversion to taking measurements and experimenting - these are all serious tools to allow you to analyse or determine the suitability of any given transformer.

2.1 - Transformer Analysis 1

The transformer analysis program (xformer.exe) can be downloaded from the Downloads page or from the downloads section of this page, as a zipped archive. It has very extensive help facilities, and is complete with test circuits, a transformer equivalent circuit (with all explanations), and the complete sequence to evaluate an unknown transformer. It will provide the DC output at the specified load, and includes duty cycle calculations so that you can see what happens when the transformer is overloaded.

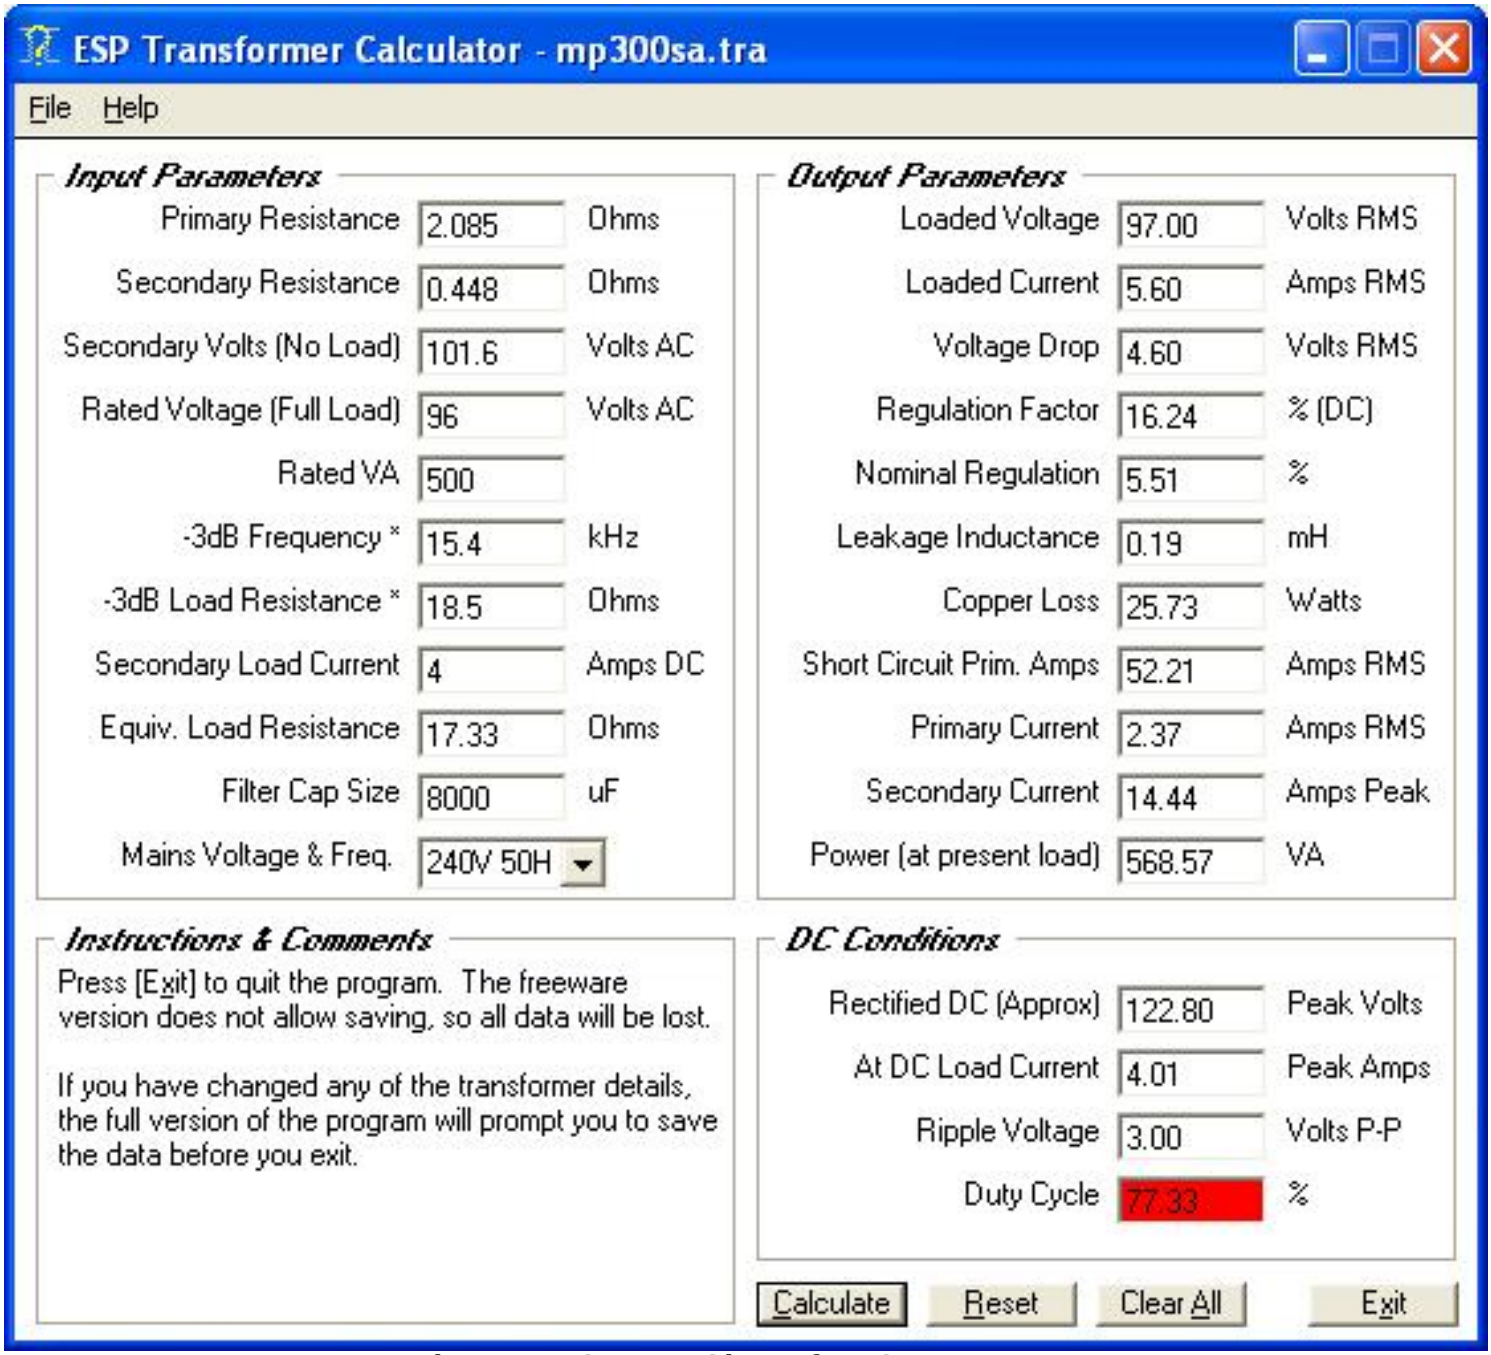

Figure 1 - Screen Shot of XFORMER.EXE

The box marked 'Instructions & Comments' is context sensitive, so it will display relevant information based on the current mouse position. To find out more about any parameter, simply position the mouse over the text box or its adjacent label. A great deal more information is available from the help screens.

As with any program, there will be some variation between what it claims and reality, so the measured values will not always be in complete agreement with those calculated. There is only so much that can be conveniently determined, but the results will be close enough for almost all applications. Where extreme accuracy is needed, you will have to build the circuit to verify exactly what it does, however the very nature of a power supply

is such that accuracy is not normally a major issue.

The program uses SI units only, and assumes a dual polarity full-wave bridge rectifier (conventional ± amplifier type power supply). At this stage, no other supply types are available, and probably will not be added because the default is suitable for most applications. In normal use, a single supply is still easily tested. You will need to experiment with the program to find out if it does exactly what you need.

2.2 - Transformer Analysis 2 (Martin Czech) - How to use the Excel spreadsheet

2.2.1 - Purpose

This Excel spreadsheet is made for convenient "linear PSU" design. This is a PSU made using a transformer, rectifier diodes and filtering capacitors. The load presented to the PSU is a resistor. The sheet was tested against SPICE simulations and has shown accuracy to about 2% or better.

However, since not all possible configurations can be checked it should always be verified by a subsequent SPICE simulation.

Figure 2 - Partial Screen Shot of TRAFO7.XLS

2.2.2 - Assumptions

This Excel spreadsheet tries to model the nonlinear behaviour of such a PSU with simple equations and estimations. The transformer is modelled as a non ideal voltage source, i. e. an ideal voltage source plus series resistance. It uses only SI units (m,A,V, Ohm, etc.).

Four common circuits can be calculated ...

- Bridge - single coil transformer with diode bridge
- d. Bridge - double coil transformer with diode bridge for each coil, dual output voltage, very heavy load (1000W)
- Center - centre tap two coil circuit with two diodes for single output voltage, only useful for very low power and low voltage, less diode drop
- d. Center - centre tap two coil circuit with four diodes for dual output, for low to high output power until the highest, less diode losses than "d. Bridge"

Usually a given transformer is specified with Uneff (effective value of secondary voltage under full resistive load, and Pn (nominal output power with said resistive load) and loss factor f (ratio between U0eff and Uneff, U0eff being the effective value of output voltage with no load), and of course the primary effective voltage Unetz.

I.e.: $U0eff = f * Uneff$

Out of *Pn* and *Uneff* we get the load current *In* (*In = Pn / Un*). The series resistance is therefore

$$(U0eff - Uneff) / Ineff = (f * Uneff - Uneff) / Ineff$$
$$= Uneff * (f - 1)/In$$
$$= Uneff * 2 * (f - 1) / Pn$$

the latter is convenient because it uses only the usually given parameters. This applies also to transformers with several identical coils. It does not apply for additional auxiliary windings and taps, which can have lower power spec and therefore more series resistance than perhaps expected.

The sheet works for one coil or two identical coils, due to the symmetry of the circuit and load situation the same current and voltage values will appear. Therefore they are only given once in the sheet.

Sadly, *f* (loss factor) is not given by many vendors. So the spreadsheet has some heuristic formula to determine *f* out of the transformer total power rating. This works from about 5 VA up to 1000 VA. This is no big science, but relates to the usual tradeoffs when

winding transformer coils. The value is valid for toroidal types, *f* is often lower for EI types. However, if you can obtain a data sheet with *f*, then do not use the heuristic value.

The spreadsheet does also include mains voltage variation. In central Europe this is tending to +-10% of the nominal value, guaranteed at the house main power entry. Some additional wiring can be added to that (be it house installation or additional cables, perhaps during live shows). The transformed total mains resistance will simply add to the transformer series resistance.

The remaining interesting part of the formulas is derived by approximating the voltage sine waves with parabola, in order to get any analytic result. Unfortunately the resulting nonlinear equation can only be solved by program, I used an iteration approach in this Excel sheet.

The load is assumed to be a resistor. In reality this not always the case. Some circuits tend to be constant current drains (regulator plus electronic circuit). Others have variable current consumption (power amplifiers), but also there the current does not depend on PSU voltage. A starting point for the later cases is to make the delivered output power equal, i.e. choosing the output current and resistor in that way.

2.2.3 - How to do it

The Excel sheet has a yellow title range. Below that on the left hand side we find explanations to the parameters, the salmon colored column shows the parameter name. The next column is commonly used for all four possible circuits, the next four columns carry the results and entries for each circuit individually.

Anything shown below in *italics* indicates that it is a field in the spreadsheet.

First you have to enter data into the white common fields. Each field must be filled. Most of this is very easy. You enter ...

- The Si diode forward voltage drop [*Ud*] (recommended 1V)
- Specify peak-to-peak ripple voltage under load [*Ubrss*]
- The desired nominal output current [*Ia*] (together with output voltage this will define the delivered power)
- The current form factor [*alpha*]. The transformer has to deliver current peaks instead sine AC current, the copper losses will be higher than nominal.

This makes it necessary to use a higher transformer nominal power. Under-dimensioning can lead to ...

1. More than nominal copper loss
2. Enormous heat development in coil wires

Usually alpha is chosen to be 1.5 ... 2, even large over dimensioning is possible with modern toroid types, because idle losses are still low.

Imax >> In means that in this PSU the peak current is much larger than in the situation where the transformer drives only a resistive load to the rated power. One should compute the RMS value from simulation to estimate the loss. Based on that choose alpha to be higher.

- Your desired nominal DC output voltage [*Uaminn*] (just to remember)
- Your desired minimum nominal output voltage [*Uamin*] this has to be higher than *Uaminn* because of wiring losses and mains power variation, if the mains variation to lower is perhaps 10%, give *Uamin* 10% more, as a starting point
- The assumed wiring length from mains house entry to your transformer [*L*], in a normal house this can be 10 - 20 m, in a big hall this can be 100m
- The mains wiring cross section area [*A*], typical 1.5 mm²
- The mains nominal effective voltage [*Unetz*] (e.g. 110V or 230V)
- The mains AC frequency [*fn*] (e.g. 50Hz or 60Hz)
- The mains tolerance upper value [*tolup*] (e.g. 10% by law in Germany, meaning 230V and up to 253V)
- The mains tolerance lower value [*toloe*] (e.g. -10% by law in Germany, meaning 230V and down to 207V)

You are done with the common data. Now you can decide which circuit column you need to use. It is only necessary to fill in that column, but it is also possible to use several or all in parallel for study or comparison.

Now the Excel sheet knows the output power [*Pa*], nominal power per coil [*Pns*], and the total nominal transformer power [*Pn*]. The heuristic formula can therefore suggest a value for the toroid loss factor [*f*]. If you have no better data, enter this value in the white field "actual transformer loss factor". Now you have completed all white fields, you are nearly done.

In the last step you solve the nonlinear equation by manual iteration. You enter a nominal coil voltage [*Uneff*] (pink field) and change it, until the relative iteration difference [*r*] (light blue) is 0.0% (or near to that). In this case the single coil output voltage under load with infinitely large capacitor [*Ua8*] will match the iterated single coil output voltage [*Uaber*]

(darker blue).

Now you have solved the equation, but is the worst case voltage [*Ua-*] as expected? You should compare this lowest per coil output voltage under load [*Ua-*] with your intended desired minimum nominal output voltage [*Uaminn*]. If [*Ua-*] is too low, the circuit will have too low voltage in case of low mains voltage, a longer than expected cable can add to that.

This makes perhaps no difference for a power amp, since a few % amplitude loss is not audible. In the case of a subsequent voltage regulator a too low voltage will simply mean loss of regulation with perhaps additional artefacts, this is clearly not acceptable. Give more [*Uamin*] in such a case, and iterate again.

Take care: this can influence the power, so the current [*Ia*] may need some adjustment, too. Finally power change can change loss factor [*f*], so this has also to be adapted. If the initial guess was good enough, little or no modification needs to be made on that side.

So now you are done. You should take the relevant data from the sheet (*U0, Un, Pn, f*) and do a SPICE simulation to verify. A second computation is always good, since you are going to spend a lot of money for a PSU!

2.2.4 - What else does the sheet tell you

It not only tells you *Uneff, Pn, f, Unetz* to order your transformer, it also tells you the size of the filter capacitors *Cl*, and *Ua0+*, this idle output voltage plus tolerance tells you about the voltage stress these and other devices connected to your PSU have to take.

Imax is the periodic peak current in the transformer windings and diodes, so it will tell you something about fuse stress and diode stress, as well as capacitor ripple current.

The total rectifier loss power *Pg* and the maximum diode reverse voltage *Usper+* will also help to buy the right rectifier.

All the devices need not only cope with the rated voltage stress, but even more has to be considered because of possible mains transients. A factor of 2 over dimensioning is not too expensive in most cases, an exploded cap or whole PSU plus circuit certainly is.

If your output voltage is so high that voltage over dimensioning is not possible, primary side varistors should be used to handle transients. They should be used anyway.

2.2.5 - Explanation of Parameters

The parameters used in the spreadsheet are listed here. Although some of these may appear daunting at first, it is not difficult to figure out what they are all for. Note that the derivation of some of the terms is directly from German (netz = mains, for example). Many of the parameters used are fixed - there is no need to change them once they have been set for local conditions - examples are mains voltage and frequency, upper and lower tolerances, etc. The line length applies only if there is a significantly long extension lead used, such as setup in an auditorium where a nearby power outlet is not available. For most applications this may be set to 1 (metre) with little loss of accuracy.

3.0 - Transformer Design

This next program is thanks to 'Particle' otherwise known as Geoff Sevart. With this, you can either analyse or design a transformer, although for proper design work you need to know a bit more than the program provides from its interface. Although fairly simple, it does give good results if you know what you are trying to achieve, and know some of the basics of the core material.

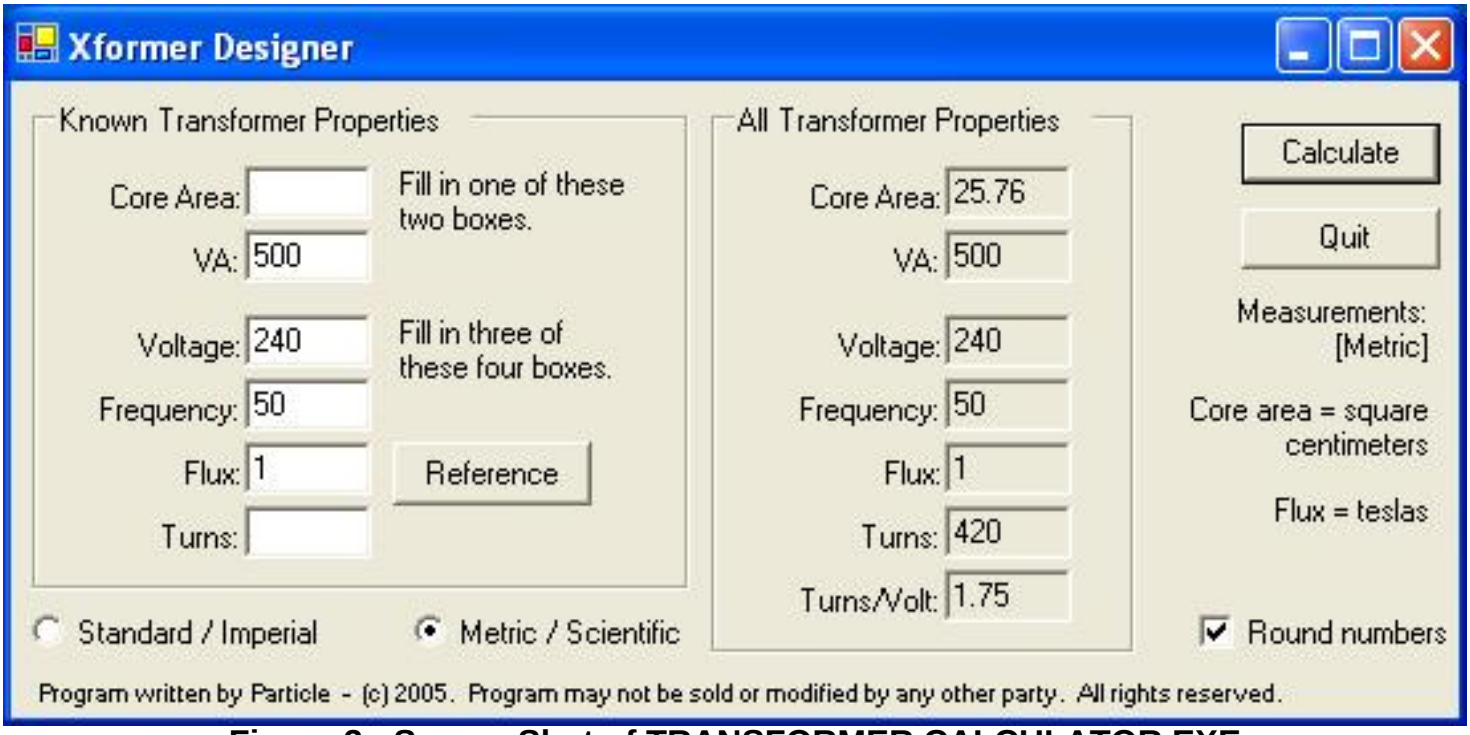

Figure 3 - Screen Shot of TRANSFORMER CALCULATOR.EXE

The screen shot above shows the complete program interface. You insert your known data into the section on the left side, and all calculated values are shown on the right. You need to input either the core area or the VA rating of the transformer, but not both. When that is done, you enter any *three* of the four remaining fields ...

- Voltage - the primary voltage for the transformer. This will nearly always be known.
- Frequency - mains frequency for a power transformer, or the lowest frequency of interest for a signal or output transformer
- Flux - the maximum flux density that the transformer core will be subjected to. *
- Turns - the number of turns on the primary. This is the least likely to be known, but it can be determined (see below)

* Click the 'Reference' button for hints. Typical power transformers will operate at around 1 Tesla. Higher flux density means the core is likely to saturate and be noisy, lower flux makes a mechanically quiet transformer, but at the expense of efficiency. Low flux density is essential for audio transformers, as even approaching saturation can cause high distortion levels.

If your transformer allows you to add some temporary turns, you can determine the number of turns/volt by adding 10 turns of thin insulated wire. Apply power to the primary, and measure the mains voltage (very carefully!). Now, measure the voltage across your extra 10 turn winding. If (for example) you measure 3.3V AC, that means the transformer has ...

TPV = *Turns / Voltage*= 10 / 3.3 = 3 Turns Per Volt

From that, you can calculate the number of turns on the primary, using the measured applied mains voltage (assume 230V) ...

Tp = *Vp* * *TPV*= 230 * 3 = 690 turns

This figure may be used instead of the assumed flux density, and you will then know the actual flux density being used for the transformer you are testing.

When you click 'Calculate', the program shows the following calculated values ...

- Core area, in cm² or inches², depending on whether you selected metric or imperial
- VA rating for the transformer
- Primary voltage
- Frequency
- Flux density
- Primary turns
- Turns per volt

Although it may be more difficult using metric calculations as a matter of course, it is

highly recommended that you do so anyway. There is nothing in the imperial system that actually makes any sense, so it is far better to use metric whenever possible.

4.0 - Taking Measurements

The equivalent circuit shown in Figure 5 allows you to see where the main losses occur with any transformer. The lumped parameter model is the most commonly used, as it gives a very good representation of a real component and is easy to manage for almost any normal load or signal.

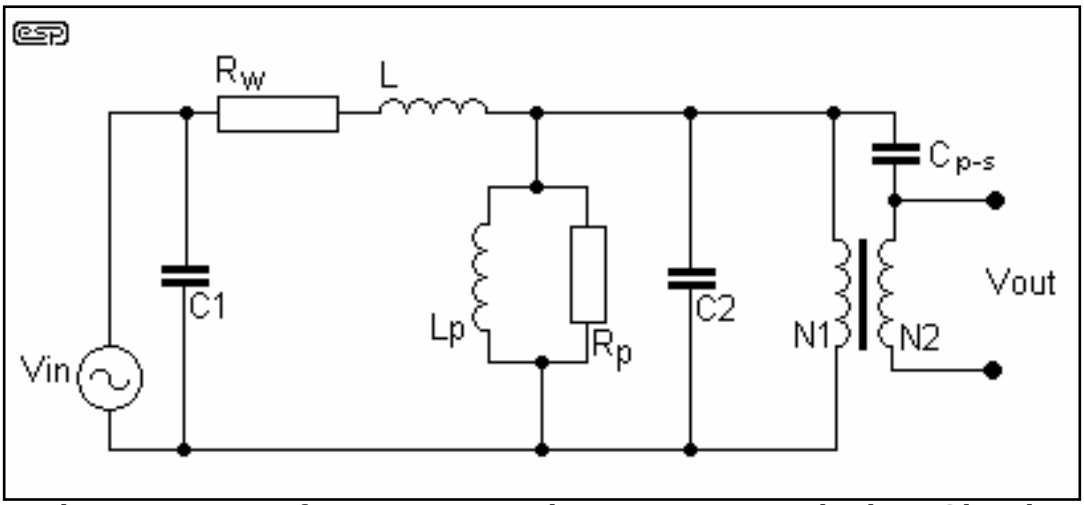

Figure 5 - Transformer 'Lumped Parameter' Equivalent Circuit

For most measurements in electronics, a multimeter is all you need. This is not good enough and will become inaccurate when working with transformer winding resistances. Because very low resistances are to be measured, few multimeters have a useful low ohms range. To get sensible results, the measurements you take *must* be accurate. Very low resistance is always hard to measure, and it can only be done using DC. Many very low ohm meters use AC, but this will give large errors because of the transformer inductance.

The easiest way to measure a very low resistance is to inject a known current, and measure the voltage across the device under test. For example, if you subject a transformer winding to (exactly) 1A DC, and measure 448mV across the winding, its resistance is 0.448Ω. A regulated DC supply and a 10 ohm 5W resistor is ideal for this. Measure its value carefully - if it measures 10.1 ohms, then 10.1V dropped across the resistor means the current is exactly 1A. This is shown in Figure 4.

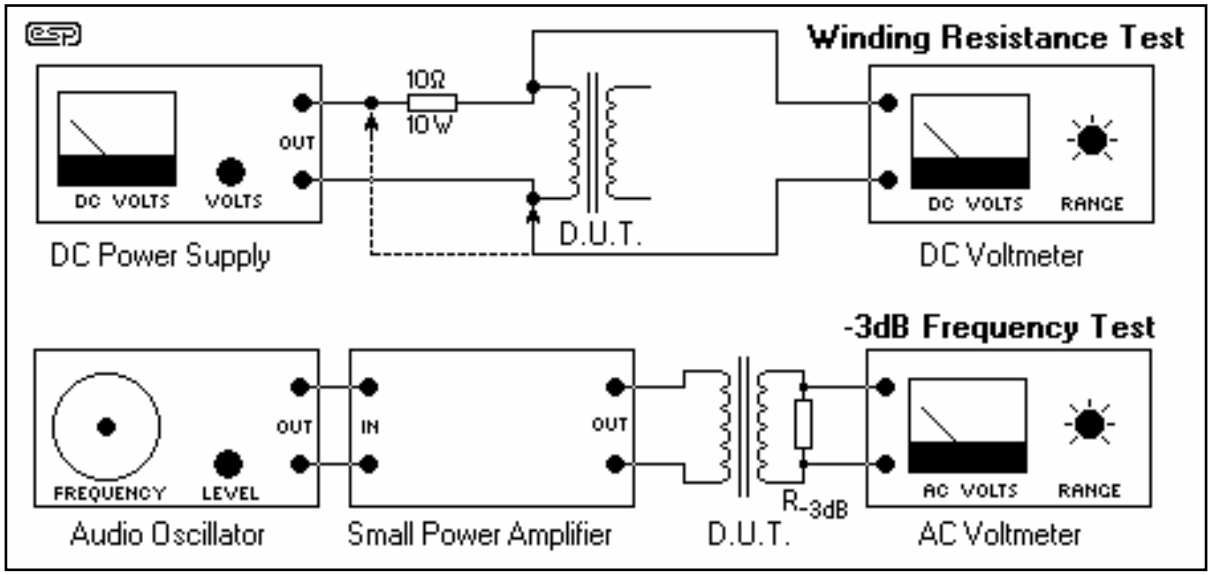

Figure 4 - Measuring Very Low Resistance & Leakage Inductance

Figure 4 also shows the basic method for measurement of leakage inductance. The load resistance across the secondary is determined by ...

$R_{-3dB} = VS / (VA / VS)$ Where R_{-3dB} = Test resistance, *VS* = Secondary Voltage, *VA* = Volt-Amp Rating

So for a 300VA transformer having a rated total secondary voltage of 70V ...

R_{-3dB}= 70 / (300 / 70) = 70 / 4.3 = 16Ω

Note that this does not have to be extremely accurate, as it is only designed to provide a representative load. This value is only used in the first program shown (TRANSFORMER.EXE), and it is used primarily to determine the transformer's short circuit (fault) current. Leakage reactance can then be determined using the -3dB frequency and the load impedance. Leakage inductance is also useful to know as a comparative figure, allowing you to make meaningful comparisons between different transformers. Transformers with high leakage inductance will inject noise into adjacent circuits, and generally have poorer regulation when high peak currents are expected.

5.0 - Conclusion

With the programs and spreadsheet detailed here, you have an excellent range of tools at your disposal to ensure that the power supply for your latest masterpiece is as good as you can get it. At last, it is possible to easily analyse an existing transformer, work out just how well (or badly) a given transformer will work in the intended circuit, or even

design your own transformer from scratch.

The performance of a transformer when loaded by a diode bridge and capacitor input filter (99% of all power supplies used) is never as good as we might hope or imagine, and these tools will allow you to predict how the supply will behave. By comparing the performance of the final supply with the predictions, you will find that there is fairly good correlation - certainly well within the accepted mains tolerance.

6.0 - Downloads

These downloads are free for personal use. They may be re-distributed, but no fee is to be charged for the software. No part of the software may be de-compiled, reverse engineered or used in any way contrary to the general principles of free software distribution. Program copyright belongs to the author of the program. No warranty is expressed or implied - the programs and spreadsheet are provided 'as is', and no responsibility is accepted by the authors for any damages howsoever caused. It is the wholly the users responsibility to determine the validity of the calculations.

All programs are tested and checked and are believed to be free of any computer virus or other 'malware'. It is the user's responsibility to scan all files to ensure that they have not been corrupted or infected.

Various support files needed may or may not be available on your PC, and if not, you will need to obtain them so the programs will run. Full details of the necessary files are shown below for each program.

TRANSFORMER.EXE © Rod Elliott
The executable file is 188,416 bytes. It is in a compressed archive, along with a 'readme' file that explains the support files and their required locations within the Windows file system. It requires the Visual Basic 6.0 runtime library vbrun60sp5.exe which is available from Microsoft, and contains all files needed to run any application written in Visual Basic 6.0

Click TRANSFORMER1.ZIP (or right click, and select 'Save [Link] Target As ...') to download the zipped archive for the program.

TRAFO7.XLS © Martin Czech

This is the Excel spreadsheet analyser (25,600 bytes). You will need Microsoft Excel™ so it will run. Alternatively, you may use OpenOffice, a free version that appears to run the spreadsheet perfectly.

Click TRANSFORMER2.ZIP (or right click, and select 'Save [Link] Target As ...') to download the zipped archive for the spreadsheet. Make sure that you read the file 'readme.txt' - this is a plain text file, and contains a full description of all fields used and their meanings.

XFORMER.EXE © Geoff Sevart
The transformer design program (61,440 bytes) requires the Microsoft '.NET' framework. Click here to find out more about the .NET system as a whole. This is normally supplied with Windows® XP, and more information (including download) is available from the Microsoft .NET Framework Developer Center.

Introduction

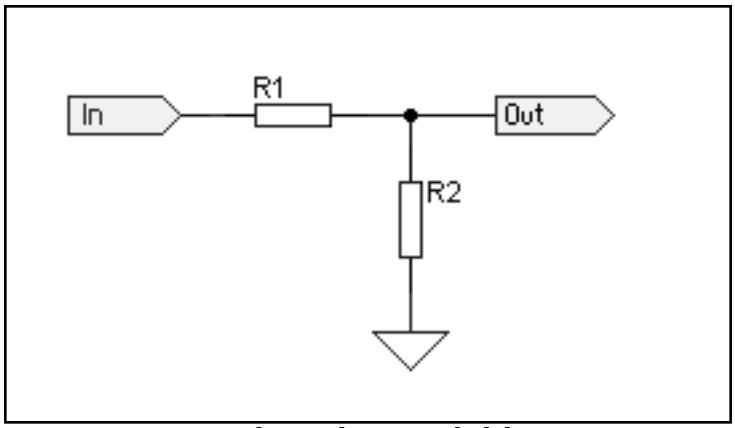
Based on the number of requests for help I receive from people wanting to know how to connect a volume control, or convert speaker level to line level, I must conclude that voltage dividers (or attenuators) are not well understood.

A volume control is, in most cases, nothing more than a variable attenuator. Exactly the same formula applies to determine the output level for any given input level, and there is nothing mysterious about any of these building blocks. This small article will de-mystify the voltage divider in any of its forms, and will be useful for the beginner and accomplished hobbyist alike.

Although simple, there are a great many uses for the humble voltage divider, and indeed, without it many of the circuits we take for granted would not exist.

Decription

A voltage divider is created whenever you have two resistors (or impedances) in series, with the signal "take-off" point between the two. Although there are literally hundreds of different possibilities, I shall only look at the standard connection for a voltage divider, and this will be all that is needed in the vast majority of cases. A traditional voltage divider is shown in Figure 1, and this is the form taken by volume and balance controls, general purpose attenuators, and similar configurations.



Basic Voltage Divider

This circuit is used for both AC and DC, and performs identically in either case. The voltage division is given by the formula ...

$$V_d = 1 + (R1 / R2)$$

Where V_d is the voltage division ratio. So, using two 1k resistors for example, voltage division is 1 + (1 / 1) = 2 [1]. 1V input will result in 0.5V output, and this holds true for DC, AC (RMS), or AC peak (as measured on an oscilloscope).

Any combination of R1 and R2 will create a voltage divider, and a pot (used for volume, for example) will still obey the same rule, except that the wiper (the moving contact in the pot) allows an infinite number of voltage division ratios.

Let's assume that you have a 25V RMS signal (the speaker output of an amp, for example), and want to reduce that to 1V RMS at maximum power from the amp. The voltage divider obviously must divide the voltage from 25V to 1V - or a 25:1 ratio. If we make R2 1k as before, R2 must be (25 - 1) * 1k = 24k [2].

Hold on a minute - how did I arrive at that? The formula (in the form I have used here) can be transposed easily - it follows from the original that ...

$$V_d - 1 = R1 / R2$$

allowing you to easily determine the values needed for any voltage division ratio you need.

To convert voltage division to dB (attenuators are commonly referred to in dB), you need to apply the dB formula ...

$$dB = 20 * Log_{10} (V_{d)}$$

... where V_d is the voltage division ratio determined as above. The two voltage dividers we used as examples above will give ...

$$dB = 20 * Log_{10} (2) = 6dB$$ [1] and ...

$$dB = 20 * Log_{10} (25) = 28dB$$ [2]

... respectively (close enough).

The only other point to consider is the loading on the previous circuit, and the power dissipation in the voltage divider resistors. A voltage divider used to convert speaker level to line level (as shown in the second example) could just as easily use 1 Ohm or 1 Megohm for R2 (instead of 1k). The voltage divider / attenuator will still work exactly as before, so why would 1k be "better" than any other value? The answer is not especially simple, and it comes down to a compromise (all too common in electronics).

Let's look at the case of R2 = 1 ohm first. R1 will be 24 ohms, and there will be 24V across it (you *must* understand this concept - draw it out on paper to make sure that you do!). Power dissipation will be 24^2 / 24 = 24W. This is power that the amp must supply, and the resistor will get hot. Using 1 ohm for R2 is obviously not a good idea. Ok, how about 1M?

R2 will now be 24 Megohms - not an easy value to find! We will also come up against another issue - output impedance.

It is essential that any attenuator or voltage divider is driven from a low impedance source, or the load of the divider itself will reduce the available voltage (the formula

shown will appear to be in error). Likewise, the load (the impedance connected to the output) must be high compared to the divider output impedance. It is generally considered that the signal source should have an impedance of at most 1/10 that of the attenuator, and the load should have an impedance (at least) 10 times the attenuator's output impedance.

The output impedance is the parallel combination of R1 and R2, so again using the examples above, we can determine input and output impedances.

Z_{in} = R1 + R2 = 1k + 1k = 2k	[1]
Z_{in} = R1 + R2 = 24k + 1k = 25k	[2]
Z_{out} = (R1 * R2) / (R1 + R2) = (1k * 1k) / (1k + 1k) = 500 ohms	[1]
Z_{out} = (R1 * R2) / (R1 + R2) = (24k * 1k) / (24k + 1k) = 960 ohms	[2]

These figures tell us that the maximum source impedance should be 2k / 10 = 200 ohms [1] and 25k / 10 = 2.5k [2], and the minimum load impedances should be 500 * 10 = 5k [1] and 960 Ohms * 10 = 9.6k [2]. As it turns out, these are easily achieved by all common circuits used in audio.

It must be understood that even with a "safety factor" of 10 as described, there will still be an error when the voltage divider is driven from any source impedance above zero, or is loaded by any circuit whose impedance is less than infinite - i.e. all voltage dividers will be in error to some (usually insignificant) degree, unless the source and load impedances are included in the calculation. The load impedance is effectively in *parallel* with R2, and the source impedance is in *series* with R1.

Returning to the R1 = 1M, R2 = 24M impedances, it is obvious that the divider will be very easy to drive from any common circuit (due to the minimal loading), but the output impedance is much too high. The final voltage divider will be loaded excessively by any load impedance less than around 9.6 Megohms, and because of the high impedance, high frequency losses will be excessive if a cable is used at the output of the attenuator (the capacitance of the cable will be sufficient to shunt HF signals to earth, instead of allowing them to reach the source). Even stray capacitance in the attenuator itself will have an effect!

It is outside the scope of this little article to cover capacitive voltage dividers (or Resistor Capacitor dividers), but they are commonly used in high impedance circuits. Project 16

(Audio Millivoltmeter) does show a perfect example of this technique, which eliminates stray capacitance effects (at the expense of higher than normal input capacitance).

In fact, a voltage divider can be made using capacitors or inductors - but only for AC. These are much less common than resistive dividers, but still work in much the same way (they are a lot harder to design though).

Conclusion

As is obvious from the above, the humble attenuator or voltage divider is not so humble after all. The maths are simple, and it is easy to convert any high voltage to a lower voltage. The divider technique is not suitable for *power* circuits however. It is used to reduce voltages, *not* current or power (although both are affected, that is a side effect, and not the real purpose).

Make sure that the resistance values you use are "sensible", and do not impose excessive loading or introduce excessive output impedances, and it is hard to go wrong. Sensible (in this context) is something that comes with experience, but the guidelines given here should be more than enough to get you under way.

Introduction

I am amazed at the number of amplifier designers who have, for one reason or another, failed to take some of the well known basics and pitfalls of amp design into consideration during the design phase. While some of these errors (whether of judgement or through ignorance is uncertain) are of no great

consequence, others can lead to the slow but sure or instantaneous destruction of an amplifier's output devices.

When I say "of no great consequence", this is possibly contentious, since a dramatic increase in distortion is hardly that, however in this context it will at least not destroy anything - other than the listener's enjoyment.

Even well known and respected designs can fall foul of some basic errors - this is naturally ignoring the multitude of "off the wall" designs (e.g. Single-ended MOSFETs without feedback (yecch! - 5% distortion, phtooey), transformer-coupled monstrosities, amplifiers so complex and bizarre that they defy logic or description, etc). This is not including valve amps, these are a "special" case and in many areas, such as guitar amps, they remain unsurpassed.

In this article, I have attempted to cover some of the areas which require their own special consideration, and the references quoted at the end are excellent sources of more detailed information on the items where a reference is given.

Reference Amplifier

My reference amplifier is shown in Project 3A, and is a hard act to follow. As I have been refining these pages and experimenting with simulations and real life, I have found that this amp is exemplary. It does need a comparatively high quiescent current to keep the output devices well away from crossover distortion, but this is easily accommodated by using decent heatsinks. Even a Class-A system (Death of Zen) fails to come close at medium power, and is barely better at low power.

This amp uses the following...

- long tailed pair input stage
- single stage bootstrapped Class-A driver
- complementary compound pair output stage
- RC Zobel network (it hates inductors)
- no current mirrors or sources (other than the bootstrap)

It is stable with all conventional loads, capable of 80W into 8 Ohms, and simple to build. Using only commonly available parts, it is also very inexpensive.

Note:

This article is not intended to be the "designers' handbook", but is a collection of notes and ideas showing the influences of the various stages in a typical amplifier. Although I have made suggestions that various topologies are superior to others, this does not mean to imply that they should automatically be used. If one were to combine all the "best" configurations into a single amp, this is no guarantee that it will perform or sound any better than one using "lesser" building blocks.

There is a school of thought that the fewer active devices one uses, the better an amp will sound. I do not believe this to be the case, but my own design philosophy is to make any given design as simple as possible, consistent with the level of performance expected of it.

Additional schools of thought will make all manner of claims regarding esoteric components, 'unexplained' phenomena, or will imply that most amplifiers as we know them are useless for audio because they do not have predictable performance at DC and/or 10GHz, cannot drive pure inductance or capacitance, etc., etc. Regardless of these claims, most amplifiers actually work just fine, and do not have to do any of the things that the claimants may imply. The vast majority of all the off-the-wall claims you will come across can safely be ignored.

Input Stages

There are two main possibilities for an input stage for a power amplifier. The most common is the long tailed pair, so we shall look at this first.

Long Tailed Pair

It has been shown [1] that failing to balance the input Long Tailed Pair properly leads to a large increase in the distortion contributed by the stage. Some designers attempt to remedy the situation by including a resistor in the "unused" collector circuit, but this is an aesthetic solution - i.e. it looks balanced, but serves no other useful purpose. (See Figure 1a) Note that the "driver" transistor is simply there to allow us to make comparisons between the circuit topologies, and to provide current to voltage conversion. It is worth noting that even though this resistor serves no purpose electronically, it can make the PCB layout easier.

Use of the long-tailed (or differential) pair in an amplifier means that the amplifier will operate with what is generally called "voltage feedback" (VFB). The feedback is introduced as a voltage, since the input impedance of both inputs is high (and approximately equal), and input current is (relatively speaking) negligible.

The feedback resistor and capacitor are selected to allow the circuit to operate at full open loop gain for the applied AC, but unity gain for DC to allow the circuit to stabilise correctly with a collector voltage at (or near) 0V. The transistors used in the simulations that follow are "ideal", without internal capacitances etc, and have an Hfe of 100 in all cases. The simulated circuits were operated at a voltage of +/- 12.

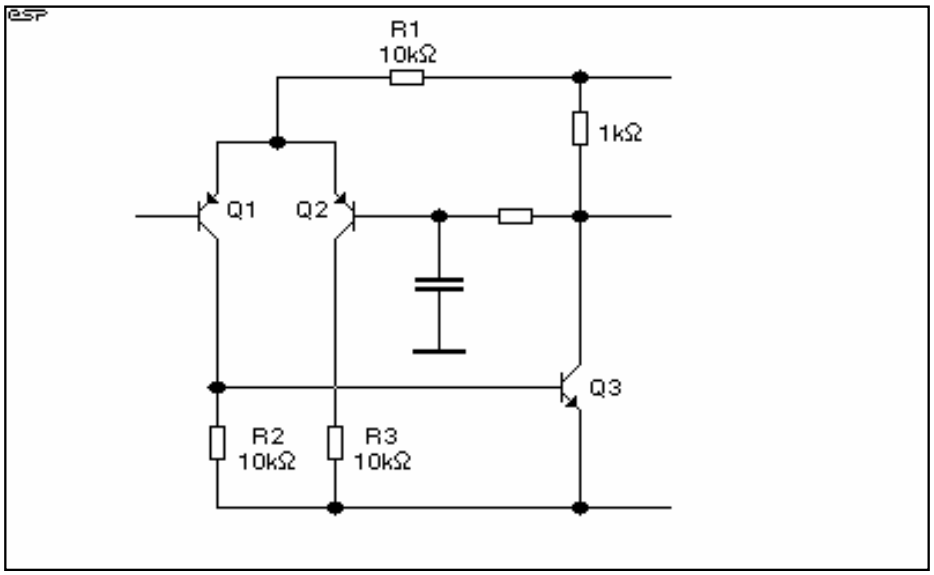

Figure 1a - Aesthetic addition of resistor to balance the collector load.

As shown, and with a 12mA collector current for Q3, the load imbalance at the LTP is 202uA for Q1, and 915uA for Q2. Simply by reducing the value of R2, it is possible to improve matters, but it is still not going to give the performance of which the circuit is capable. Again, as shown the gain of the LTP is a rather dismal 66 (as measured at the collector of Q2).

Changing R1 for a current source does not help (gain is actually reduced slightly), but provides an improvement in power supply hum rejection and in particular improves common mode rejection. A common mode signal is one that is applied in the same phase and amplitude to both inputs at once.

The overall gain of this configuration (measured at the collector of Q3) is 590, but by reducing R2 to 1.8k, it can be raised to 910. This also improves collector current matching in the LTP, but the value will be device dependent, and is not reliable for production units..

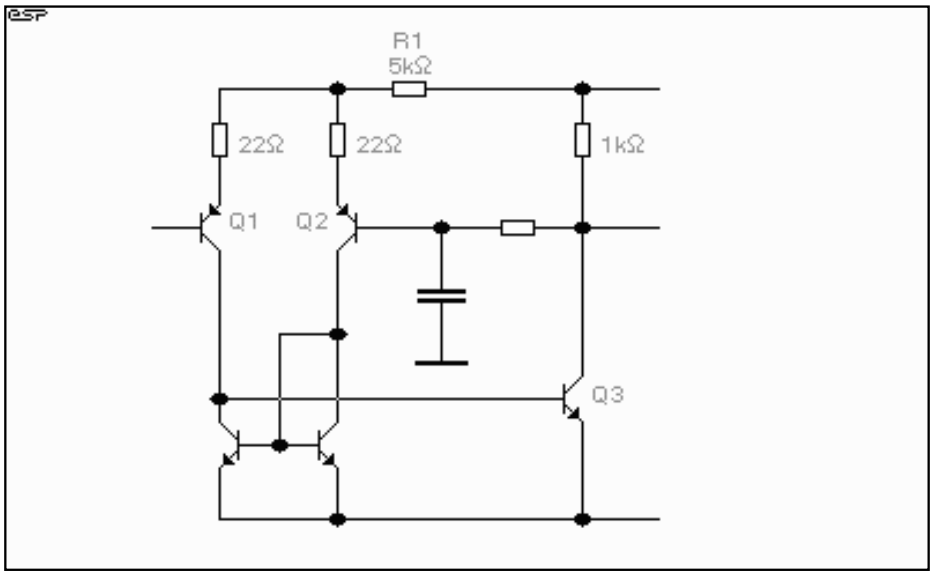

Figure 1b - A current mirror and local feedback applied to the LTP

The circuit shown in Figure 1b has improved overall gain to 2010, a fairly dramatic improvement on the earlier attempt. A further improvement in linearity is to be had by adding resistors (100 Ohm or

thereabouts) into the emitter circuits of the current mirror transistors. This will swamp the base-emitter non-linearities, and provide greater tolerance to device gain variations.

Proper selection of the operating current will improve matters considerably, and also help to reduce distortion, especially if local negative feedback (as shown in Figure 1b) is applied. This has been discussed at length by various writers [1], and a bit of simple logic reveals that benefits are bound to accrue to the designer who takes this seriously.

Since the value of the transistor's internal emitter resistance (r_e) is determined by the current flow -

$$r_e = 26 / I_e (\text{in mA})$$

at very low operating currents this value can be quite high. For example, at 0.5 mA, r_e will be about 52 ohms, increasing further as the current is reduced. Although this will introduce local feedback (and reduce the available gain), it is non-linear, resulting in distortion as the current varies during normal operation. Increasing the current, and using resistors (which are nice and linear) to bring the gain back to where it was before will reduce the distortion, since the resistor value - if properly chosen - will "swamp" the variations in the internal r_e due to signal levels.

At small currents (where the current variation during operation is comparatively high), this internal resistance has a pronounced effect on the performance of the stage. Simple solutions to apparently complex problems abound.

Use of a current mirror as the load for the long-tailed pair (LTP) again improves linearity and gain, allowing either more local feedback elsewhere, or more global feedback. Either of these will improve the performance of an amplifier, provided precautions are taken to ensure stability - i.e. freedom from oscillation at any frequency or amplitude, regardless of applied load impedance.

Single Transistor

There is another (not often used these days) version of an amplifier input stage. This is a single transistor, with the feedback applied to the emitter. It has been claimed by many that this is a grossly inferior circuit, but it does have some very nice characteristics.

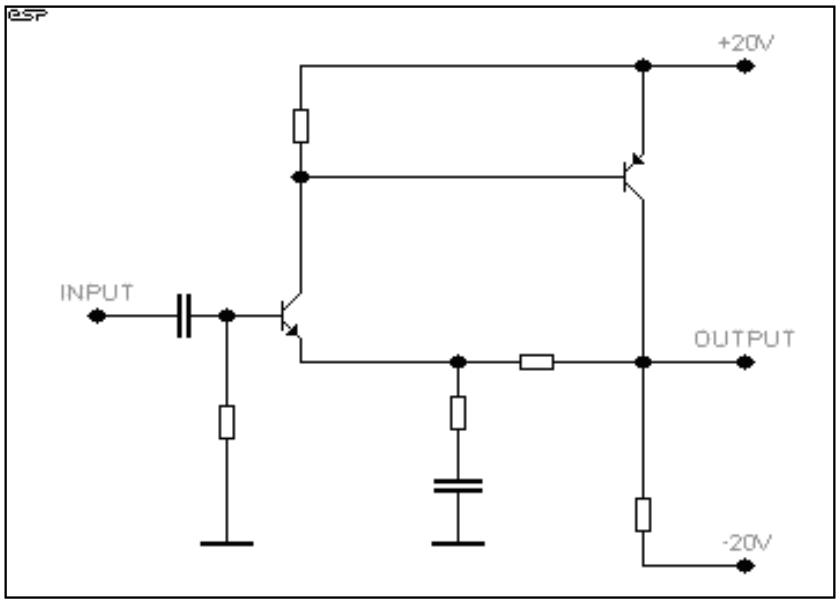

Figure 2a - Single Transistor Input Stage

So what is so nice about this? In a word, stability. An amplifier using this input stage requires little or no additional stabilisation (the "Miller" cap, or "dominant pole") which is mandatory with amps having LTP input stages.

An amplifier using this input stage is referred to as a "current feedback" (CFB) circuit, since the feedback "node" (the emitter of the input transistor) is a very low impedance. The base circuit is the non-inverting input, and has a relatively high input impedance - but not generally as high as the differential pair. The +ve and -ve inputs are therefore asymmetrical. CFB amplifiers are used extensively in extremely fast linear ICs, and are capable of bandwidths in excess of 300MHz (that is not a misprint!).

This is the input stage used in the 10W Class-A amp (John Linsley-Hood's design, which is no longer a part of The Audio Pages), and also in the "El-Cheapo" amp described in my Projects Pages. "Well if it is so good, why doesn't anybody use it?" I hear you ask (you must have said it pretty loudly, then, because Australia is a long way away - from everywhere).

There is one basic limitation with this circuit, and this was "created" by the sudden requirement of all power amplifiers to be able to faithfully reproduce DC, lest they be disgraced by reviewers and spurned by buyers.

> (I remain perplexed by this, since I know for a fact that I cannot hear DC, my speakers cannot reproduce it, I know of no musical instrument that creates it, and it would probably sound pretty boring if any of the above did apply. If you don't believe me, connect a 1.5V torch cell to your speaker, and let me know if I'm wrong. I seem to recall something about phase shift being bandied about at the time, but given the acoustics involved in recording in the studio and reproducing in a typical listening room - not to mention the "interesting" phase shifts generated by loudspeaker enclosures as the speaker approaches resonance - I feel that the effects of a few degrees of low frequency phase shift generated in an amplifier are unlikely to be audible. This is of course assuming that human ears are capable of resolving absolute phase anyway - which they have been categorically proven to be unable to do.)

This input stage cannot be DC coupled (at least not without using a level shifting circuit), because of the voltage drop in the emitter circuit and between the emitter-base junction of the transistor. Since these cannot be balanced out as they are with an LTP input stage, the input must be capacitively coupled.

In addition, some form of biasing circuit is needed, and unfortunately this will either have to be made adjustable (which means a trimpot), or an opamp can be used to act as a DC "servo", comparing the output DC voltage with the zero volt reference and adjusting the input voltage to maintain 0V DC at the output. The use of such techniques will not be examined here, but can provide DC offsets far lower than can be achieved using the amplifier circuit itself. There is no sonic degradation caused by the opamp (assuming for the sake of the discussion that opamps cause sonic degradation anyway), since it operates at DC only (it might have some small influence at 0.5Hz or so, but this is unlikely to be audible).

It has also been claimed that the single transistor has a lower gain than the LTP, but this is simply untrue. Open loop gain of the stage is - if anything - higher than that of a simple LTP for the same device current.

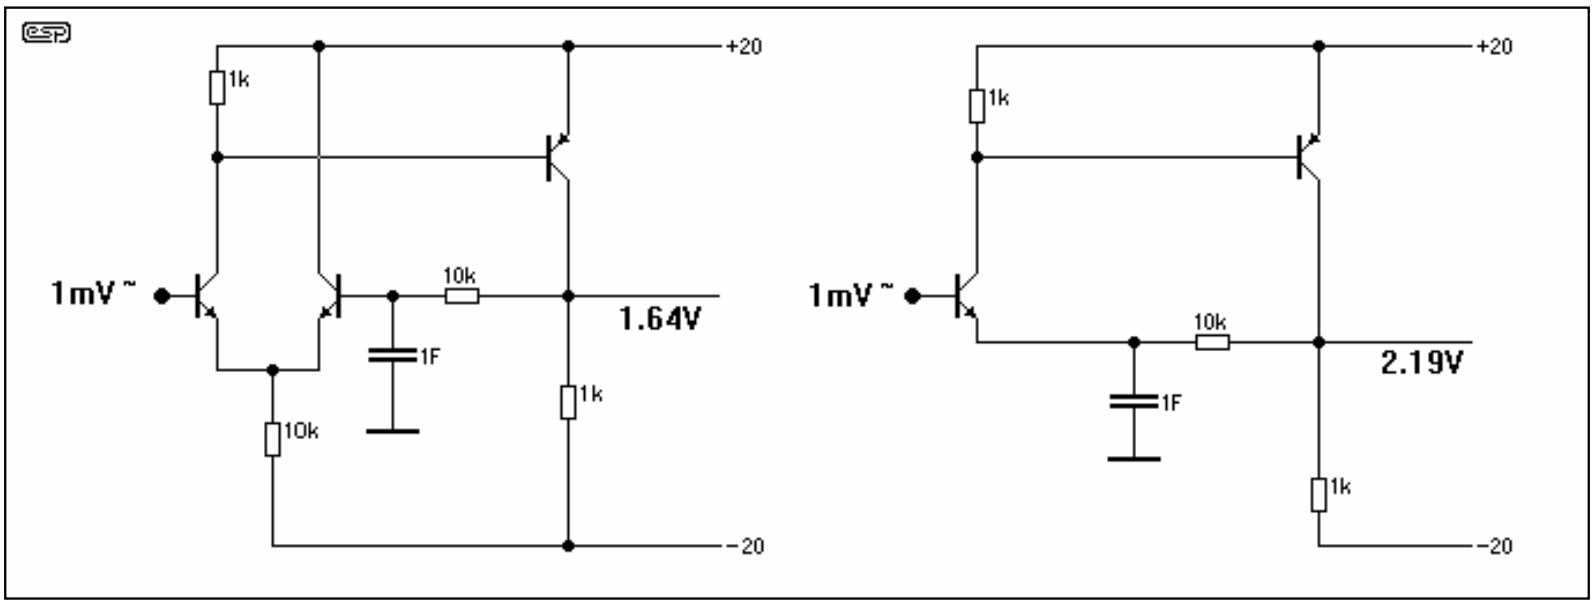

Figure 2b - Voltage Gain Comparison Of Input Stages

I simulated a very simple pair of circuits (shown in Figure 2b) to see the difference between the two. Collector current is approximately 1mA in each, and the output of the LTP shows a voltage gain of 1,640 from the combined circuit (the input stage cannot properly be measured by itself, since it operates as a current amp in both cases). In neither case did I worry about DC offset, since the effects are minimal for the purpose of simply looking at the gain - therefore offset is not shown. (Did you notice that the gains obtained in this simulation are completely different from those obtained earlier for the simple LTP circuit - I used a different voltage (the previous example used +/- 12V). This in no way invalidates anything, they are just different.)

By comparison, the open-loop gain of the single transistor stage is 2,190 - considering that all other things were maintained equal, this is considerably better. Admittedly, the addition of a current mirror would improve the LTP even more dramatically, but do we really need that much more gain? A quick

test indicates that we can get a gain of 3,570. This looks very impressive, but is only an increase of a little over 4.2dB compared to the single transistor. By the same logic, the single transistor only has a 2.5dB advantage over the simple LTP, however the difference may be moot ....

Because the single transistor stage requires no dominant pole Miller capacitor for stability, it will maintain the gain for a much wider frequency range, so in the long run might actually be far superior to the LTP. Further tests were obviously required, so I built them. Real life is never quite like the simulated version, so there was a bit less gain from each circuit than the simulator claimed. The LTP came in with an open loop gain of 1000, while the single transistor managed 1400. The test conditions were a little different from the simulation, in that +/-15 volts was used, so the gain difference is about what would be expected, and is very close to the +/-12V results obtained in the first set of simulations on the LTP.

Distortion was interesting, with the LTP producing 0.7% which was predominantly 3rd harmonic. The single transistor was slightly worse for the same output voltage with 0.9%, and this had a dominant 2nd harmonic.

As expected, the LTP was unstable without a Miller capacitor, and 56pF managed to tame it down. Quite unexpectedly, the single transistor also required a Miller cap, but only when running open-loop. When it was allowed to have some feedback the oscillation disappeared. The LTP could not be operated without the Miller capacitor at any gain, and as the gain approached unity, more capacitance was needed to prevent oscillation.

The next step was a test of each circuit providing a gain of about 27, since this is around the "normal" figure for a 60W power amp. Here, the LTP is clearly superior, with a level of distortion I could not measure. The single transistor circuit had 0.04% distortion, and again this was predominantly 2nd harmonic. In this mode, no Miller capacitor was needed for the single transistor, and it showed a very wide frequency response, with a slight rise in gain at frequencies above 100kHz. This was also noticeable with a 10kHz square wave, which had overshoot, although this was reasonably similar for positive and negative half-cycles. The LTP was well behaved, and showed no overshoot (it had the 56pF Miller cap installed), but it started to run out of gain at about 80kHz, and there was evidence of slew-rate limiting. This effect was not apparent with the single transistor.

All in all, I thought this was a worthwhile experiment, and the use of a simple resistor for the collector load of the gain stage allowed the final circuit to have a manageable gain. Had a current source or similar been used as the load, I would not have been able to measure the gain accurately, since the input levels would have been too small. As it was, noise pickup proved to be a major problem, and it was difficult to get accurate results without using the signal averaging capability on the oscilloscope.

Conclusions

Based on the tests, there are pros and cons to both approaches - and I bet that came as a surprise. The LTP in its simple form is a clear loser for gain, but use of a current mirror allows it to "blow away" the single transistor, which cannot capitalise on this technique since there is nothing to mirror.

Stability is very important to me, and I tend towards an amp which absolutely does not oscillate, even at the expense of a little more distortion, but my own 60W reference amp is unconditionally stable with

normal loads, and it uses an LTP for the input.

Protection From Radio Frequency Interference

A favourite pastime of many designers is to connect a small capacitor as shown in Figure 3 directly to the base of the input transistor. This is supposed to prevent detection (rectification) of radio frequency signals picked up by the input leads. Well, to a certain degree this is true, as the Resistor-Capacitor (RC) combination forms a low pass filter, which will reduce the amount of RF applied to the input. As shown this has a 3dB frequency of 159kHz.

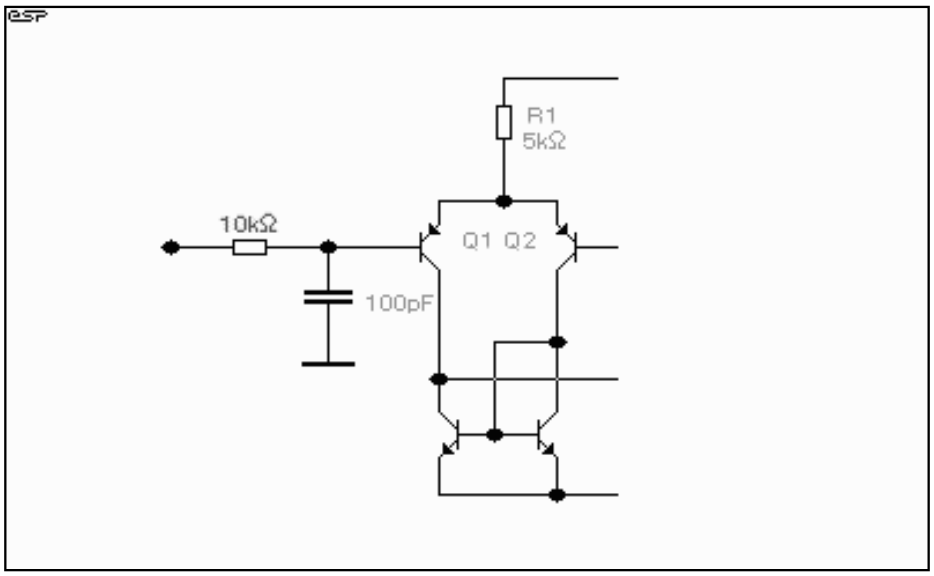

Figure 3 - The Ttraditional Method for Preventing RF Detection

Where things get really sneaky, is when the levels of RF energy are so high that some amount manages to get through anyway. I once had a workshop/lab which was triangulated by three TV transmission towers - very nasty.

The traditional method not only did not work, but made matters worse by ensuring that the transistor base was fed from a very low impedance (from an RF perspective). A vast number of commercial amplifiers and other equipment which I worked on in that time picked up quite unacceptable amounts of TV frame buzz, caused by the detection of the 50Hz vertical synchronisation pulses in the TV signal. As the picture component of TV is amplitude modulated RF, this was readily converted into audio - of the most objectionable kind.

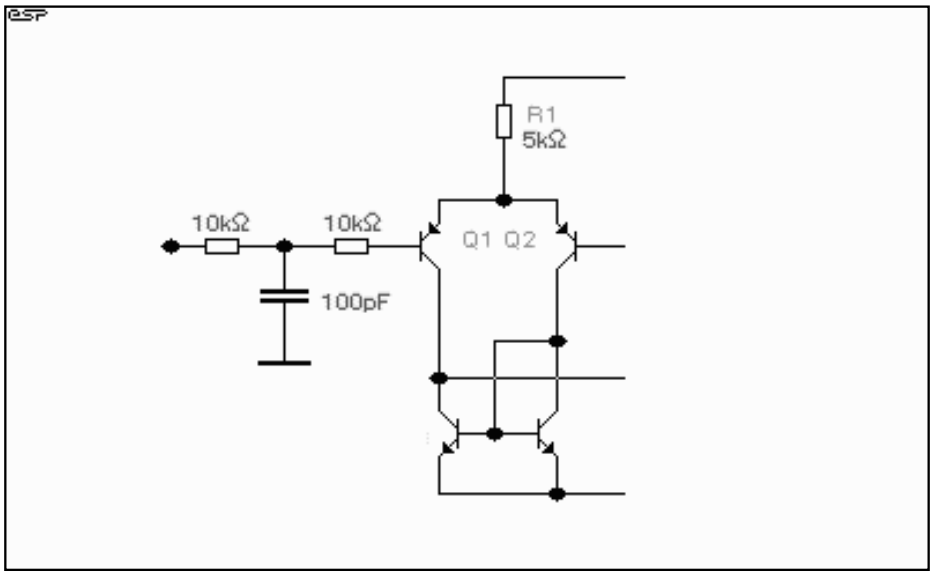

Figure 4 - Use of a Stopper Resistor to Prevent RF Detection

Figure 4 shows the remedy - but to be effective the resistor must be as close as possible to the base, or the performance is degraded. How does this work? Simple, the base-emitter junction of a transistor is a diode, and even when conducting it will retain non-linearities. These are often sufficient to enable the input stage to act as a crude AM detector, which will be quite effective with high-level TV or CB radio signals. Adding the external resistance again swamps the internal non-linearities, reducing the diode effect to negligible levels. This is not to say that it will entirely eliminate the problem where strong RF fields are present, but will at least reduce it to "nuisance" rather than "intolerable" levels.

UPDATE: I have been advised by a reader who works in a transmitting station that connecting the capacitor directly between base and emitter (in conjunction with the stopper resistor) is very effective. He too found that the traditional method was useless, but that when high strength fields are encountered, the simple stopper is not enough.

With opamps, the equivalent solution is to connect the stopper resistor in series with the +ve input, and the capacitor between the +ve and -ve inputs, with no connection to earth.

In all both cases it is essential to keep all leads and PCB tracks as short as possible, so they cannot act as an antenna for the RF. Needless to say, a shielded (and grounded) equipment case is mandatory in such conditions.

Gain Stage (Class-A Amplifier Section) The Class-A amp stage is also commonly known as the Voltage Amplification Stage (VAS), but both terms are common, and are generally interchangeable. There are a number of traps here, not the least of which is that it is commonly assumed that the load (from the output stage) is infinite. Oh, sure, every designer knows that the Class-A stage must carry a current of at least 50% more than the output stage will draw, and this is easily calculated ...

$$I_A = Peak_V / Op_R / Op_Gain * 1.5$$

where I_A is the Class-A current, Peak_V is the maximum voltage across the load Op_R, and Op_Gain

is the current gain of the output transistor combination.

For a typical 100W / 8 Ohm amplifier this will be somewhere between 5 and 10mA. Assuming an output transistor combination with a current gain of 1000 (50 for the driver, and 20 for the power transistor), with an 8 Ohm load, the impedance presented to the Class-A stage will be about 2k Ohms, which is a little shy of infinity.

Added to this is the fact that the impedance reflected back is non-linear, since the driver and output transistors change their gain with current - as do all real-life semiconductors. There are some devices available today which are far better than the average, but they are still not perfect in this respect.

The voltage gain is typically about 0.95 to 0.97 with the compound pair configuration. It must be noted that this figure will only be true for mid-range currents, and will be reduced at lower and higher values. Figure 5 shows the basic stage type - the same basic amplifier we used before, with the addition of a current source as the collector load. Also common is the bootstrapped circuit (not shown here, but evident on many ESP designs).

There is not a lot of difference between current source and bootstrap circuits, but the current source has slightly higher gain. With either type, there are some fairly simple additions which will improve linearity quite dramatically. Figure 5 shows the typical arrangement, but with the omission of the dominant pole stabilisation capacitor, which would normally be connected between the Class-A transistor's collector and base.

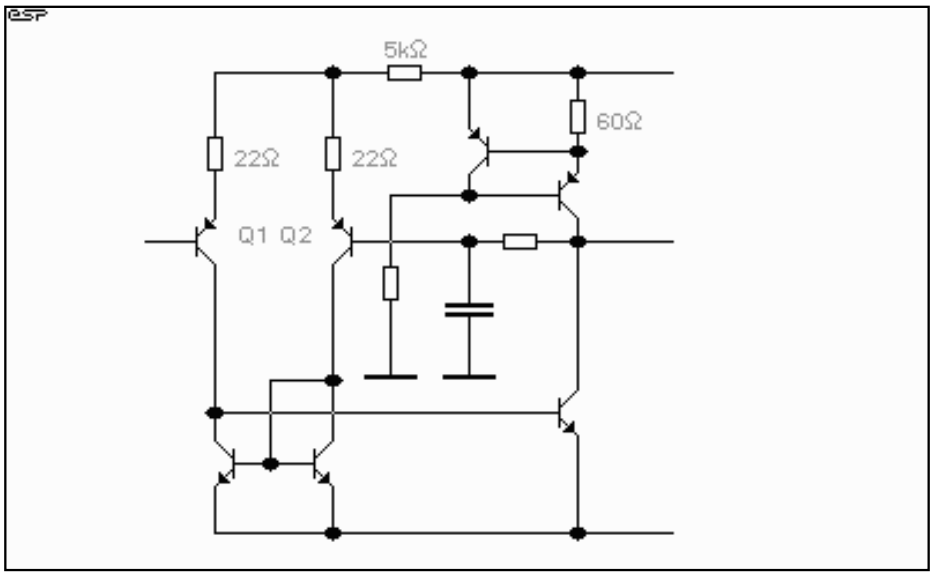

Figure 5 - Typical Class-A Driver Configuration

It is therefore important to try to make the Class-A stage capable of high gain, even when loaded by the output stage. There have been many different methods used to achieve this, but none is completely successful. The biggest problem is that many designers seem completely oblivious to this problem area, or create such amazingly complex "solutions" as to make stabilisation almost impossible.

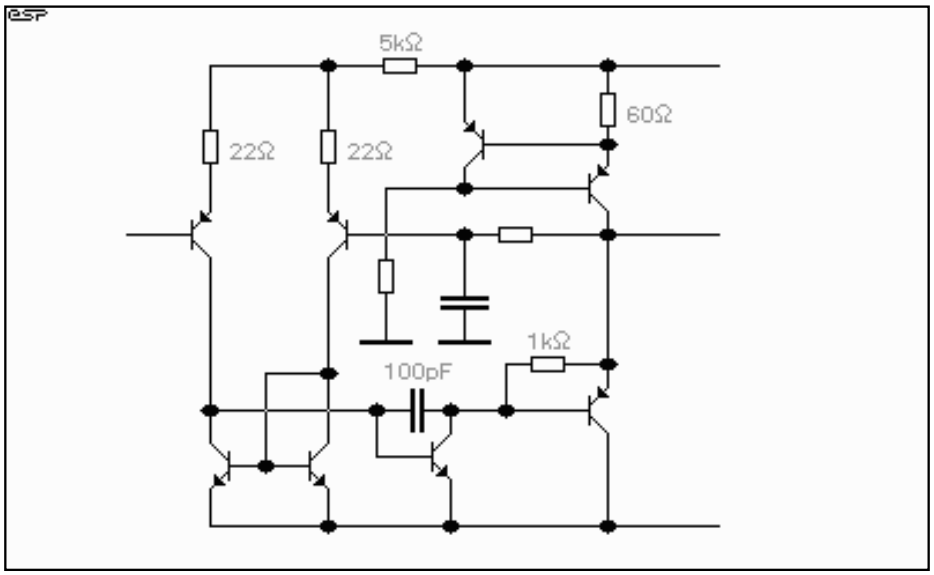

Figure 6 - Improving Open Loop Output impedance of Class-A Driver

The above is simple and very effective. This straightforward addition of an emitter follower to the Class-A driver (with the "bootstrap" resistor) has increased the combined LTP and Class-A driver gain to 1,800,000 (yes, 1.8 million!) or 125dB (open loop and without the dominant pole capacitor connected). Open loop output impedance is about 10k, again without the cap. Once the latter is in circuit, gain is reduced to a slightly more sensible 37,000 at 1kHz with the 100pF value shown. Output impedance at 1kHz is now - comparatively - very low, at about 150 Ohms.

Note that in the above, I have used a 5k resistor instead of the more usual current source. This is for clarity of the drawing, and not a suggestion that the current source should be forsaken in this position.

A special note for the unwary - If one is to use a single current control transistor for both the LTP and Class-A driver, do not use the Class-A current as the reference, but rather the LTP. If not, the varying current in the Class-A circuit will cause modulation of the LTP emitter current, with results that are sure to be as unwelcome as they are unpredictable [4].

I have often seen amplifier designs where the circuit is of such complexity that one must wonder how they ever managed to stop it from becoming high power radio frequency oscillators. The maze of low value capacitors sometimes used - some with series resistance - some without, truly makes one wonder what the open loop frequency and phase response must look like. Couple this with the fact that many of these amps do not have wonderful specifications anyway, and one is forced to ponder what the designer was actually trying to accomplish (being 'different' is not a valid reason to publish or promote a circuit in my view, unless it offers some benefit otherwise unattainable).

UPDATE: Having carried out quite a few experiments over a period of a few weeks, I am not completely certain that vast amounts of gain from the input stage and Class-A amplifier stage are necessary. As long as the circuit is linear (i.e. has low distortion levels before the addition of feedback), the final result is likely to be satisfactory. I have seen many circuits with far more open loop gain than my reference amp (Project 3A), and that in theory should be vastly superior - yet they are not.

Active Current Source or Bootstrap?

There are essentially two ways to create a constant current feed to the Class-A driver stage. The active current source (as shown above) is one method, and this is very common. It does introduce additional active devices, but it is possible to make a current source that has an impedance so close to infinity that it will be almost impossible to measure it without affecting the result just by attaching measurement equipment. For more detailed information on current sources, see the article Current Sources Sinks and Mirrors.

A simpler way is to use the bootstrap circuit, where a capacitor is used from the output to maintain a relatively constant voltage across a resistor. If the voltage across a resistor is constant, then it follows that the current flowing through it must also be constant. Figure 6a shows the circuit of a bootstrap constant current source. Unlike a true current source, the current through the bootstrap circuit will change with the supply voltage. This is a gradual change, and is outside the audio spectrum - or at least it should be if the circuit is designed correctly.

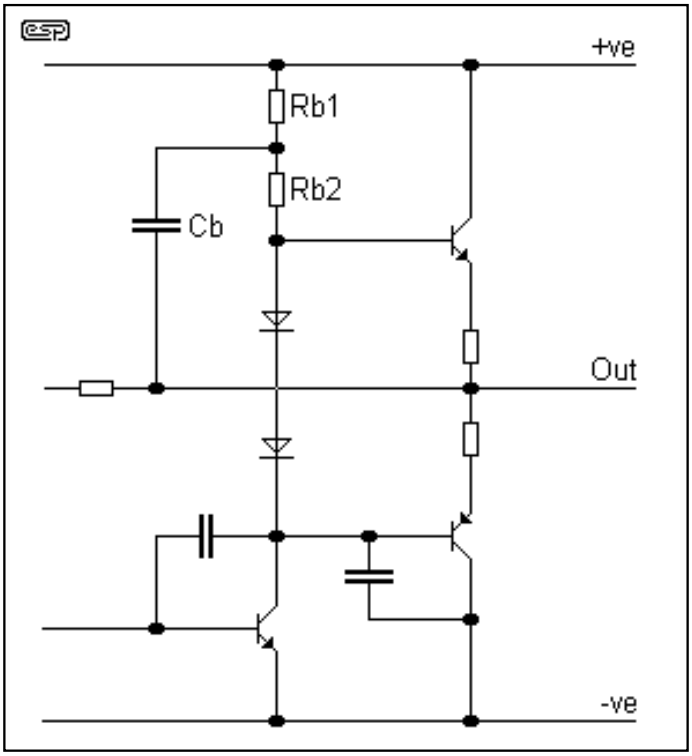

Figure 6a - Bootstrap Current Source

This circuit works as follows. Under quiescent conditions, the output is at zero volts, and the positive supply is divided by Rb1 and Rb2. The base of the upper transistor will be at about +0.7V - just sufficient to bias the transistor. As the output swings positive or negative, the voltage swing is coupled via Cb, so the voltage across Rb2 remains constant. The current through Rb2 is therefore constant, since it maintains an essentially constant voltage across it. Note that this applies only for AC voltages, as the capacitor will charge if there is a DC variation.

The overall difference is not great in a complete design. Although the current source is theoretically better, a bootstrap circuit is simpler and cheaper, and introduces no additional active devices.

Output Stage

There are countless amplifiers which still use the Darlington type configuration, even though this was shown by many [2] to be inferior to the complementary pair. Both configurations (in basic form, since there are many variations) are shown in Figure 7. There are two main areas where the Darlington configuration is inferior, and we shall look at each ...

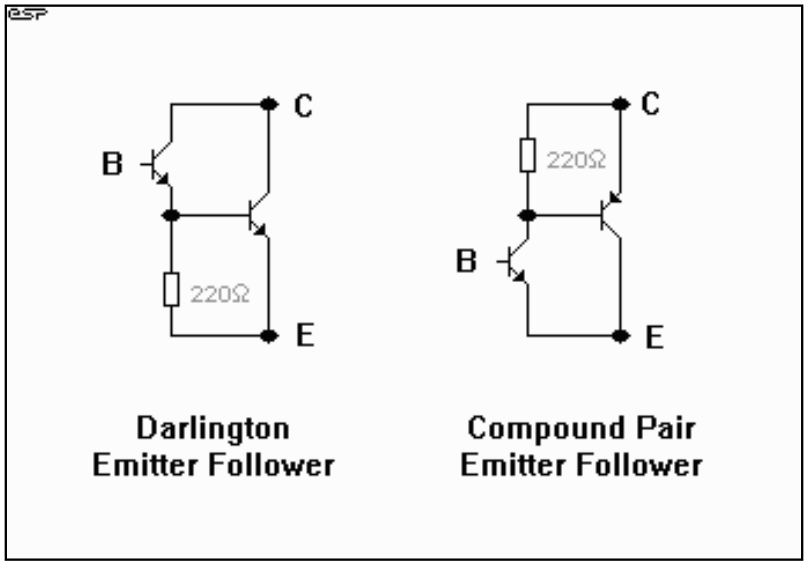

Figure 7 - The basic configurations of output stages in common use

Of the two shown, it will be apparent that I have ignored MOSFET output stages - this is because MOSFETs require no driver transistor as such - they are normally driven directly from the Class-A amplifier (or a modified version - often a modified long-tailed-pair. As can be seen, the component count is the same for those shown, but instead of using two same polarity (both PNP or both NPN), the compound pair (also called a Sziklai pair) uses one device of each polarity. The final compound device assumes the characteristics of the driver in terms of polarity, and the Emitter, Base and Collector connections for each are shown. The resistor is added to prevent output transistor collector to base leakage current from allowing the device to turn itself on, and also speeds up the turn-off time. Omission of this resistor is not a common mistake to make, but it has been done. The results are degraded distortion figures - especially at high frequency - and poor thermal stability.

The value must be selected with reasonable care, if it is too low, the output transistor will not turn on under quiescent (no signal) conditions, the driver transistor(s) will be subject to excessive dissipation, and crossover distortion will result. If too high, turn-off performance of output devices will be impaired and thermal stability will not be as good. The final value depends (to some extent) on the current in the Class-A driver stage and the gain of the driver transistor, but the final arbiter of quiescent is the Vbe multiplier stage. These comments apply equally to the Darlington and compound pairs.

Values of between 100 Ohms up to a maximum of perhaps 1k should be fine for most amplifiers, with lower values used as power increases, which creates higher currents throughout the output stage and makes the transistors harder to turn off again, especially at high frequencies..

Thermal Stability

It can be seen that in the Darlington configuration, there are two emitter-base junctions for each output device. Since each has its own thermal characteristic (a fall of about 2mV per degree C), the combination is notoriously difficult to make thermally stable. In addition, the gain of transistors often increases as they get hotter, thus compounding the problem. The bias 'servo', typically a transistor Vbe multiplier, must be mounted on the heatsink to ensure good thermal equilibrium with the output devices, and in some cases can still barely manage to maintain thermal stability.

If stability is not maintained, the amplifier may be subject to thermal runaway, where after a certain output device temperature is reached, the continued fall of Vbe causes even more quiescent current to flow, causing the temperature to rise further, and so on. A point is reached where the power dissipated is so high that the output transistors fail - often with catastrophic results to the remainder of the circuit and/or the attached loudspeakers.

The compound pair has only one controlling Vbe, and is thus far easier to stabilise. Since the single Vbe is that of the driver (which in many cases will not be mounted on the main heatsink, and in some will have no heatsink at all), the requirements for the Vbe multiplier are less stringent, mounting is far simpler and thermal stability is generally very good to excellent.

I have used the compound pair for over 20 years, and when I saw it for the first time, it made too much sense in all respects to ignore. Thermal stability in a fairly basic 100W/4 Ohm amplifier of my design (of which hundreds were built -it was the predecessor of the P3A design in the projects section) was assured with a simple 2-diode string - no adjustment was ever needed.

Linearity

Numerous articles have been written on the superior linearity of the compound stage (Otala [3], Self, Linsley Hood among others) and I cannot help but be astonished when I see a new design in a magazine, still using the Darlington arrangement. The use of the compound pair requires no more components - the same components are simply arranged in a different manner. It was with great gusto that an Australian electronics magazine proudly announced (in 1998) that "this is the first time we have used this arrangement in a published design" (or words to that effect). I don't know the reason(s) they may have had for not using the complementary pair in *every* design they published (this magazine is a lot younger than I). Words fail me. The magazine in question is not the only one, and the Web abounds with designs old and new - all using the dreaded Darlington emitter-follower.

This is not to say that the Darlington stage shouldn't be used - there are many fine amplifiers that use it, and with a bit of extra effort to get the bias servo right, such amps will give many years of reliable service. It is particularly suited to very high power amps, because of its simplicity - especially with multiple paralleled output devices.

Darlington		
Driver	O/P Transistor	Total Gain
50	25	1310

Compound		
Driver	O/P Transistor	Total Gain
50	25	1290

Figure 8 - Relative Forward Current Gain of Compound Pair vs. Darlington Emitter Follower.

The lower gain of the compound pair indicates that there is internal local negative feedback inherent in the configuration, and all tests that have been performed indicate that this is indeed true. Although the gain difference is not great, much of the improved linearity can be assumed to result from the fact that only one emitter-base junction is directly involved in the signal path rather than two, so only one set of direct non-linearities .is brought into the equation. The second (output) device effectively acts as a buffer for the driver.

Having said that, there are some very well respected amplifiers using Darlington emitter-follower output stages. There are no hard and fast rules that can be applied to make the perfect amplifier (especially since it does not yet exist), and with careful design it is quite possible to make a very fine sounding amplifier using almost any topology.

Design of Bias Servo

It would seem (at first glance at least) that there is nothing to this piece of circuitry. It is a very basic Vbe multiplier circuit, and seemingly, nothing can go wrong. This is almost true, except for the following points.

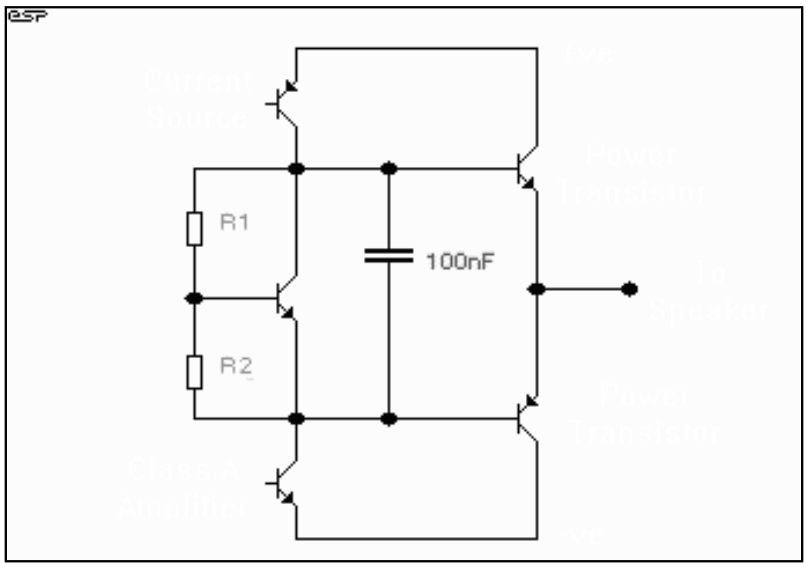

Figure 9 - The basic bias servo circuit

The design of many amps (especially those using a Darlington output stage) requires that the bias servo be made adjustable, to account for the differing characteristics of the transistors. If resistor R1 (in Fig 9) is instead a trimpot (i.e. variable resistor), what happens when (if) the wiper decides (through age, contamination or rough handling) to go open-circuit?

The answer is simple - the voltage across the bias servo is now the full supply voltage (less a transistor

drop or two), causing both the positive and negative output devices to turn on as hard as they possibly can. The result of this is the instantaneous destruction of the output devices - this will happen so fast that fuses cannot possibly prevent it, and even the inclusion of sophisticated Load-Line output protection circuitry is unlikely to be able to save the day.

The answer of course is so simple that it should be immediately obvious to all, but sadly this is not always the case. By making R2 the variable component, should it happen to become open-circuited the bias servo simply removes the bias. This will introduce crossover distortion, but the devices are saved. To prevent the possibility of reducing the pot value to 0 ohms (which will have the same effect as described above!), there should be a series resistor, whose value is selected to allow adequate adjustment while retaining a respectable safety margin.

An additional precaution must be taken here, in that if the resistor values are too low, the offset voltage seen by the output transistors is simply the voltage drop across the resistors, with the transistor having little or no control over the result. This is easily avoided by ensuring that the resistor current is 1/10 (or thereabouts) of the total Class-A bias current.

UPDATE: It is also quite possible to make the resistance too large, so the bias servo will amplify the temperature change too much. This will cause the amplifier's quiescent current to fall as it gets hotter. While this is a good thing from the reliability point of view, if it causes crossover distortion to appear when the amp is hot, the audible effect will obviously be a disaster. It will generally be necessary to experiment with the values to ensure that stability is maintained - there is no way to calculate this that comes to mind, although I am sure it is possible. The base-emitter voltage falls at 2mV / degree C, but the variation in gain with temperature is not as readily calculated.

As a secondary safeguard, using a suitable diode string in parallel with the servo is suggested. These should be chosen to prevent destructive current, but some method of over temperature protection will be needed.

Output Stage Stability

It is a simple fact of life that an emitter follower (whether Darlington or compound) is perfectly happy to become an oscillator - generally at very high frequencies. This is especially true when the output lead looks like a tuned circuit. A length of speaker cable, while quite innocuous at audio frequencies, is a transmission line at some frequency determined by its length, conductor diameter and conductor spacing. A copy of the ARRL handbook (from any year) will provide all the formulae needed to calculate this, if you really want to go that far.

All power amplifiers (well, nearly all) use emitter follower type output stages, and when a speaker lead and speaker (or even a non-inductive dummy load) are connected, oscillation often results. This is nearly always when the amp is driven, and is more likely when current is being drawn from the circuit. It is a little sad that the compound pair is actually more prone to this errant behaviour than a Darlington, possibly because the driver is the controlling element (and its emitter is connected to the load), and has a higher bandwidth.

Some of the 'super' cables - much beloved by audiophiles - are often worse in this respect for their ability to act as RF transmission lines than ordinary Figure-8, zip cord or 3-core mains flex, and are therefore more likely to cause this problem.

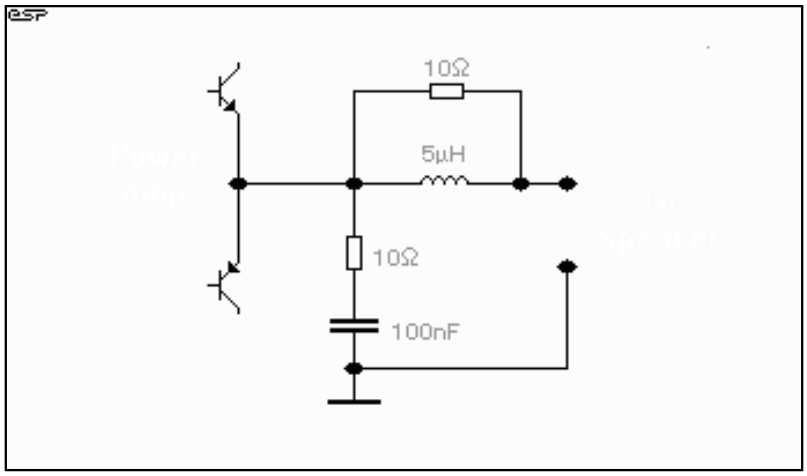

Figure 10 - The standard output arrangement for power amp stability

The conventional Zobel network (consisting of the 10 Ohm resistor and 100nF capacitor) generally swamps the external transmission line effect of the speaker cables and loudspeaker internal wiring, and provides stability under most normal operating conditions.

With capacitive loading (as may be the case when a loudspeaker and passive crossover are connected), the Zobel network has no additional effect whatsoever. The only sure way to prevent oscillation or severe ringing is to include an inductor in the output of the amplifier. This should be bypassed with a suitable resistor to reduce the Q of the inductor, and the typical arrangement is shown in Fig 10. For readers wishing to explore this in greater depth, read "The Audio Power Interface" [2]. Of late (see the note below), I have been suitably perplexed by the sudden appearance of distortion in an amp, simply by adding the inductor. On the basis of this, it might be better to use a far lower resistance than the 10 Ohms specified above - I am thinking 1 Ohm or maybe even less !

Another alternative is to include a resistor in series with the output of the amplifier, but this will naturally have the dual effect of reducing power output and reducing damping factor. At resistor values sufficient to prevent oscillation, the above losses become excessive - and all wasted power must be converted into heat in the resistor.

The choice of inductor size is not difficult - for an 8 Ohm load it will be typically a maximum of 6uH, any larger than this will cause unacceptable attenuation of high frequencies. A 6uH inductor as shown in Figure 10 will introduce a low frequency loss (assuming 0.03 Ohm resistance) of 0.03dB and will be about 0.2dB down at 20kHz. These losses are insignificant, and will not be audible. In contrast, ringing (or in extreme cases, oscillation) of the output devices will be audible (even at very low levels) as increased distortion, and in extreme cases may destroy the transistors.

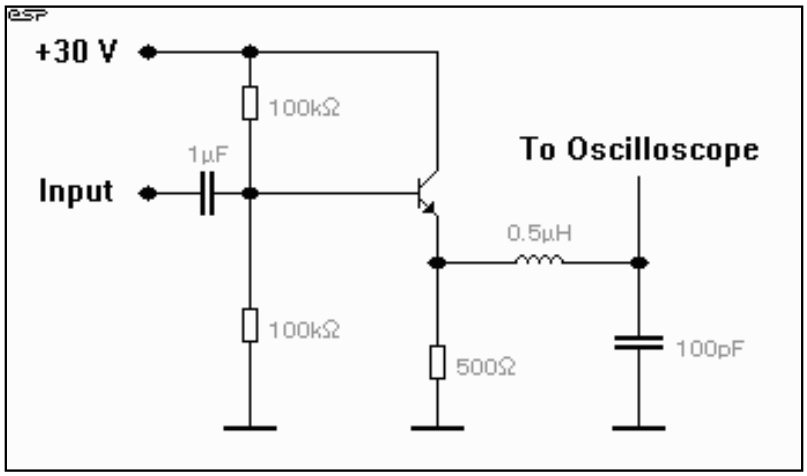

Figure 11 - Lumped component transmission line causes emitter follower to oscillate

In simulations and on the lab bench, I have been able to make a single transistor emitter follower circuit oscillate quite happily, with a real transmission line (such as a length of co-axial cable), or a lumped component equivalent of a transmission line, consisting of a 5nH inductor and 100pF as a series tuned circuit. This is shown in Figure 11.

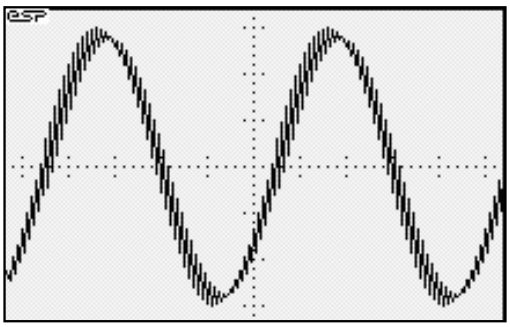

Figure 12 - Simulator oscilloscope display of oscillation in emitter follower

This effect is made worse as the source impedance is lowered, but even a base stopper resistor will not prevent oscillation - only the swamping effect of the transmission line by a Zobel network succeeds. In case you were wondering why the oscilloscope take-off point is at the junction of the L and C components, this allows series resonance to amplify the HF component, making it more readily seen.

In my own amp (the one that hundreds of were made), I did not use an output inductor, but instead made the dominant pole (the capacitance from the collector to base of the Class-A driver) somewhat larger than normal. This managed to keep the amp stable under all operating conditions, but at the expense of slew rate (and consequent slew rate limited power at high frequencies). This was largely an economic decision, since a couple of ceramic capacitors are much cheaper than an inductor, and the amp was used largely for musical instrument amplification so an extended high frequency response was actually undesirable. Full power bandwidth - the ability of an amp to supply full power over its entire operating frequency range - is a sure way to destroy hearing, HF horn drivers (etc) in a live music situation, so the compromise was not a limitation. However ….

There is another reason that a series output inductor may be helpful. It has been suggested (but by whom I cannot remember) that radio frequencies picked up by the speaker leads may be injected back

into the input stage via the negative feedback path. When one looks at a typical circuit, this seems plausible, but I have not tested the theory too deeply.

The basics behind it are not too difficult to work out, however. Since it is known that there must be a dominant pole in the amplifier's open-loop frequency response (the capacitor shown in Figures 5 and 6) if it is to remain stable when feedback is applied, it follows that as internal gain decreases with increasing frequency then the output impedance must rise (due to less global feedback). Indeed this is the case, and by the time the frequency is into the MHz regions, there will be negligible loading of any such frequencies by the output stage.

If appropriate precautions are not taken (as in Figure 4) for the negative feedback return path, then it is entirely likely that RF detection could occur. In my own bi-amped system (which uses the amplifier described above, still without an output inductor), I recently had problems with detection of a local AM radio station. Fitting of RF "EMI" suppression chokes (basically, loop the speaker cable through a ferrite ring 3 or 4 times) completely eliminated the problem, so I must conclude that it is indeed possible or even probable.

Output Current

The maximum output current of a power amplifier is often thought to be something that affects the output transistors only, and that adding more transistors will automatically provide more current to drive lower impedances. This is only partially true, because bipolar transistors need base current, and this must come from the driver stage.

It is common to bias the Class-A driver stage so that it can provide between 1.5 to 5 times the expected base current needed by the output transistors. As the current in this stage is lowered, there is likely to be a substantial increase in the distortion, since the current will change by a larger percentage. If the Class-A driver current is too high, there will be too much heat to get rid of, and it is possible to exceed the transistor's maximum ratings. I normally work to a figure of about double the expected output device base current, but in some cases it will be less than this.

As an example, let's look at a typical power amplifier output stage. Assuming a power supply of +/-35V, the maximum output current will be 35 / 8 = 4.375 Amps (an 8 ohm load is assumed). Since we know that there will be some losses in the driver / power transistor combination, we can safely assume a maximum current of 4A. A suitable power transistor may be specified for a minimum gain (Hfe) of 25, with a collector current of 4A. The driver transistors will generally have a higher gain - perhaps 50 at a collector current of 250mA. The product of the two current gains is accurate enough for what we need, and this gives a combined Hfe of 1,000. The peak base current will therefore be 4mA.

If we choose to use a Class-A driver current of double the expected output device base current, this means that the driver will operate at about 8mA. This could be achieved with a current source, or a bootstrapped circuit using a pair of 2.2k resistors in series. At the maximum voltage swing (close to +/-35V), the driver current will be increased to 12mA or decreased to 4mA, depending on the polarity. The current source or bootstrap circuit will maintain a constant current, but the driver has to deal with a current that varies by +/-4mA as the current into the load changes.

If the load impedance is dropped to 4 ohms, the current source will still only be able to provide 8mA, so output current will be limited to 8A - the driver at this point in the cycle has zero current. At the opposite extreme, the driver will have to cope with 16mA when it is turned on fully. At lower impedances, the driver will be able to supply more current, but the current source will steadfastly refuse to provide more than the 8mA it was designed for, so the peak output current will be limited to 8A in one direction (when the current source provides the drive signal and the Class-A driver is turned off), or some other (possibly destructive) maximum current in the opposite polarity.

But hang on! A Class-A driver is called a Class-A driver because it never turns off - we now have a Class-AB driver, which is not the desired objective! The amplifier will clip asymmetrically, and is no longer operating in the linear range - it is distorting.

Adding more power transistors will provide a very limited benefit, since the maximum base current is still limited by the current source supplying the Class-A driver. In order to obtain maximum power at lower impedances requires that either the gain of the output stage is increased, or the Class-A driver current must be increased. Increasing the gain of the output stage devices is not trivial - you must either use a different topology or higher gain power and driver transistors.

The design phase of an amplifier follows similar guidelines, regardless of topology. From Amplifier Basics ...

- **Power Output vs. Impedance**
  The power output is determined by the load impedance and the available voltage and current of the amplifier. An amplifier that is capable of a maximum of 2A output current will be unable to provide more, just because you want it to. Such an amp will be limited to 16W peak (or 8W RMS) into 8 ohms, regardless of the supply voltage. Likewise, and amp with a supply voltage of +/-16V will be unable to provide more than 8W RMS into 8 ohms, regardless of the available current. Having more current available will allow the amp to provide (for example) 16W into 4 ohms (4A peak current) or 32W into 2 ohms (8A peak current), but will give no more power into 8 ohms than the supply voltage will allow.

- **Driver Current**
  Especially in the case of bipolar transistors, the driver stage must be able to supply enough current to the output transistors - with MOSFETs, the driver must be able to charge and discharge the gate-source capacitance quickly enough to allow you to get the needed power at the highest frequencies of interest.

  For the sake of simplicity, if bipolar output transistors have a gain of 20 at the maximum current into the load, the drivers must be able to supply enough base current to allow this. If the maximum current is 4A, then the drivers must be able to supply 200mA of base current to the output devices.

- **Class-A Driver Stage**
  The stages that come before the drivers must be able to supply sufficient current for the load imposed. The Class-A driver of a bipolar or MOSFET amp must be able to supply enough current to satisfy the base current needs of bipolar drivers, or the gate capacitance of MOSFETs.

Again, using the bipolar example from above, the maximum base current for the output transistors was 200mA. If the drivers have a minimum specified gain of 50, then their base current will be

200 / 50 = 4mA.

Since the Class-A driver must operate in Class-A (what a surprise), it will need to operate with a current of 1.5 to 5 times the expected maximum driver current, to ensure that it never turns off. The same applies with a MOSFET amp that will expect (for example) a maximum gate capacitance charge (or discharge) current of 4mA at the highest amplitudes and frequencies. For the sake of the extercise, we shall assume a Class-A driver (VAS) current of double the base current needs of the drivers ... 8mA.

- **Input Stages**
  The input stages of all transistor amps must be able to supply the base current of the Class-A driver. This time, a margin of between 2 and 5 times the expected maximum base current is needed. If the Class-A driver operates with a quiescent current of 8mA, the maximum current will be 12mA (quiescent + driver base current. Assuming a gain of 50 (again), this means that the input stage has to be able to supply 12 / 50 = 240uA, so it must operate at a minimum current of 240uA * 2 = 480uA to preserve linearity.

- **Input Current**
  The input current of the first stage determines the input impedance of the amplifier. Using the above figures, with a collector current of 480uA, the base current will be 4.8uA for input devices with a gain of 100. If maximum power is developed with an input voltage of 1V, then the impedance is 208k (R = V/I).

  Since the stage must be biased, we apply the same rules as before - a margin of between 2 and 5, so the maximum value of the bias resistors should be 208 / 2 = 104k. A lower value is preferred, and I suggest that a factor of 5 is more appropriate, giving 208 / 5 = 42k (47k can be used without a problem).

These are only guidelines (of course), and there are many cases where currents are greater (or smaller) than suggested. The end result is in the sound of the amp, and the textbook approach is not always going to give the expected result.

Some Notes on Power Supply Design

When specified, regulation is based upon a resistive load over the full cycle, but when used in a capacitor input filter (99.9% of all amplifier power supplies), the quoted and measured figures will never match.

Since the applied AC spends so much of its time at a voltage lower than that of the capacitor, there is no diode conduction. During the brief periods when the diode conducts, the transformer has to replace all energy drained from the capacitor in the intervening 7 to 8ms or so (assuming 50Hz and full wave rectification).

Consider a power supply as shown in Figure 13. This is a completely conventional full-wave capacitor input filter (it is shown as single polarity for convenience). The circuit is assumed to have a total effective series resistance of 1 Ohm - this includes transformer winding resistances (primary and secondary) and diode losses. The capacitor C1 has an initial value of 4,700uF.

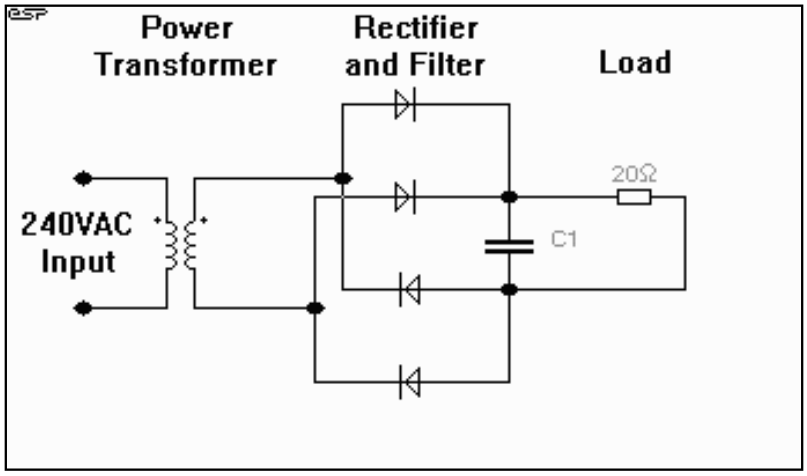

Figure 13 - Full Wave, Capacitor Input Filter Rectifier

The transformer is rated at 60VA and has a primary resistance of 15 Ohms, and a secondary resistance of 0.5 Ohms. This calculates to an internal copper loss resistance of 0.75 Ohm.

With a 20 Ohm load as shown, and at an output current of about 1.7 amps (1.69A actually), diode conduction is about 2.8ms, and the peak value of the current flowing into the capacitor is 6A - 100 times per second (10ms interval). Diode conduction is therefore 28% of the cycle. (To check that these figures are valid, we can take the peak capacitor current and the duty cycle, and calculate the average

$$I_a = (I_p / 100) * \text{duty cycle so, } I_a = (6 / 100) * 28 = 1.68 \text{ (close enough for our purposes)}$$

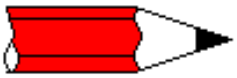
Ripple across the load is 2.4V peak-peak (or about 740mV RMS), and is the traditional sawtooth waveform. Average DC load voltage is 33.8V. The no-load voltage of this supply is 41V, so at a mere 1.7A load, the regulation is ...

$$\text{Reg (\%)} = ((V_n - V_l) / Vn) * 100$$

Where V_n is the no-load voltage, and V_l is the loaded voltage

For this example, this works out to 17.5% which is terrible. By comparison, the actual transformer regulation would be in the order of 5% for a load current of 2A at 30V. Note that the RMS current in the secondary of the transformer will be 2A AC (i.e. DC current multiplied by √2), for a load current of 1.7A DC - this must be so, since otherwise we would be getting something for nothing - a practice frowned upon by physics and the taxman.

Output power is 33.8V * 1.7A = 57.46W, and input power is 240V * 0.25A = 60W (VA actually, but we won't split hairs here). The losses are caused by the diode voltage drop and winding resistance of the transformer.



Capacitor Ripple Current - It is well known that bigger transformers have better efficiency that small ones, so it is a common practice to use a transformer that is over-rated for the application. This can improve the regulation considerably, but also places greater stresses on the filter capacitor due to higher ripple current. This is quoted in manufacturer data for capacitors intended for use in power supplies, and must not be exceeded. Excessive ripple current will cause overheating and eventual failure of the capacitor.

Large capacitors usually have a higher ripple current rating than small ones (both physical size and capacitance). It is useful to know that two 4,700uF caps will usually have a higher combined ripple current than a single 10,000uF cap, and will also show a lower ESR (equivalent series resistance). The combination will generally be cheaper as well - one of the very few instances where you really can get something for nothing.

For further reading on this topic, see the Linear Power Supply Design article.

Measurements Versus Subjectivity

If I *never* hear someone complaining that "distortion measurements are invalid, and a waste of time" again, it will be too soon. I am so fed up with self-proclaimed experts (where 'x' is an unknown quantity, and a 'spurt' is a drip under pressure) claiming that 'real world' signals are so much more complicated than a sinewave, and that static distortion measurements are completely meaningless.

They ***are not*** meaningless, and real world signals ***are*** sinewaves! The only difference is that with music, there is usually a large number of sinewaves, all added together. There is not a myriad of simultaneous signals passing through an amp, just one (for a single channel, naturally).

Since physics tells us that no two masses can occupy the same physical space at the same time, so it is with voltages and currents. There can only ever be one value of voltage and one value of current flowing through a single circuit element at any instant of time - if it were any different, the concept of digital recording could never exist, since in a digital recording the instantaneous voltage is sampled and digitised at the sampling rate. This would clearly be impossible if there were say 3 different voltages all present simultaneously.

So, how do these x-spurts determine if an amplifier has a tiny bit of crossover distortion (for example). I can see it as the residual from my distortion meter, and it is instantly recognisable for what it really is, and I can see the difference when I make a change to a circuit to eliminate the problem. If I had to rely on my ears (which although getting older, still work quite well), It would take me much longer to identify the problem, and even longer to be certain that it was gone. I'm not talking about the really gross crossover distortion that one gets from an under-biased amp, I am referring to *vestiges* - miniscule amounts that will barely register on the meter - I use my oscilloscope to see the exact distortion waveform. I suspect that this dilemma is 'solved' by some by simply not using the push-pull arrangement at all, thereby ensuring that power is severely limited, and other distortion is so high that they would not dare to publish the results.

These same x-spurts will wax lyrical about some really grotty single ended triode amp, with no power and a highly questionable output transformer, limited frequency response and a damping factor of unity if it is lucky.

Don't get me wrong - I'm not saying that this is a definition of single-ended triode amps (for example), there are some which I am sure sound very nice - not my cup of tea, but 'nice'. I have seen circuits published on the web that I would not use to drive a clock radio speaker (no names, so don't ask), and 'testimonials' from people who have purchased this rubbish, but there are undoubtedly some that do use quality components and probably sound excellent at low volume levels.

Sorry if I sound vehement (vitriolic, even), but quite frankly this p****s me off badly. There are so many people waving their 'knowledge' about, and many of them are either pandering to the Magic Market, or talking through their hats.

The whole idea of taking measurements is to ensure that the product meets some quality standard. Once this standard is removed, and we are expected to let our ears be the judge, how are we supposed to know if we got what we paid for? If the amp turns out to sound revolting (to us), should we accept this, or perhaps we should listen to it for long enough that we get used to the sound (this will happen - eventually). I am not willing to accept this, and I'm sure that many others feel the same.

Please don't think that I am advocating specsmanship, because I'm not. I just happen to think that consumers are entitled to some minimum performance standard that the equipment should meet (or exceed). I have yet to hear ***any*** amplifier with high distortion levels and/or limited bandwidth sound better than a similar amplifier with lower distortion and wider bandwidth. This implies that we compare like with like - a comparison between a nice valve amp and a nasty transistor amp will still show the transistor amp as having better specs, but we can be assured that it will sound worse.

Valves Vs. Transistors Vs. MOSFETs

This is an argument that has been going for years, and it seems we are no closer to resolving the dilemma than we ever were. I have worked with all three, and each has its own sonic quality. Briefly, we shall have a look at the differences - this is not an exhaustive list, nor is it meant to be - these are the main points, influenced by my own experiences (and I must admit, prejudices). Please excuse the somewhat random order of the comparisons :

Valves :
Valves are Voltage to Current Converters, so the output current is controlled by an input voltage. It is necessary to apply the varying output current to a load (the anode resistor or transformer) to derive an output voltage.

- Valves themselves are inherently quite linear, and can operate with no feedback at all within a restricted range, and still provide a high quality signal. The range is usually more than sufficient for preamps, but is pushed to its limits in power amplifiers.
- Relatively low gain per device, meaning that more are needed, or less feedback can be used.
- 'Soft' distortion characteristics, meaning that most of the distortion is low order (including

crossover distortion and clipping) - this is not as obtrusive or fatiguing as 'hard' distortion.
- Distortion onset is gradual, and effectively warns the listener that the limits are being approached by losing clarity, but in a manner that is not too obtrusive.
- Distortion is usually measurable at nearly any power level, but is low order (mainly 2nd, with some 3rd harmonics - vestigial amounts of additional harmonics are usually also present).
- Limited feedback, mainly due to the fact that the output transformer introduces low and high frequency phase shift, so large amounts of global feedback are generally not possible without oscillation. This results in a (comparatively) limited bandwidth.
- High output impedance, meaning that damping factor in power amps is generally rather poor. Extremely low values of output impedance are very difficult to achieve.
- Valves have a perfect dielectric (mainly a vacuum, with some mica), leading to a highly linear Miller capacitance - it is unknown if this contributes any audible benefit.
- Inefficient output stage, allowing the amp to sound louder than it really is on a watt for watt basis. This may sound like a contradiction, but a valve amp has a 'compliant output, that allows it to provide a larger voltage swing to high impedance loads (such as a loudspeaker driver at resonance).
- Very rugged, and can withstand short circuits without damage - BUT open circuits can cause the output transformer to create high flyback voltages that can cause insulation breakdown in the transformer windings or the valve sockets (short circuits are OK, open circuits are bad)
- Usually quite tolerant of difficult loads, such as electrostatic loudspeakers.
- A wonderful nostalgia value, which allows people to accept the shortcomings, and truly believe that the amp really does sound better than a really good solid-state unit. Proper double-blind testing will usually reveal the truth - provided that the solid-state equivalent is modified to match the output impedance of the valve unit ***!!!***

Transistors :

By default, transistors are Current to Current Converters. This means that they use an input current change to derive an output current change that is greater than the input (therefore amplification occurs). Again, it is necessary to use a resistor or other load to allow an output voltage to be developed.

- Transistors are also quite linear within a restricted range, but due to the lower operating voltages cannot successfully be used without feedback if a quality signal is desired, even in preamp stages.
- High to very high gain per device, allowing local feedback to linearise the circuit before the application of global feedback.
- Onset of distortion is sudden and without warning. This is worsened as feedback is increased.
- Low to very low distortion, provided clipping is not introduced. This creates both the low order harmonics of the valve amp, plus high order harmonics which are very fatiguing, and generally sound hard and nasty.
- Wide to very wide bandwidth, and low phase shift, largely due to the elimination of the output transformer. The wide bandwidth is obviously an advantage, the phase response is highly debatable as to its overall value to the listener.
- Usually large amounts of global feedback, which is needed to linearise the output stage, especially at the crossover point between output devices (0 Volts).
- Completely oblivious to open circuit loads, but must be protected against instant damage with short circuited outputs (open circuits are OK, short circuits are bad - i.e. the opposite of valves)

- The Miller capacitance of transistors has an imperfect dielectric, and varies with applied voltage. This might be the reason that some transistor amps can be seen to oscillate at a specific voltage level (small bursts of oscillation on the waveform, but only above a certain voltage across the device). Tricky.
- Intolerant of difficult loads, unless extensive measures are taken to ensure stability. This can increase complexity quite dramatically.

MOSFETs :
MOSFETs, like valves, are voltage to current converters, and rely on a voltage on the gate to control the output current. As before, a resistor or other load converts the varying current into a voltage.

- Similar to most of the comments about transistors, with the following differences:
- Onset of (clipping) distortion is (usually) not quite as savage as transistors, but is much more sudden than valves. This is a very minor difference, and can safely be ignored.
- Not as linear as valves or transistors, especially near the cutoff region. Big differences between different types (lateral/ vertical)
- More efficient than valves, but not as efficient as transistors. There will always be less output voltage swing available from a MOSFET amp than a transistor amp (for the same supply voltage), unless an auxiliary power supply is used.
- Gain is (usually) higher than valves, but lower than transistors - limited ability to apply local feedback, and even overall (global) feedback may not produce distortion figures as good as transistors - especially with vertical MOSFETs.
- Low distortion (lateral types), but may require more gain in the preceding stages to allow sufficient feedback to eliminate crossover distortion.
- Very wide bandwidth (better than transistors), allowing less compensation and full power operation up to 100 kHz in some amps - the value of this is debatable.
- More rugged than transistors, and do not suffer from second breakdown effects - fuses can be used for short circuit protection, and no open circuit protection is needed.
- Reasonably tolerant of difficult loads without excessive circuit complexity.

To make matters worse, there are two main types of MOSFET as hinted at above - lateral and vertical. This applies to the internal construction. Lateral MOSFETs are well suited to audio (see Project 101), while vertical (e.g. HEXFETs) are not really suitable at all. Despite this, it is possible to make an amplifier using HEXFETs that performs very well, and this has been achieved by many hobbyists and manufacturers.

Because of the differences outlined above, it is very important to compare like with like, since each has its own strengths and problems. Also, each of the solid state amp types has its niche area, where it will tend to outperform the other, regardless of specifications. The valve amp is the odd man out here, as it is far more likely to have devoted fans who would use nothing else - most solid state amp users are (or should be) a pragmatic lot, using the most appropriate configuration for the intended application.

There is no such thing at the time of writing as the much sought after (but elusive) 'straight wire with gain'. But wait - there's more ....

Slew Rate and Intermodulation

Another aspect of amplifier design is slew rate. This term is not well understood, and the possible effects even less so.

Slew Rate Nomograph

It has been claimed by many writers on the subject that a slew-rate limited amplifier will introduce transient intermodulation distortion, or TIM. In theory, this is perfectly true, provided that the slew rate is sufficiently low as to be within the audible spectrum (i.e. below 20 kHz), and the program material has sufficient power at such high frequencies to cause the amplifier to limit in this fashion.

The following nomogram is helpful in allowing you to determine the required slew rate of any amplifier, so that it can reproduce the required audio bandwidth without introducing distortion components as a result of not being fast enough.

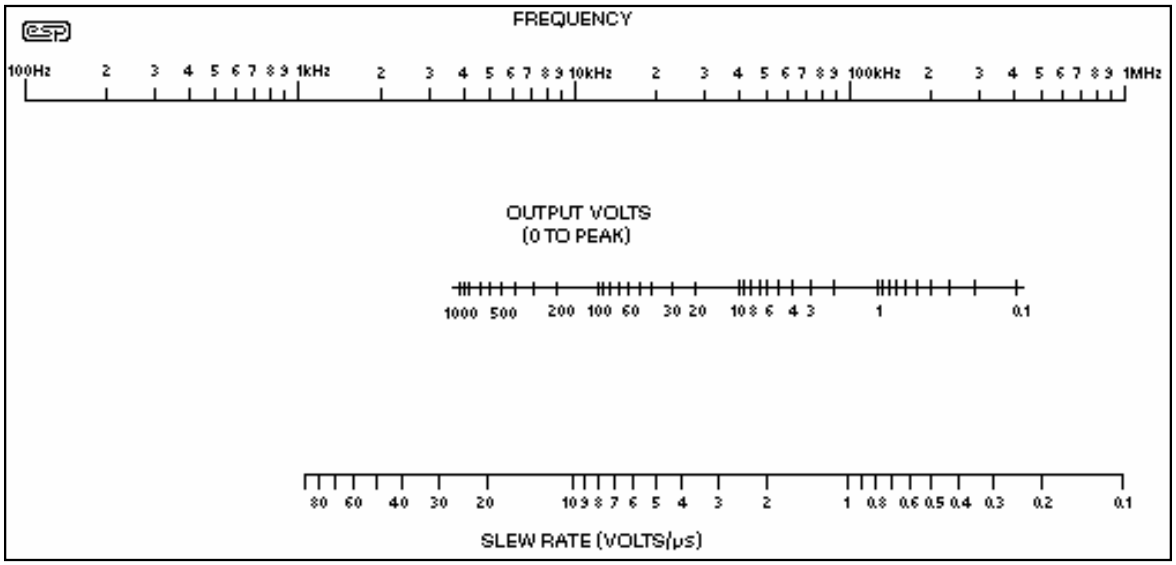


Figure 14 - Slew Rate Nomograph

To use this nomograph, first select the maximum frequency on the top row. Let's assume 30kHz as an example. Next, select the actual output voltage (peak, which is RMS * 1.414) that the amplifier must be able to reproduce. For a 100W 8 Ohms amp, this is 28V RMS, or 40V peak. Now draw a line through these two points, and read the slew rate off the bottom row. For the example, this is 8V/us. This is in fact far in excess of what is really needed, since it is not possible for an amp reproducing music to have full power at 30kHz.

By 20kHz, our 100W amp will need a maximum of 10W (typically much less), and this is only about 12V peak. Using the nomograph with this data reveals that a slew rate of about 2V/us is quite sufficient. Such an amp will go into what is known as slew-rate limiting at full power with frequencies above 10kHz or so, converting the input sinewave into a triangular wave whose amplitude decreases with increasing frequency.

Some claim that this is audible, although this is purely subjective. That a typical audio signal is a complex mixture of signals is of no real consequence, because an amp has no inherent concept of 'complex' any more than it has an opinion about the date. At any given point in time, there is an

instantaneous value of input voltage that must be increased in amplitude and provide the current needed to drive the loudspeaker. As long as this input voltage does not change faster than the amplifier is capable of doing, then no degradation is should occur.

Although this is a fine theory, there seems to be too much entrenched prejudice against 'slow' amplifiers, which may indeed sound different from another that is not constrained by slew rate limiting - at least within the full audible range.

As shown above, the slew rate of an amplifier is usually measured in Volts / microsecond, and is a measure of how fast the amplifier's output can respond to a rapidly changing input signal. Few manufacturers specify slew rate these days (mainly because few buyers understand what it is), but it is an important aspect of an amplifier's design.

As can be seen from the above, for an amplifier (of any configuration) to reproduce 28V at 20 kHz (about 100W / 8 Ohms) requires a slew rate of 4.4 V / us. This is to say that the output voltage can change (in any direction) at the rate of 4.4 Volts in one microsecond. This is not especially fast, and as should be obvious, is dependent upon output voltage. A low power amp need not slew as fast as a higher powered amp. There is no real requirement for any amp to be able to slew faster than this, as there is a significantly large margin provided already. This can be calculated or measured - I measured it at 22V maximum rate of change in 5us (give or take a little), which works out to 4.4V/us again.

Doubling the amplifier's output voltage (four times the power) requires that the slew rate doubles, and vice versa, so a 400W amp needs a slew rate of 8.8 V / us, while a 25W amp only needs 2.2 V /us. This is a very good reason to use a smaller amplifier for tweeters in a tri-amped system, since it is much easier to achieve a respectable slew rate when vast numbers of output devices are not required.

Essentially, if the amplifier's output cannot respond to the rapidly changing input signal, an error voltage is developed at the long-tailed pair stage, which tries to correct the error. The LTP is an amplifier, but more importantly, an error amplifier, whose sole purpose is to keep both of its inputs at the same voltage. This is critical to the operation of a solid state amp, and the LTP output will generally be a very distorted voltage and current waveform, producing a signal that is the exact opposite of all the accumulated distortions within the remainder of the amp (this also applies to opamps).

The result is (or is supposed to be) that the signal applied to the inverting input is an inverted *exact* replica of the input signal. Were this to be achieved in practice, the amp would have no distortion at all. In reality, there is always some small difference, and if the Class-A driver or some other stage enters (or approaches) the slew rate limited region of operation, the error amp (LTP) can no longer compensate for the error.

Once this happens distortion rises, but more importantly, the input signal is exceeding the capabilities of the amplifier, and the intermodulation products rise dramatically. Intermodulation distortion is characterised by the fact that a low frequency signal modulates the amplitude (and / or shape) of a higher frequency signal, generating additional frequencies that were not present in the original signal. This also occurs when an amplifier clips, or if it has measurable crossover distortion.

Sounds like ordinary distortion, doesn't it? That too creates frequencies that were not in the original,

but the difference is that harmonic distortion creates harmonics (hence the name), whereas intermodulation distortion creates frequencies that have no harmonic relationship to either of the original frequencies. Rather, the new frequencies are the sum and difference of the original two frequencies. (This effect is used extensively in radio, to create the intermediate frequency from which the audio, video or other wanted signal can be extracted.) The term 'harmonic' basically can be translated to 'musical', and 'non-harmonic' is mathematically derived, but not musically related .... if you see what I mean.

Whenever the LTP loses control of the signal, intermodulation products will be generated, so the bandwidth of an amplifier must be wide enough to ensure that this cannot happen with any normal audio input signal. There is nothing wrong or difficult about this approach, and it is quite realisable in any modern design. Although unrealistic from a musical point of view, it is better if an amplifier is capable of reproducing full power at the maximum audible frequency (20 kHz) than if it starts to go into slew rate limiting at some lower frequency.

The reason I say it is unrealistic musically is simply because there is no known instrument - other than a badly set up synthesiser - that is capable of producing any full power harmonic at 20 kHz, so in theory, the amp does not have to be able to reproduce this. In reality, inability to reproduce full power at 20 kHz means that the amp will very likely suffer from some degree of transient intermodulation distortion with some program material.

This is not a problem that affects simple amps with little or no feedback - they generate enough harmonic distortion to more than make up for the failings of more complex circuits with lots of global feedback. This fact tends to annoy the minimalists, who are often great believers in no feedback under any circumstance, which relegates them to listening to equipment that would have been considered inferior in the 1950's.

Frequency Response, etc.

Few sensible people would argue that measurements of frequency response are unimportant or irrelevant, and this is one of the simplest measurements to take on an amplifier. Again, the subjectivists would have it that these fail to take into account some mysterious area of our brain that will compensate for a restricted response, and allow us to just enjoy the experience of the sound system. This is true - we will compensate for diminished (or deranged) frequency response, but it need not be so.

If you listen to a clock radio for long enough, your brain will think that this is normal, and will adjust itself accordingly. Imagine your surprise when you hear something that actually has real low and high frequencies to offer - the first reaction is that there is too much of everything, but again, the brain will make the required allowances and this will sound normal after a time.

There are so many standard measurements on amplifiers that are essential to allow us to make an informed judgement (is this amp even worth listening to?). I really object to the attitude that "it does not matter what the measurements say, it sounds great". In reality this is rarely the case - if it measures as disgusting, then it will almost invariably sound disgusting. There is no place for hi-fi equipment that

simply does not meet some basic standards - and I have *never* heard an amp that looked awful on the oscilloscope, measured as awful on my distortion meter, but sounded good - period.

Further Reading

For further reading, I strongly recommend The Self Site, and in particular 'Science and Subjectivism in Audio' and also my own article on the subject Cables, Interconnects & Other Stuff - The Truth. There is also an article called Amplifier Sound - What Are The Influences? that goes a little deeper into the measured and subjective performance of amplifiers, and suggests a couple of new tests that might be applied.

Introduction

When we build linear power amplifiers, we always need to choose some device for the output stage. This could be any power device including valves, BJTs, IGBTs, and MOSFETs. Each has its own strengths and weaknesses which forces us to choose between them. If, perchance, we wanted to build a very simple and accurate amplifier, we can safely ignore valves, since they all need heating circuitry and are not simple for a true hi-fi amplifier. That it is possible to build a valve amp to a high specification is not in doubt, but they tend to be complex and expensive.

BJTs are often used, but they do not respond well to even momentary overloads. This is because they suffer from second-breakdown - an instantaneous and catastrophic failure mode. IGBTs (Insulated Gate Bipolar Transistors) are seldom used, and will be very similar to a BJT, only with an insulated gate. They still need thermal compensation and a suitable gate drive design, and can suffer from a 'latch-up' condition in some cases. Lastly there is the MOSFET, which does not suffer any second-breakdown effects. MOSFETs (Metal Oxide Semiconductor Field Effect Transistors) come in two primary types - vertical and lateral.

These devices are extremely rugged, yet they do have a large nonlinear gate capacitance to deal with. If driven incorrectly, they show high distortion levels, especially vertical types - most commonly these days, HEXFETs. This is why I wrote this article - to show how to use HEXFETs properly in audio applications.

The update below has some important information that I recommend you read thoroughly and make sure you understand before settling on the use of HEXFETs in your next amp project. While there appear to be many advantages to their use over BJTs, HEXFETs may often suffer from exactly the same problems - thermal runaway and a failure mode that is suspiciously similar to second breakdown. On top of this, there is a much larger voltage loss ... 2-4V is needed to bias the HEXFETs to the on condition, vs. 0.65V (nominal) for BJTs. This voltage is usually taken from the main supplies, so for a given supply voltage, expect less output power.

2 - Description

Many people say (including IRF) that HEXFETs are not suited for linear audio circuits and should be avoided. Well, that is the easy route to take for designing an output stage. *Any* device can be used for audio and give great performance if a proper design is found. It is just easier to use more linear devices. Lateral MOSFETs are usually specified for audio, but there are relatively few different devices on the market. When found, they tend to be quite expensive. On the other hand, HEXFETs are very common, reasonably priced, and only need a good design to do well.

This article is intended for Class-AB designs. HEXFETs will run Class-A with barely any problems besides driving the gate. If you are designing a class A amplifier, the first trick (see below) should be used (the second is not needed since the bias is already quite high).

Alright, now for some explanations. Comparatively, HEXFETs usually have a low gate capacitance than other vertical MOSFETs, yet have a higher gate capacitance than their lateral counterparts. There is not only one capacitance to deal with, but two (one from the gate to source and the other from the gate to drain). This is the main problem: to find a way to drive the gate capacitance of the HEXFETs. Through a lot of time and molten breadboards, I found the best two things to design for are the following:

1. Fix: Drive the gates with as much current as possible. This may include adding a class AB driver stage.
   Why: HEXFETs have a nonlinear transfer curve up to about an amp or two, depending on the device(s) used. In a class AB amplifier, this characteristic is the cause for a majority of the THD. When driven with enough current, the device will follow the 'new' linear curve, since it is balancing out the nonlinear gate capacitance. The lower impedance of the driver stage the better.
2. Fix: HEXFETs like to run hot. This does not mean use an inadequate heatsink, but the bias between devices should be a bit more than many are used to. 250mA of idle current is not a bad bias figure for these devices.
   Why: To balance out the nonlinear curve, we can simply cut if off where it seems too bad by using bias. This will increase dissipation, though.

For the design of the amplifier, I will assume a single LTP input stage. Better performance can be seen by using multiple LTPs, but this will not be a simple design (in fact it will be quite complex with high frequency stability issues needing attention).

When choosing the complementary output components, one can obviously choose the IRFPXXX and its IRFP9XXX complement. If we look at these complementary device data sheets, we will see very different figures for current capability, on resistance, and, most importantly, gain (or forward transconductance). But if we use a matching tool, we will find that the gain varies considerably from the actual devices vs. the data sheet. That is why we need to buy a few extra and match them together. Since the gain varies a bit from batch to batch, it is quite easy to find a IRFPXXX and IRFP9XXX that are very similar, at least with gain factors.

Also take note that HEXFETs will require a Vbe multiplier for thermal compensation, since the negative temperature coefficient does not come into play until the device has about 10 amps through it (at least for the IRFP240). The exact values around the Vbe multiplier (also known as a bias servo) are critical to ensure that the thermal performance is matched as closely as possible.

In every practical design I have tried I had to use a class AB driver stage. A class-A driver will work fine if you really want an electric heater, as you will see in the next calculation. Now, in order to size-up the proper driver for the FETs, we need to do a little maths. I promise it is not hard. An example would work nicely here ... if we wanted to design a class AB driver stage with five IRFP240 and five IRFP9240 devices, how much current will we need at *minimum* for full functionality up to 50kHz? For a better understanding, a simplified output stage circuit is shown below.

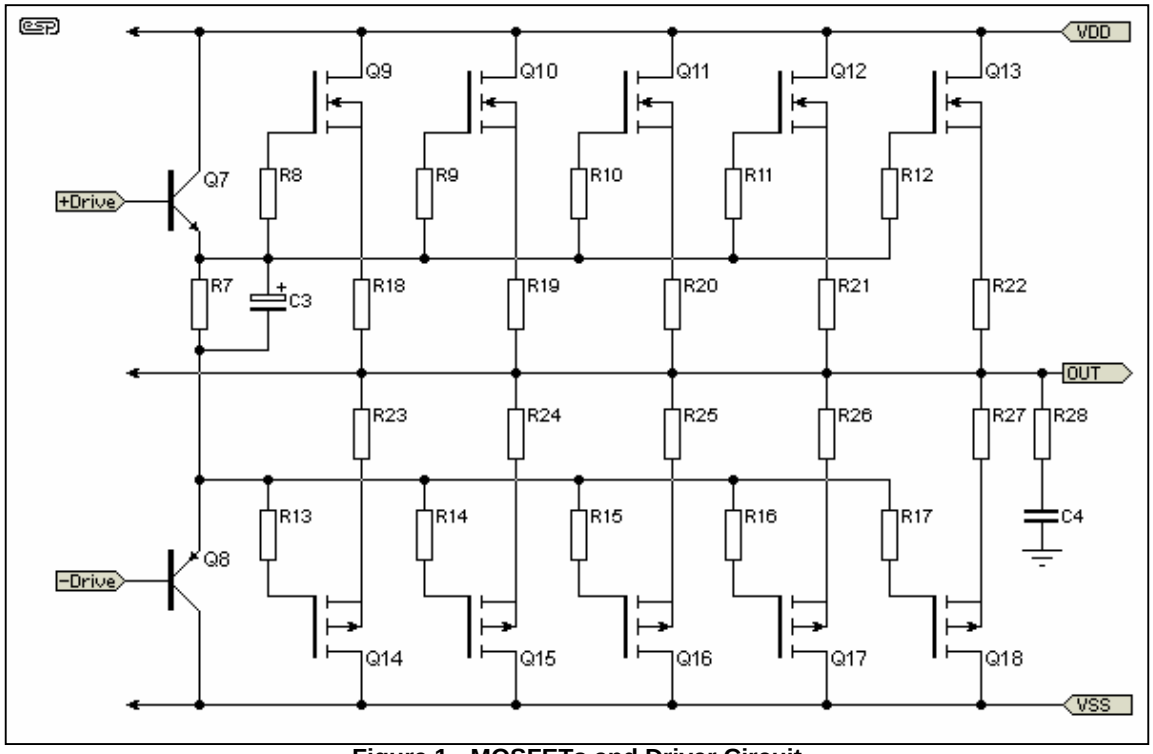

Figure 1 - MOSFETs and Driver Circuit

We will do calculations using the gate charge method, which IRF recommends (AN-944). Looking at the data-sheets, we find the IRFP240 has a total gate charge (Qg) of 70nC and the IRFP9240 has a Qg of 44nC. Don't add these yet! We will find each device's needs individually. The general formula to determine gate current is ...

$I = 100Q_g f$ where I is current needed, Q_g is the total gate charge in Coulombs, and f is frequency of operation.

The multiplication factor of 100 gives the headroom needed for accurately reproducing a square wave (or high frequency sinewave), since the gate driver needs a lot of current to quickly switch the MOSFET from OFF to ON. Although the requirement for this is minimal (the CD format is incapable of anything even approaching a square wave above a couple of kHz), it has become an expectation that power amps should be able to reproduce perfect square waves at 10kHz as a minimum.

When we plug our figures in for the IRFP240, we get $I = 100 * (70^{E-9} * 50{,}000)$ = 350mA per device

For the IRFP9240 we get $I = 100 * (40^{E-9} * 50{,}000)$ = 200mA per device

Multiplying each figure by five (because there are five devices of each polarity) gives us 1.75 amps for the upper driver and 1 amp for the lower driver. So a Class-A driver would need bias set to 3.5 amps to get the job done with a reasonable safety margin.

The value for R7 will depend on the linearity of the driver transistors. I had to guess and check with my ammeter to get a good value. This can range anywhere from 100 Ohms up to perhaps 5k. Make sure you check the idle current before calling the design done! These drivers (Q7 and Q8) may need a heatsink. Also note the capacitor in parallel with R7. This should be of a high value (i.e. 100uF or more), and 470uF works fine for my 10 MOSFET stage shown here. It helps with discharging the MOSFET gates by providing a path for the gate current.

These current figures seem quite high, but keep in mind this current will only last a very short time compared to the signal, and virtually no current is needed to keep the devices either in the OFF or ON state. The current to reproduce a sinewave will be a bit lower, since it is a smooth curve, but this much headroom will drastically lower distortion. This is why we cannot practically use a class A driver, unless, of course we use one pair of output devices.

For some comparison, below is a HEXFET setup driven by a class A driver at 13mA bias:

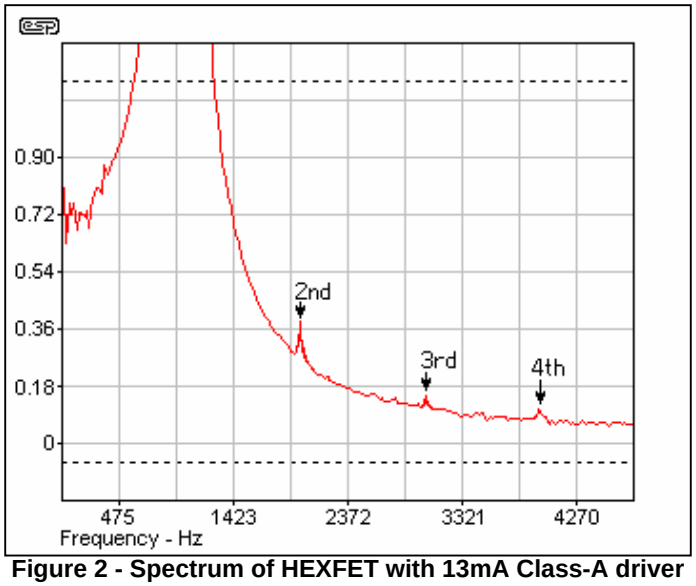

Figure 2 - Spectrum of HEXFET with 13mA Class-A driver

The large notch is at the second harmonic, and the small bump to the right is the fourth harmonic. Barely any third harmonic is seen. This shows 0.25% distortion at the second harmonic at ¾ power, and 250mA amp bias. Not very good for a true hi fi, unless we are making a valve-like amplifier. Even this will not show the same effects as a true valve amp - the nature of the distortion components will almost certainly be different.

Adjusting the bias to 1 amp removes nearly all distortion, yet now we are approaching a heater... I mean class A.

After fixing the problem by adding a class AB driver, distortion was greatly decreased ...

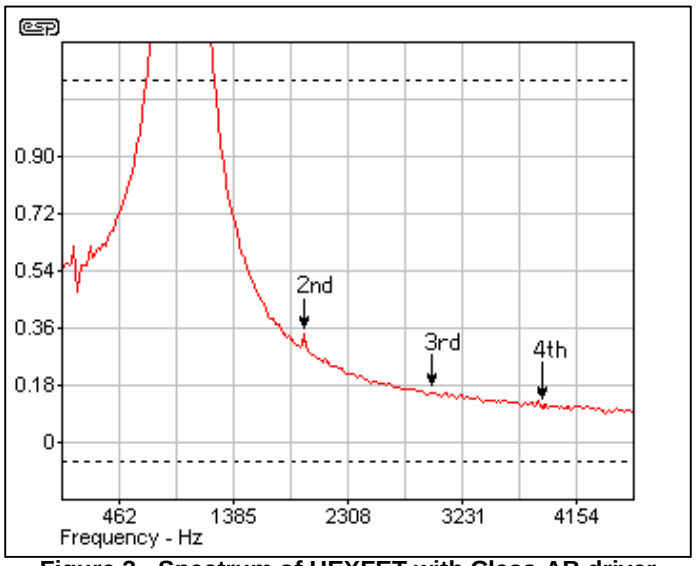

Figure 3 - Spectrum of HEXFET with Class-AB driver

As the picture shows, the second harmonic was reduced considerably, while the fourth harmonic is below the noise floor. This shows 0.04% distortion solely on the second harmonic at ¾ power and still with 250mA bias. This greatly improved the amplifier. At one watt, the distortion is not measurable at all, unlike with the class A driver. Reducing the gate resistors to 4.7 Ohms to get more current through does nothing noticeable, so the use of 10 Ohm resistors is fine. There is no evidence of “notch” distortion or any other nasty odd harmonic, only a “nice” second harmonic added in. Also note that this amp was built on a breadboard. A compact and nicely wired PCB should decrease distortion even further.

Below is the final simplified schematic of the entire amplifier ...

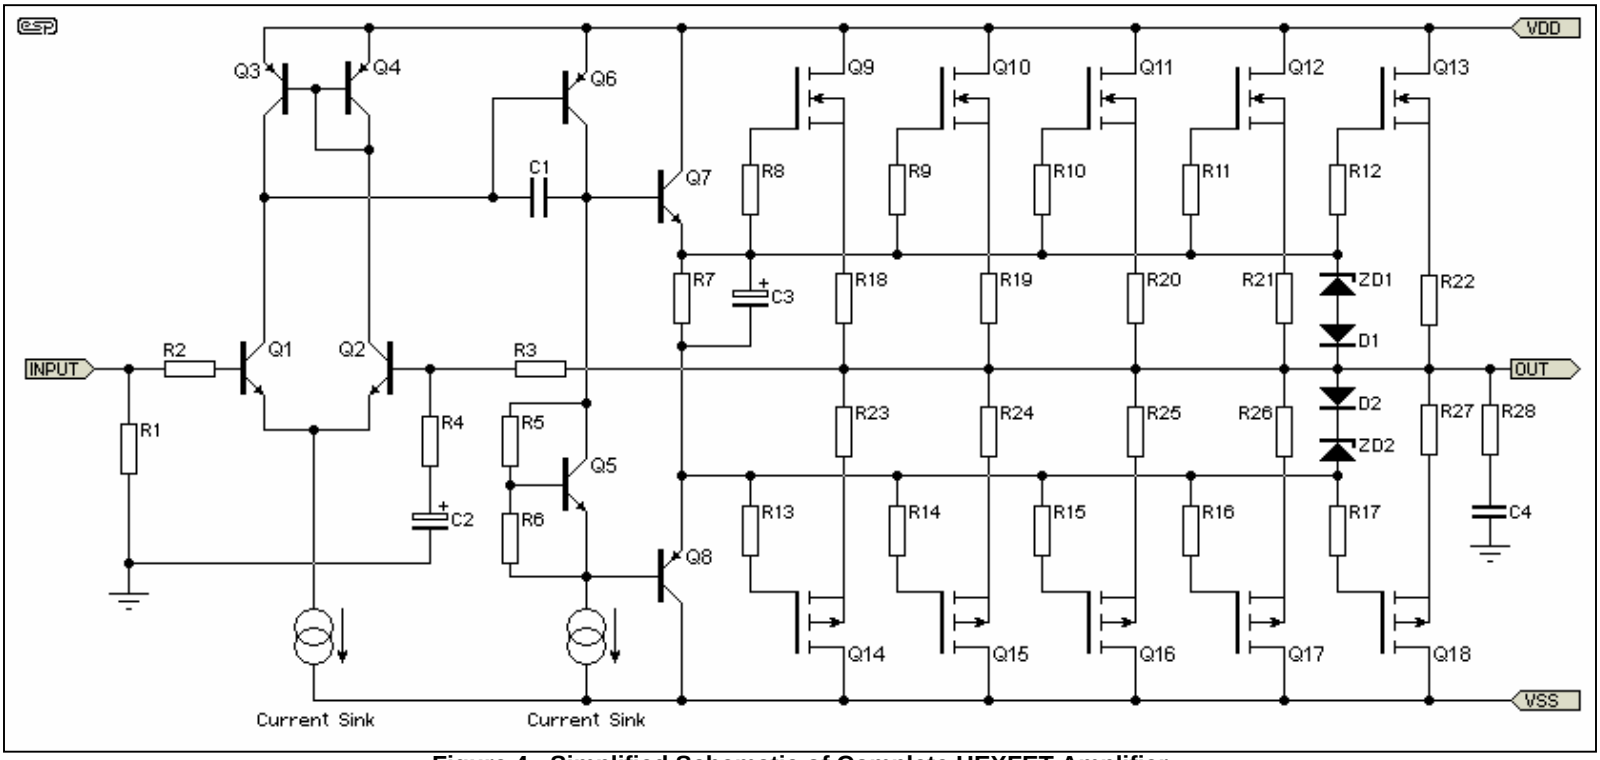

Figure 4 - Simplified Schematic of Complete HEXFET Amplifier

It looks very simple, and includes the class AB driving stage to improve gate driving. Very simple compared to the multiple LTP amps. The minimum stability network (Zobel) shown is always needed, and a series inductor (with parallel resistor) may also be required. The values of these components will be found by experiment.

For some further reductions in distortion, the following work quite well:

1. Design a compact PCB layout with feedback taken as close as possible to the load terminal. We want to measure what the load is doing, not what it should be doing.
2. Try not to run any signal wire close to a power supply wire or the power transformer.
3. Make big traces on the PCB with decent sized spacing between other traces.
4. Make sure your measuring equipment is decently calibrated!
5. For any output device, use some sort of emitter/source resistors (as shown) to help balance the load when parallelling.
6. Use a current mirror with the LTP input to get as much gain as possible to allow for negative feedback, but do not solely rely on the feedback to make the amplifier better.
7. Match the output devices as close as possible, especially for transconductance at low values of V_{GS}.

---

3 - Conclusion

HEXFETs are decent devices once the gates are driven correctly. They are much more rugged than BJTs as my burned parts pile shows, and sound very good when a class AB driver is added. I hope this short article with aid others in using these “switching” and “not linear enough for audio” devices to get distortion figures below many good amplifiers with 'very linear' devices. And remember one thing - *any* output device can be precise if a proper design is found. Finding the correct design parameters becomes more complex with non-linear devices.

5 - Footnote

The above article is a contribution from Mitch Hodges, and ESP has not verified all aspects of the design process described. While the circuit can be (and has been) simulated quite readily with good results, this is no guarantee that everything will work as expected. I added diodes and zeners to protect the MOSFET gates from excessive voltage. It may be possible to select the zeners to achieve basic current limiting, giving the amp some protection from overload conditions. Because of the high gain of HEXFETs, this simple protection scheme will not be particularly effective. Also, remember to that a series inductor may also be required.

It will be noted that there are no component values supplied - this is quite deliberate, and is not an omission. The article is intended to describe the design process and how to work around the inherent non-linearity of vertical MOSFETs, and is not intended to be a construction project. Requests for component values will *not* be fulfilled.

It must be understood that at the suggested current (250mA per MOSFET pair), the total quiescent current will be in the order of 1.25A - at a typical supply voltage of perhaps ±50V, this represents a total quiescent dissipation of 125W! This is a formidable amount of heat to dispose of, and will require very large heatsinks (and/ or forced air cooling). It is probable that the constructor will be forced to compromise, using a significantly lower quiescent current than suggested just to maintain a sensible heatsink size and temperature. Reducing your expectations of the maximum frequency that needs to be passed at full power will reduce the loading on the Class-AB drivers, but does nothing for the MOSFET low current linearity. Compromise will be almost essential (IMHO).

Finally, I'd like to thank Mitch for his contribution, since it describes the issues and how to solve them in an easy to follow manner, keeping complexity to the absolute minimum in the final design example.

Rod Elliott

5.1 - Update (March 2006, ESP)

I have had occasion to build a HEXFET based power amp as a test for a client. While it worked well enough, giving the expected power output and with fairly low distortion, as noted above the required bias current is quite high to reduce crossover distortion to an acceptable figure. While the circuit I built is actually quasi-complementary (using only N-Channel MOSFETs), the basic principles apply regardless.

Bias stability is definitely an issue as discussed above. It is commonly (and erroneously) stated that MOSFETs are 'safe' because they have a positive temperature coefficient, so as a device gets hotter, its drain-source ($R_{DS(on)}$) resistance increases. This much is true, but is actually completely useless in a linear circuit.

What is *not* commonly noted is that all MOSFET devices have a fairly high negative temperature coefficient for the gate-source threshold voltage (V_{th}). At the gate-source voltages needed to obtain typical bias currents, even a small temperature increase causes a large drain-source current increase, so the use of a carefully designed bias servo (Q5, R5 and R6 in the Figure 4 schematic) is absolutely essential. This point is made above, but is sufficiently important that repetition will not go astray.

To illustrate this, Figure 5 shows the graph from the IRF540 data sheet, and although it does not continue down to the levels we are interested in, the trend is clearly visible. At a V_{GS} of 4.5V, we see I_D of around 12A at T_j = 25°C, rising to a little over

20A at T_j = 175°C. While the graph might seem to indicate that the effect will be greatly exaggerated at gate lower voltages and drain-source current, the initial tests that I did indicate that the effect is roughly similar. The graph was taken from the IRF540 data sheet, but has been colour coded to make identification of each graph easier. The use of source resistors to help force current sharing is essential, and these should be as high as practicable. While 0.1 ohms is common for BJT amplifiers, I would recommend values not less than 0.47 ohms for HEXFETs. Higher values provide more stable quiescent current with temperature variations. For example, with 1 ohm source resistors, the current can increase at a maximum of 1mA/mV or 1A/V. Should V_{th} fall by 100mV, Iq can only increase by 100mA. This eases the design of the bias servo.

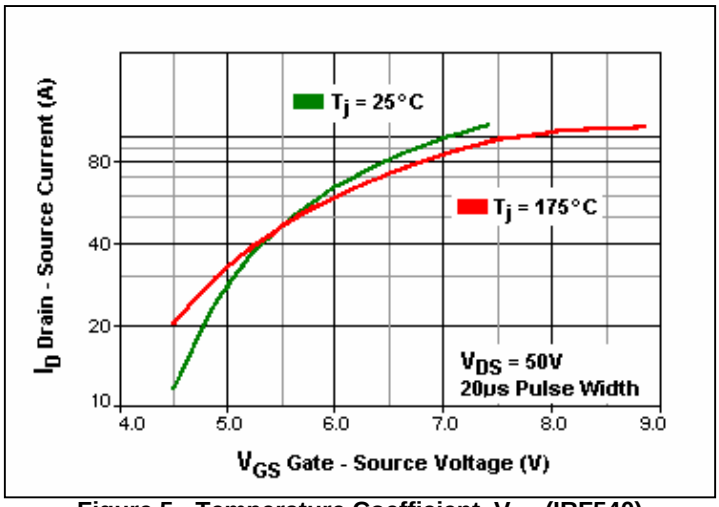

Figure 5 - Temperature Coefficient, V_{GS} (IRF540)

The test I ran was very simple. Apply a suitable voltage to the drain, then carefully adjust the gate voltage until a suitable measurement current was drawn. The current started at a relatively low value (around 1A in my test), and as the device heated up this was seen to rise. It stabilised fairly quickly because the heatsink prevented further (possibly damaging) heat levels, but with two MOSFETs in parallel, the current between them was different, and (more importantly) it remained different, even as they became hotter. The claims for better (and 'automatic') current sharing apply only to devices operated as switches, or where the two curves shown in Figure 5 cross over each other. Only lateral MOSFETs provide a crossover point on their transfer characteristics that is low enough for linear operation.

Something that is missing from nearly all MOSFET data sheets I have looked at is gate threshold voltage vs. temperature (it *is* shown in the data I have for the IRF840). This will show that the threshold voltage falls as T_j increases - a *negative* temperature coefficient. The positive coefficient of $R_{DS(on)}$ is insignificant at the current levels needed for setting quiescent current accurately. Note that the two curves cross over, but the point where the temperature curves cross is when V_{GS} is at a current of over 40A and the gate-source voltage is 5.5V - this is not useful. Lateral MOSFETs (as used in P101) have exactly the same issue, but the curve changes from negative to positive at a much lower current (around 100mA), and this is visible on the transfer characteristic graph (but you will need to look for it carefully - it is not specified in a useful manner IMO).

In an application note [1], OnSemi describe this transition as the 'inflection' point, and it is determined by V_{GS}, although it appears to be related more to the drain current than gate voltage. However, the two are directly related, so the point is moot. Lateral MOSFETs are usually quite safe here, because the inflection point is at such a low voltage and current, but vertical MOSFETs (HEXFETs and similar) are prone to thermal runaway. There is also the possibility of a failure mode very similar to second breakdown when HEXFETs used in linear circuits, where V_{GS} is usually (well) below the inflection point. This must remain a very good reason to stay clear of these devices for audio, unless you are fully aware of the potential risks, and how to avoid them. Note that the article above does not address this potential failure mode, (nor do any others I have seen), and your only choice is to find MOSFETs where the thermal 'changeover' occurs at the lowest possible drain current. Lateral devices are almost unbeatable in this respect.

A careful examination shows that the 'inflection' point is actually the region where the negative temperature coefficient of V_{GS} exactly compensates for the positive temperature coefficient of $R_{DS(on)}$. That's the reason it's at such a high current for HEXFETs (because of the usually low $R_{DS(on)}$ value), and it is known that the inflection point is inversely proportional to R_{DS}

$_{(on)}$. Note that this only applies if the device is used in linear mode. When switching, V_{th} and its temperature coefficient is not relevant because the gate voltage is invariably selected to provide 'hard' switching to minimise losses.

In contrast, a typical lateral MOSFET (such as the 2SK1058) has an $R_{DS(on)}$ of around 1 ohm at 10A, compared to an IRF540N with 0.044 ohms at 16A.

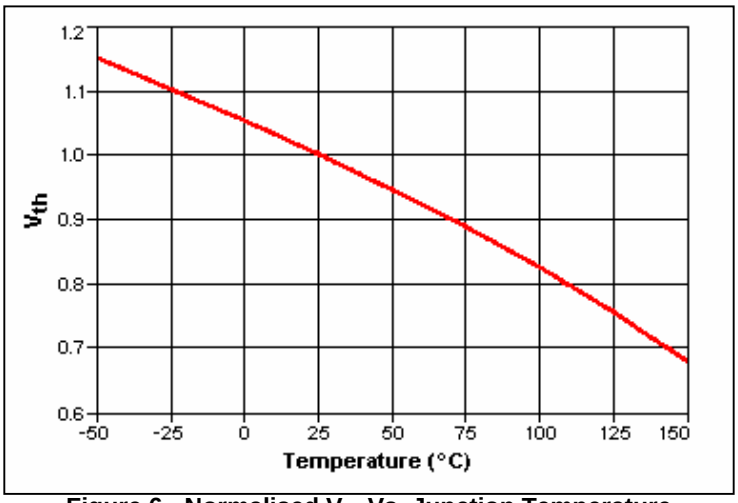

Figure 6 - Normalised V_{th} Vs. Junction Temperature

From Advanced Power Devices, their application note [2] provides the graph shown in Figure 6. Normalising simply means that everything is taken back to a reference of unity, so simply multiply the claimed V_{th} by the figure shown along the left side, for the temperature at which your device will operate. If your MOSFET will undergo a temperature change from 25° to 100°, then V_{th} will fall to 0.83 of the ambient temperature value at 100°C. This application note also mentions the possibility of a failure mode similar to second breakdown when operating switching MOSFETs as linear amplifiers. Indeed, two of the articles listed below refer to the fact that using a HEXFET much bigger than needed (to provide a safety margin) has exactly the *opposite* effect. Rather than increasing the safety margin, the larger device is *more* likely to fail if it working well below the 'inflection' current in a linear circuit.

Do not be mislead by claims that MOSFETs are immune from thermal runaway, although lateral MOSFETs are much better in this respect than vertical MOSFETs (HEXFETs and similar switching devices). Based on the above, it is quite apparent that vertical MOSFETs can easily get into thermal runaway if the bias servo is not set up correctly. Using just a pot (as shown in P101) is absolutely verboten with vertical FETs - a matched bias servo is essential to prevent both thermal runaway and crossover distortion.

Further searching reveals a document from Solid State Optronics [3], where the temperature coefficient for V_{GS} is said to be -1.5mV/°C (the above chart shows it as 1mV/°C for V_{GS} of 4.5V at 25°C). It is claimed to be 'insignificant', and for switching applications this is true. It is definitely not insignificant for a linear circuit (as shown in Figure 4), and especially so because of the relatively high transconductance of vertical MOSFETs. A few (tens of) millivolts of gate voltage is the difference between acceptable quiescent current and overheating.

What of the second breakdown effect? HEXFETs, (and indeed many (most?) other MOSFET devices) are made using a multiplicity of individual small MOSFETs called cells. If the device as a whole exhibits a negative temperature coefficient for V_{GS}, so must each internal cell. If one cell has a slightly lower V_{th} than the others (due to microscopic impurities in the silicon substrate) it will take more of the total current. This will cause it to get hotter, so it will then draw more current, causing it to get still hotter. This process continues until the cell fails due to over temperature, at which point the whole MOSFET is useless.

While this scenario is not common, it does exist, and has caused problems in the past. It will continue to cause problems if designers are unaware that this failure mode even exists - after all, most comments seen describe MOSFETs as almost indestructible. While this is true to an extent, it is now obvious that it is not a general rule upon which one should rely in all circumstances.

Now you know *why* International Rectifier and other vertical MOSFET manufacturers don't recommend HEXFETs or their equivalent for linear applications - they are simply not designed for the purpose. Yes, they most certainly will work, but just be aware of the limitations. I suggest that high voltage, relatively low current devices are preferable to the reverse, as they will have an inherently higher $R_{DS(on)}$, and therefore a lower inflection point.

As it transpires, the design I was looking at is unsuitable for the intended purpose, because the quiescent current needed to remove crossover distortion is too high to be practical. In many cases, the lowest heat output possible is highly desirable, and HEXFETs are simply unsuited to any application where very low Iq is desirable or necessary. Lateral MOSFETs would be fine, but are too expensive for the application (in case anyone was wondering).

Transformerless Balanced Line Driver with Floating Output

Introduction

The article presented is a contributed design by Uwe Beis. Uwe has built and tested the unit as shown, and although more complex than the balanced line drivers and receivers presented in the original versions in the Project Pages (see Project 51 for details), it also has better performance.

However (and this is important), the sensitivity to component tolerance is high, and thermal drift will cause the circuit's characteristics to change. It is very important that Uwe's recommendations are followed closely with regard to the tolerance and type of resistors used. I have simulated the circuit, and also built one using 5% carbon film resistors to see just how far off the circuit would be. Although it worked (after a fashion at least), the balance and frequency response were quite different for each output. After trimming (using a pot, and experimenting until I found the best spot for it), the performance was excellent, but just heating any of the 10k resistors with my fingers was enough to disturb the balance.

Metal film resistors are very much better than carbon in this respect, and are essential in a circuit such as this.

Additional testing and simulations of the circuit have revealed that there is a sensible trade-off that can be made, simply by increasing the values of 2 resistors. Although the modification degrades the "perfect" balance, in reality there is only about a 0.4dB loss of signal when the circuit is connected in unbalanced mode, and this is well within the acceptable range (IMO).

The simplified version requires no adjustments. Mine uses an unbalanced input, but a balanced input can be added in the same way as with Uwe's circuit. Generally, an unbalanced input will be the most common, since if the internal circuitry is already balanced, there is little need to do it again. See Project 87 for all the details.

The following is Uwe's original material with a very small number of changes. Note that I have made minimal corrections to the grammar - Uwe is from Germany, and his English is extremely good. You will still see some evidence of his origins, but to remove all of these would be to lessen the value of the original text (IMHO anyway).

Why Use Balancing?

In the professional audio industry analogue information is transmitted as a balanced signal over symmetrical cables. The big advantage of this method is that interferences of the signals by ground loops can be totally eliminated. To balance device-internal signals, where they are usually unbalanced, transformers are often used. Transformers have another very welcome side effect: They can completely galvanically decouple source and destination, i.e., there is no ground loop they are not just compensated, in fact they do not exist any more. One transformer, either at the output or at the input, is sufficient for that, but professional equipment usually uses transformers at its inputs and outputs.

It is well known to use electronic circuits instead of transformers to balance signals at the outputs or to unbalance them at the inputs. The advantage is that this is cheap, small and works easily from DC up to very high frequencies. One major disadvantage is that they cannot

handle voltages - particularly common mode voltages - greater than their operating voltage. Rod has written some more explanation about balanced signals in his project "Balanced Line Driver".

From here on we should discriminate the difficulties between balanced inputs and outputs.

Balanced Line Receivers

The line receiver Rod describes is a single op-amp one. It is derived from the basic differential amplifier circuit. Its inputs are not totally symmetrical, i.e. signals at the -In "see" a lower impedance than those at +In. Furthermore signals at +In are "visible" at -In while vice versa this is not the case. For higher performance the following circuit is often used ...

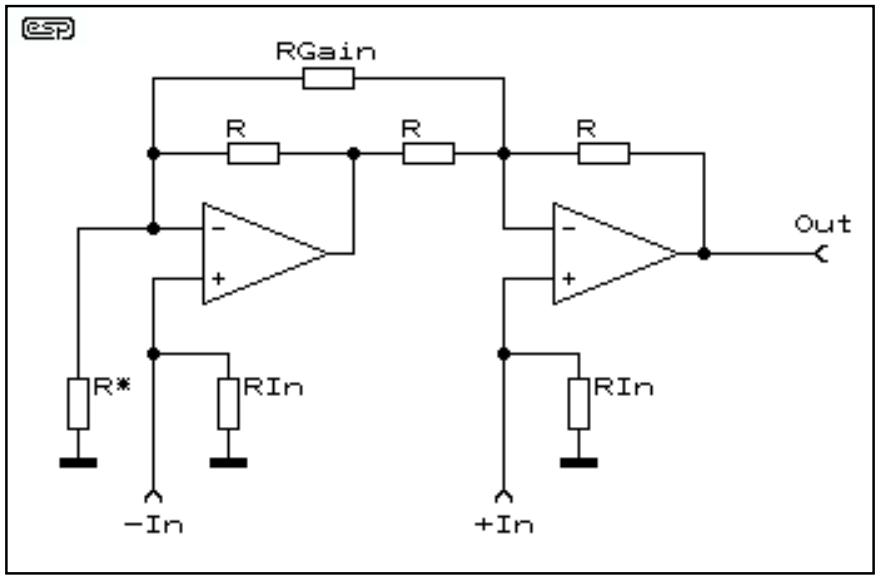

Figure 1 - Improved Balanced Line Receiver

Both inputs may be directly connected to the incoming signal - there are no resistors in between. This improves noise performance so that this circuit is well suited for microphone preamps. Furthermore there is no feed-back from the output to any input so that the inputs may have any input impedance up to nearly infinite. The common mode rejection ratio is determined by the precision of the resistors R and will be about 40dB with 1% resistors. With only one additional resistor RGain the gain can be increased without decreasing the common mode rejection ratio. Or, in other words, the ratio between differential and common mode gain is further improved.

Another improved version can be found in project 66, which is based on a dual transistor differential input.

All in all, balanced line receivers are quite easy to realise with little effort. With the exception of the limited common mode range they easily can come close to the performance of transformer

coupled inputs. They are no challenge - so I do not want to discuss them here further.

Balanced Line Drivers vs. Floating Balanced Line Drivers

The line driver Rod describes in his article is quite simple too. There is nothing to grumble at (;-)), but there is one essential difference between an output like the described one and a transformer coupled one: The common mode output resistance. A common voltage applied to the output will cause a considerable common mode current into the outputs - the output is not floating. Example: The differential output resistance in his project is 2 x 220 Ohm = 440 Ohm. If you apply a common mode voltage U at both outputs, a current of 2 x U / 220 Ohm will flow, i. e., the common mode output resistance is 110 Ohm (1/4 of the differential output resistance).

Or, another and more important point of view: With transformer coupled outputs you may short either output to ground or apply any voltage there - you will still have the full output voltage across its output ports. If you do this on one output of the simple push-pull amplifier it will not affect the other one. You can even connect several transformer coupled outputs in series and by this way sum all output voltages. This, of course, is not possible with a push-pull amplifier output stage which "looks" like a balanced output with a centre tapped earth reference.

I call transformer coupled outputs "floating outputs", because by nature they have a high or infinite common mode output resistance. So I was looking for a transformerless amplifier with floating outputs, and this is where my story starts. (Even though I'm afraid there is nobody out there raising his hand and shouting "Yes that's it! That's what I was always looking for!")

A Balanced Line Driver with Floating Output

I must admit I never really investigated in circuits to be found in literature or in the www, because on one hand I very soon had an idea myself for an appropriate circuit and on the other hand I cannot remember ever having seen anything like this before. I have since seen the schematics for the Analog Devices SSM2142 which uses almost exactly the principle described here and the complement from THAT corporation, the THAT1420/30. I should also mention the Maxim MAX435, a so-called "Wideband Transconductance Amplifier with Differential Output", which is somewhat similar but somewhat different too. At least it has a floating balanced output.

My basic circuit not only has balanced outputs but balanced inputs too and looks like this ...

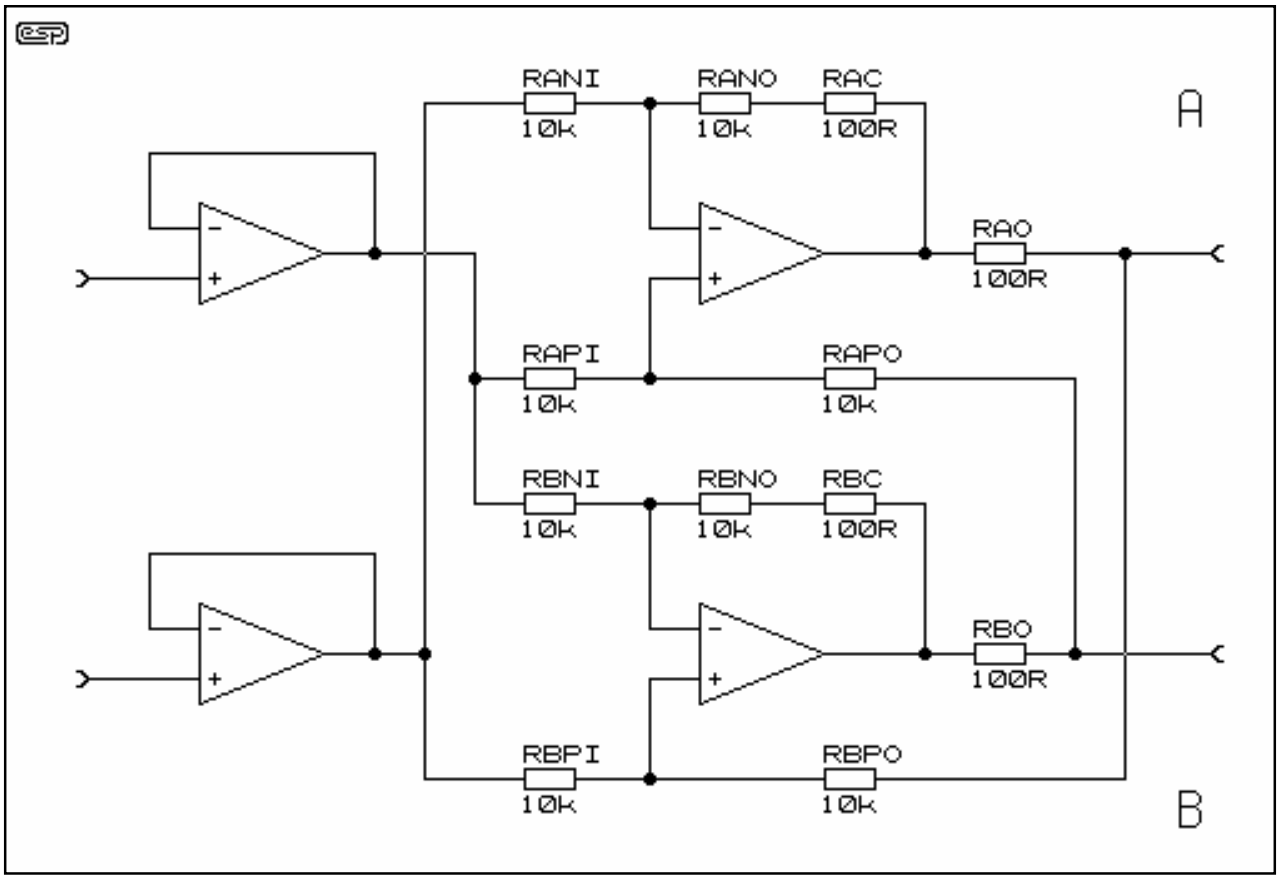

Figure 2 - Basic Form of Balanced Line Driver

Explanation of the indices used:

A, B ($R_{\mathbf{A}NI}$):	A: "Upper" ("positive") resp. B: "lower" ("negative") half
N, P ($R_{A\mathbf{N}I}$):	Connected to the negative (N) resp. positive (P) input
I, O (R_{ANI}):	Connected to the input (I) resp. output (O) op-amps
C ($R_{A\mathbf{C}}$):	Used to compensate R_{AO} resp. R_{BO}

No bias resistors are shown. The input stage is used to buffer the input signal so that the inputs may be dimensioned for almost ideal properties while the actual line drive is supplied with the required low impedance source.

The whole amplifier, as it is dimensioned here, has a gain of 1. The same amount of voltage across the input terminals appears across the output terminals. This remains true if any output terminal is supplied with any voltage - like transformer coupled outputs do (provided both output voltages stay within the supply voltage area of course). This is a consequence of the fact that the common mode output resistance (R_{COut}) is high.

The differential output resistance (R_{DOut}) is low, but not zero. It is determined by the resistors R_{AO} and R_{BO} and equal to it. In fact, $R_{COut}$and R_{DOut} (the output resistance in differential mode) are coupled at each other by the precision of the applied resistors. As R_{DOut}does not need to be very low and R_{COut} should be as high as possible, it seems obvious to start with a reasonable differential mode output resistance ($R_{DOut} = R_{XO}$) of 100 Ohm.

As mentioned, it is obvious that the precision of the resistors must have a certain influence on the performance of the whole circuit. But what is "the performance" of such a circuit?

The primary target obviously is a high R_{COut}at a given R_{DOut}. But at least three side effects must be kept in mind:

A common mode input voltage shall neither be visible at the outputs in common output mode nor in differential output mode (just like with transformers). The "Common to Common Mode Rejection Ratio" (CCMRR) and the "Common to Differential Mode Rejection Ratio" (CDMRR) tells about that. Furthermore a differential input signal shall not be visible at the outputs in common output mode. I call this "Differential to Common Mode Rejection Ratio" (DCMRR).

Of course differential input signals shall be visible at the outputs in differential output mode - this is simply called gain and by design always so close to the desired value that it does not need to be discussed.

Now we know one "primary target" (the common mode output resistance R_{COut}) and three "side effects" (CCMRR, CDMRR and DCMRR) to characterise the performance. I presume two more properties "gain" and "output resistance" as sufficiently precise given by design. I neglect other side effects and all input properties.

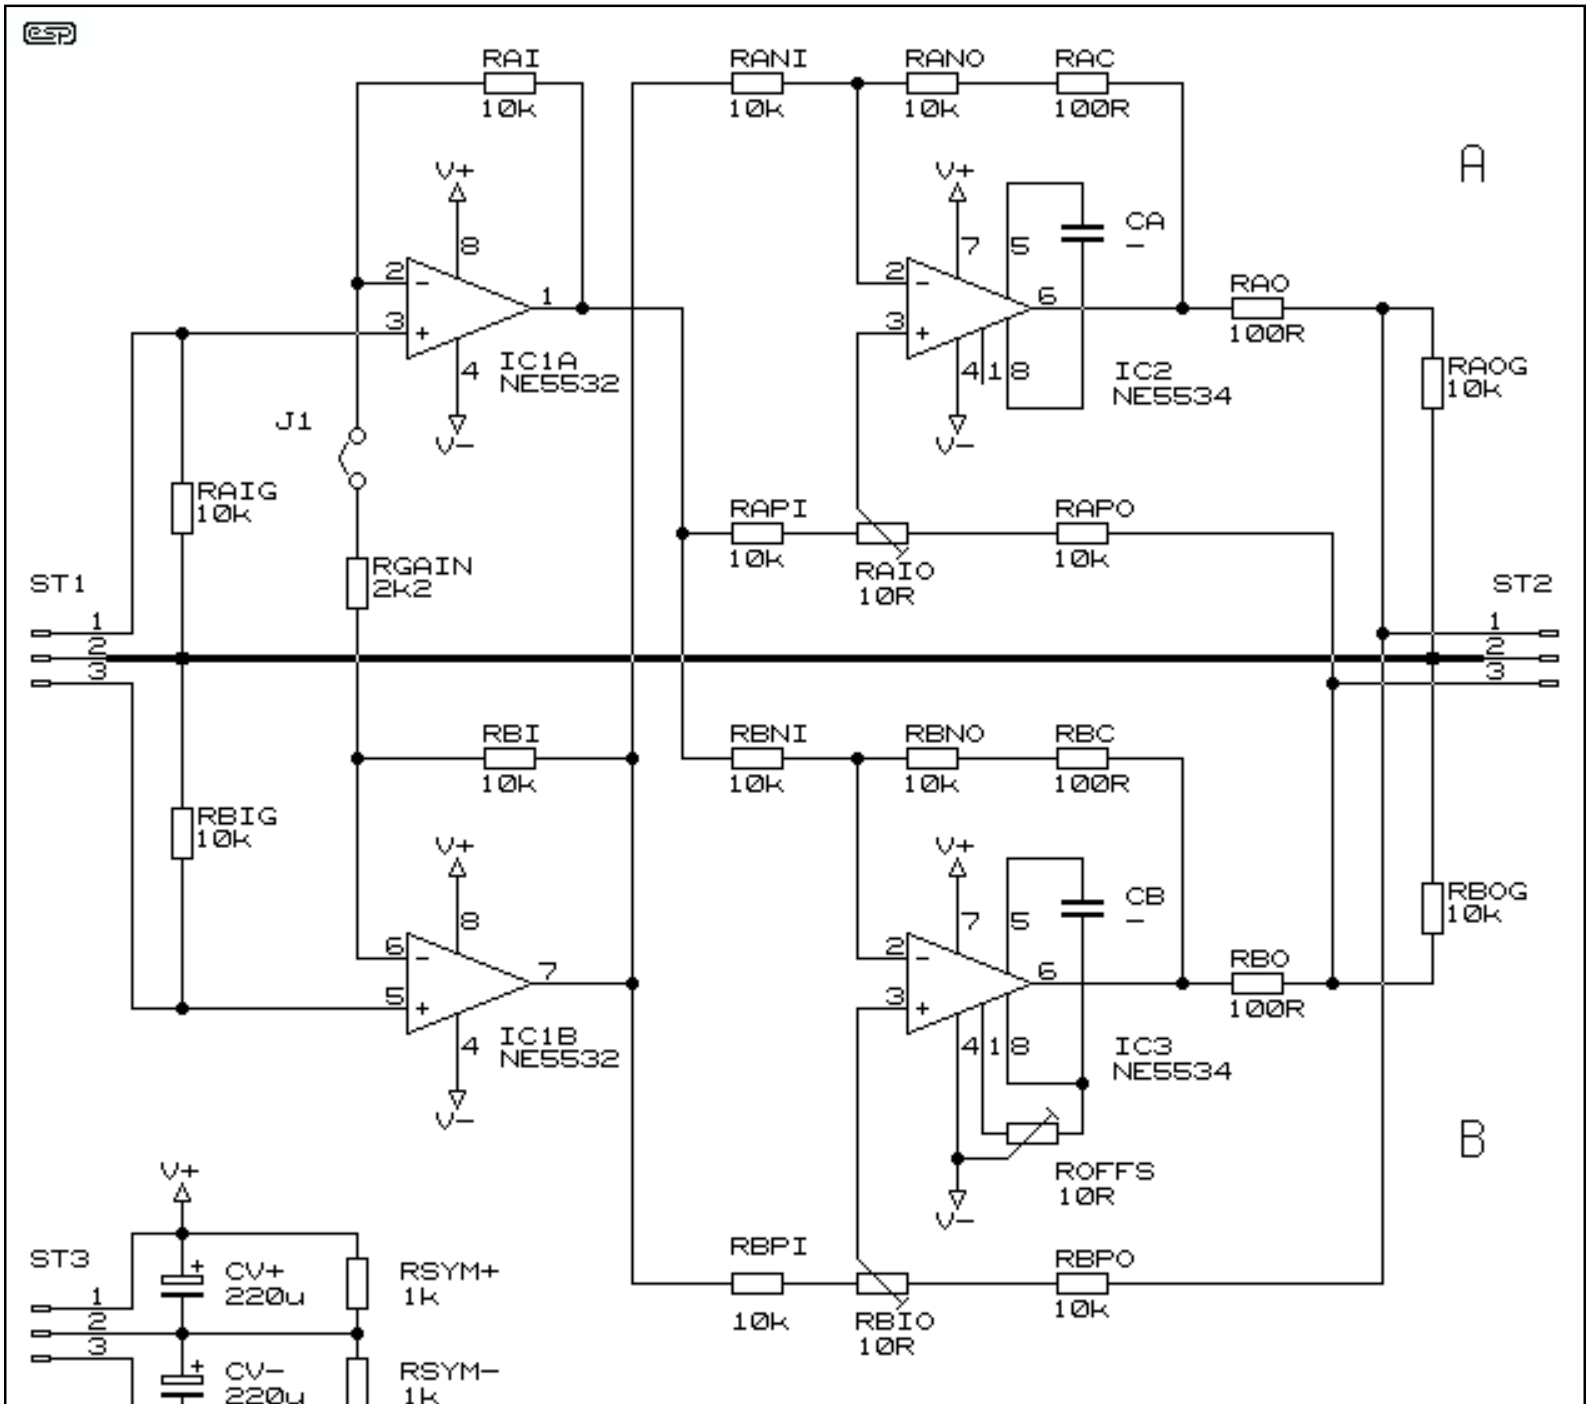
Now we can restart with the perception that it is obvious that the precision of the resistors must have a certain influence on the performance of the whole circuit and to find out this performance.

Performance Measurements

I could have tried to put the whole circuit into formulas and to solve the formulas in a way, that the influence of varying resistors on our target R_{COut} is directly visible, or I could have done this by simulation. Unfortunately my Pspice evaluation version does not support circuits as complex as this one. So at my first approach I preferred to measure the performance in a real circuit. Later I learned more by doing simulations, but I will come back on this later.

For my experimental circuit I thought about how to select the resistors. It seemed obvious that all ratios R_{XYI} / R_{XYO} had to be the same (replace X by A or B and Y by P or N). Furthermore all sums R_{XYI} + R_{XYO} had to be equal. At last all R_{XO} and R_{XC} should be the same.

But you cannot buy parts with equal values, so you have to live with similar ones. I bought 12 resistors with 10 kOhm and 4 with 100 Ohms, all specified with 0.1%. The cost of each is approx. $US0.20. I intended to select them so that the sums R_{XYI} + R_{XYO} are as equal as possible. Fortunately I have a 4 1/2 digit multimeter so that I could measure out 4 pairs of 10 kOhm resistors with difference of the summed resistances less than 2 Ohm. In order to meet the required equality of the ratios R_{XYI} / R_{XYO} I added three 10 Ohm 15-turn trimpots. The result was the following circuit:



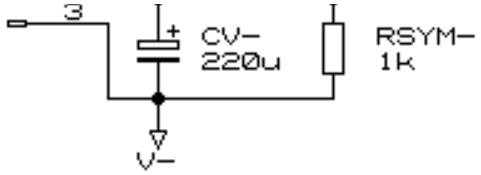


Figure 3 - Balanced Line Driver

Why R_{AOG} and R_{BOG}? With ideal parts the output resistance R_{COut} becomes infinite. With real ones it may become either positive or negative. If R_{COut} is negative, the outputs run to one of the supply rails and remains there - the circuit does not work properly, it is unstable. Thus R_{AOG} and R_{BOG} are introduced: R_{AOG} parallel to R_{BOG} must at least be lower than $-R_{COut}$ to guarantee stability. But R_{AOG} and R_{BOG}also symmetrise the output signal, and the lower R_{XOG} / 2 is compared to R_{COut}, the better the output is balanced. At the end, an extremely high R_{COut} (without R_{XOG}) is only good for a reasonable R_{COut} (including R_{XOG}) combined with reasonable common mode rejection ratios. Which explains why I declare a high R_{COut} as the primary target. Symmetrising the output means that both outputs have to carry the same voltage (but with opposite signs of course) in case they are open.

The trimpot R_{OFFS} is introduced to reduce the remaining common mode DC output current to zero. Particularly without R_{AOG} and R_{BOG} the remaining common mode DC output voltage caused by the current is extremely high, and just "a sharp look" at the trimpot may cause a difference of several volts.

Simulation Results

During our discussions Rod gave me the hint to try SIMetrix Intro as a simulator. SIMetrix was able to simulate this circuit and with this means I discovered an essential relationship between R_{COut}, R_{DOut} and the resistor tolerances:

Have a look at the schematic in Figure 2 and note that both op-amps are connected in a loop. Under ideal conditions the loop gain G_{Loop} is exactly 1. By the simulation I found out that the common mode output resistance R_{COut} can be calculated as $R_{COut} = 2 * R_{DOut} / (1 - G_{Loop})$. As R_{COut} shall be as high as possible, G_{Loop} has to be as close as possible to 1. A loop gain of 1.01 results in a negative R_{COut} of -20 kOhm must be compensated by $R_{AOG} || R_{BOG} < 20$ kOhm to maintain stability, but for balancing reasons $R_{AOG} ||$ Rsub>BOG should be << 20 kOhm. To guarantee $|R_{COut}| >= 20$ kOhm G_{Loop} must be between 0.99 and 1.01. Keep in mind that there are 8 resistors and their deviations that influence G_{Loop}! That looks difficult, but on the other

hand a Monte Carlo analysis teaches that with resistor tolerances of 1% (which theoretically could result in loop gains between 0,99 ^ 8 = 0,92 and 1.01 ^ 8 = 1,08) $|R_{COut}|$ will be > 20 kOhm (2 * R_{DOut} * G_{Loop}) as desired in more than 99% of all cases. Under these circumstances I would recommend R_{AOG} = R_{BOG} = 4.7 kOhm, which is a fair compromise between the resulting symmetry and the common mode output resistance.

Practical Assembly and Adjustment

The experimental board

I built the circuit in my favourite way on a Vero square pad board. I observe special rules for that and I would like to write more about it, but not here. I am quite convinced it looks professionally nice - on both sides of the board.

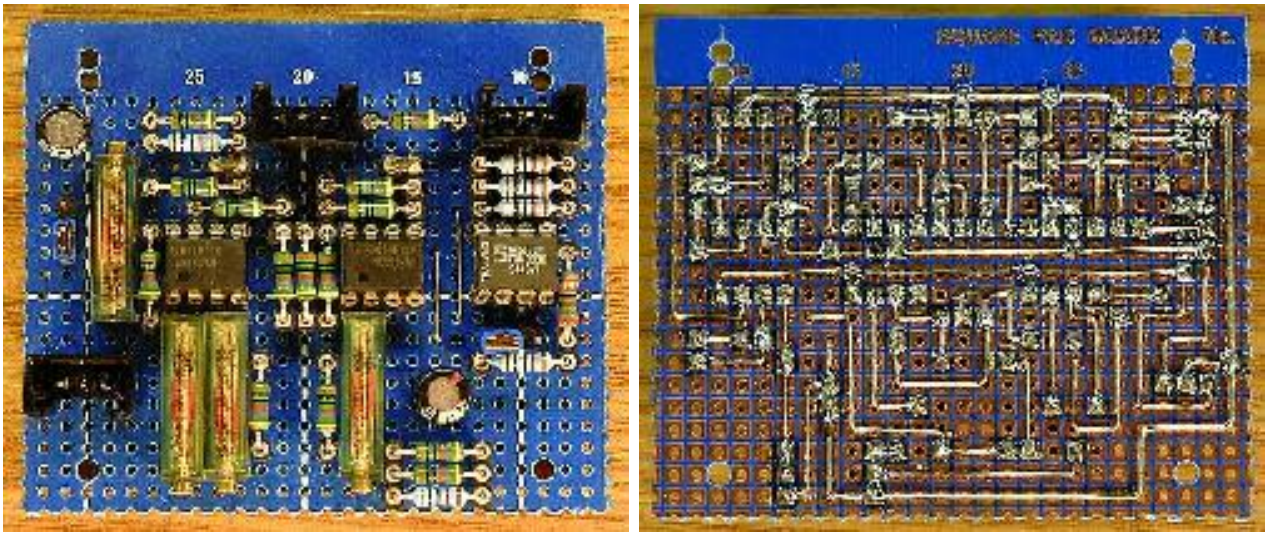

Figure 4 - Front and Rear of Veroboard Layouts

In order to be easy to change, all resistors and op-amps are pluggable.

The power supply is symmetrical. As almost no current flows out of and into the ground rail, a single, floating supply may be used with the ground rail artificially generated by a resistor divider of 2 x 1 kOhm. Actually none of the I/O- and power connector's ground pins needs to be connected externally.

The gain of the input stage may be raised with an additional resistor R_{GAIN}, similar to the resistor R_{Gain} above. The gain of the output stage may additionally be altered by varying the ratios of R_{XYI} / R_{XYO}.

In order to adjust the ratios R_{XYI} / R_{XYO} I unplugged all op-amps, connected the (former) outputs of the input op-amps (IC1, pins 1 and 7) together to V- and the (former) outputs of the

output op-amps (IC2 and 3, pins 5) together to V+. R_{AG} and R_{BG} must be removed. With the multimeter the voltage between the "untrimmed" op-amp (IC2, pin 2) input and the three trimmed op-amp inputs (IC 2, pin 3 and IC 3, pins 2 and 3) now can be minimised so that the balance between the dividers is extremely high - a resolution of 10 uV from 10V corresponds to 10E-6 or 0.0001%! But don't ask me about long term or temperature stability.

Static Performance

In order to find out more about the consequences of resistor deviations, I paralleled a resistor to 1.: R_{ANI}, 2.: R_{ANO}, 3.: R_{ANI} + R_{ANO} and 4.: R_{AO}. The resistances were reduced by 1%.

The table shows the results without R_{AG} and R_{BG}. Without these resistors I_{COut} rather than U_{COut} for or CCMRR and DCMRR have to be measured.

	Name	Formula	Units	Nominal	-1% R_{ANI}	-1% R_{ANO}	-1% (R_{ANI} + R_{ANO})	-1% R_{AO}
R_{COut}	Common Mode Output Resistance excl. R_{XOG}	U_{COut}/I_{COut}	Ohm	>> 10 M	~ -20 k	~ +20 k	-1.2 M	-2.5 M
R_{COut}	Common Mode Output Resistance incl. R_{XOG}	U_{COut}/I_{COut}	Ohm	5 k	~ 4 k	~ 6 k	5 k	5 k
CCMRR	Common to Common Mode Rejection Ratio	U_{CIn}/U_{COut}	-	> 1000 (60 dB)	~ -3 (10 dB	~ +5 (14 dB)	-120 (42 dB)	-500 (54 dB)
CDMRR	Common to Differential Mode Rejection Ratio	U_{CIn}/U_{DOut}	-	> 1E4 (80 dB)	~ 300 (50 dB)	~ 550 (55 dB)	> 1E4 (80 dB)	> 1E4 (80 dB)
DCMRR	Differential to Common Mode Rejection Ratio	U_{DIn}/U_{COut}	-	~ +400 (52 dB)	~ +6 (16 dB)	~ -10 (20 dB)	~ +140 (43 dB)	~ +160 (44 dB)

The common mode output resistance excl. R_{XOG} in this experimental circuit is extremely high. But only one of the resistors R_{XYI} or R_{XYO} changed by 1% reduces the common mode output

resistance down to +/-20 kOhm, which, in my opinion, is hardly at the edge of being acceptable. During my experiments it seemed plausible to me that with an 1% error the output resistance could not be very different from 100 or 200 times the output resistance. Later, with the simulations, I learned to know the exact relation of 200 for 1% error.

Altering either R_{ANI} or R_{ANO} imbalances the divider network at the op-amps input. Altering both by the same amount causes no imbalance here, but somewhere else where it is obviously much less critical. The same applies to an alteration of R_{AO} and R_{BO}.

Dynamic Performance

The frequency response of this amplifier reaches from DC far beyond the need of audio circuits. As two op-amps are partially connected in a loop, a danger of self-oscillation arises. In fact, with a square wave input signal some ringing can be observed at a few MHz. With an input frequency around a few MHz the amplifier becomes unstable. The NE5534 as a single op-amp is meant to be compensated by an external capacitor (C_A and C_B, ~22 pF each). Using these does not improve the situation in this special circuit: The frequency of the ringing not only lowered but it is also "un-damped", i.e. the ringing lasts for more periods. It turned out to be best to omit both capacitors and to care that higher frequencies are blocked out. I did not notice any danger of self-oscillation with various resistive or capacitive loads.

In my previous text I wrote about output resistances R rather than output impedances Z because I primarily looked at static (DC) values, i.e. the common mode output resistance R_{COut} above, which is measured as a DC value. Of course in reality it is a complex value with approx. 2 nF in parallel, so it becomes capacitive at higher frequencies. With output resistors R_{AG} and R_{BG} of 10 kOhm each, the output impedance up to 10 kHz is predominantly resistive (5 kOhm). With slower op-amps, i.e. TL072, the output impedance will remain resistive up to a few kHz only. I did not care for the dynamic properties of the rejection ratios.

Further Improvements - Input Options

The inputs of my sample circuit above are equipped with one simple buffer amplifier each. Later (unfortunately too late) I realised that I missed much room for major improvements:

Remember: R_{XOG} have been introduced not only to guarantee stability but also to symmetrise the output signal. For this reason I dimensioned R_{XOG} extra low. Stability can also be guaranteed by lowering the loop gain, i.e. by just omitting both R_{XC} (resulting in a loop gain of 0.98 typically). But just omitting both R_{XC} and both R_{XOG} results in very poor common mode

rejection ratios, i.e., an input signal applied at one input only will appear at the corresponding output only - totally unbalanced.

If both input op-amps are connected as differential amplifiers with complementary outputs, the following output stage will already be supplied with a balanced input signal and needs not to symmetrise the signal any more:

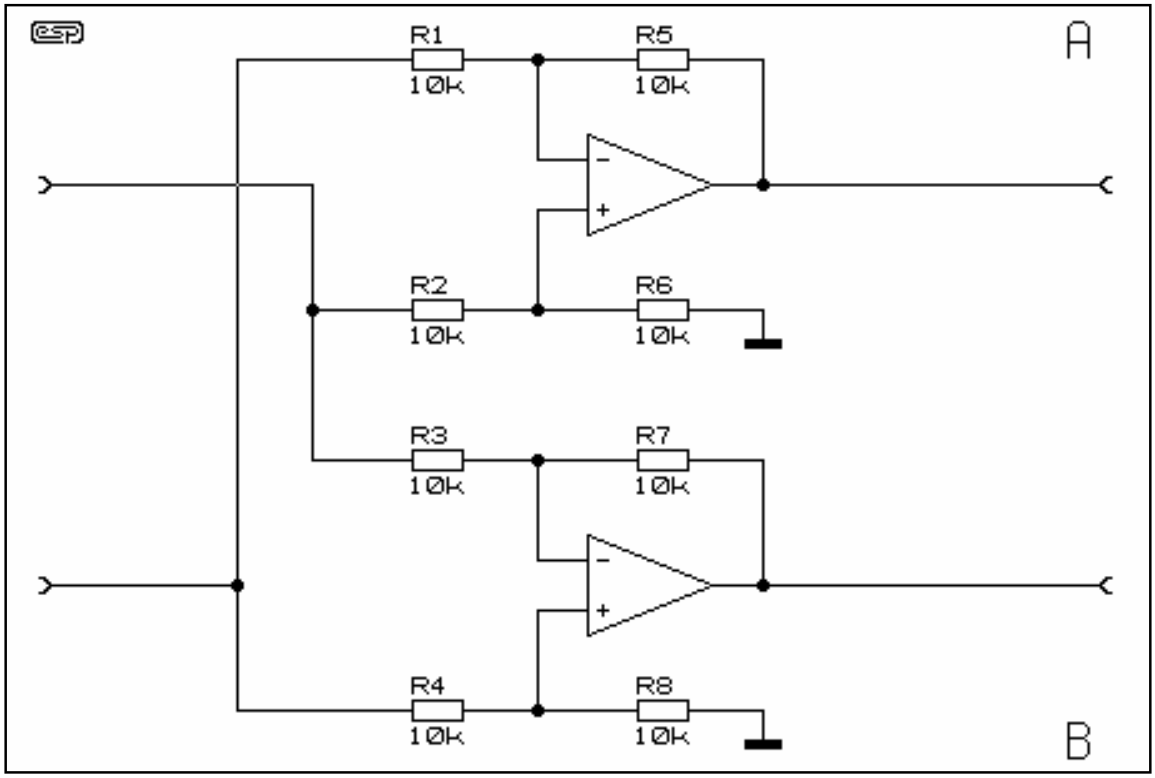

Figure 5 - Balancing Differential Preamplifier

Alternatively, if you have an unbalanced source, you may simplify the design by just inverting the input signal with a single op-amp. Omit R_{XC} and $R_{XOG}$and you have the circuit Rod has chosen in his project 87 and Analog Devices in the SSM2142 too.

But in both of these alternatives there is a snag: A reverse feedthrough from the outputs to the input(s). Therefore either a low impedance source should be used, or another op-amp connected as a buffer should precede the inverter(s). This will finally lead to "ultimate perfection" ;-)

Conclusion

Without the latter input improvement, a common mode output resistance R_{COut} of 5 kOhm, determined by R_{AG} in parallel with R_{BG}, is reasonable, but with resistor tolerances of 1% the asymmetry may become quite high. It is not likely that the amplifier becomes unstable. I prefer

to use either 0.1% resistors, or the resistors should be measured out so that R_{XYI} / R_{XYO} is quite equal or the dividers should be trimmed. With multiple of these measures R_{COut} may easily be risen far above 1 MOhm typically.

With the input improvement, R_{XC} and R_{XOG} should be omitted. By using 1% resistors R_{COut} in 99% of all cases will become between 7 and 20 kOhm, combined with very good CMRRs. With 0.1% resistors and both R_{XC} = 90 Ohm R_{COut} in 99% of all cases will even become between 70 and 200 kOhm.

But do not forget to trim at least one of the op-amps offset voltages: 1 mV offset voltage will cause 400 mV common mode offset voltage if R_{COut} is 10 kOhm or even 4 V if R_{COut} is 100 kOhm (!). In order to reduce the differential offset voltage too, the offset voltages of both op-amps must be trimmed. But this seems to me to be less important.

Justification (Why isn't it perfect?)

This project is a small, few-weekend project which does not claim to be theoretically, mathematically or scientifically correct and complete. I may have made errors, I may have overlooked better solutions. I was lucky that Rod gave the hint to do the simulation with SIMetrix Intro - as my PSpice Student was too much limited. With this simulation I learned a lot about this circuit.

Rod cared for the circuit to an extent that I really appreciated very much. He "pushed" me to have closer looks to what I was actually doing, to make simulations and lots of things that finally resulted in the current state. Without him it all would look much more amateurish. Rod, I really have to thank you. You are a great editor!

Introduction

Integral to most audio amplification systems, the current source and current sink are indispensable. For the purposes of this article, sources and sinks shall be treated as being the same thing - which they are, depending upon how one views the circuit. In essence, the functionality (and purpose) are identical - force the current through another device to be constant, as long as the voltage is within the boundaries of the power supply (less some voltage drop across the source / sink).

Current mirrors have the ability to greatly increase open loop gain and linearity, giving better closed loop performance. This short article looks at the various types, from the theoretical "perfect" device, through various practical examples.

The Perfect Current Source

A perfect current source can be constructed very simply, requiring only an infinite voltage and an infinite resistance. Unfortunately, this will also provide an infinite current (which will be infinitely constant), but is (infinitely?) excessive for most applications.

Sorry, I was being facetious, but the principle is nonetheless sound. In reality, a sufficiently high voltage can produce a current through a varying resistance that is essentially constant, provided that the voltage swing on the resistance is a small fraction (<100th) of the supply voltage. This will provide an accuracy of 1% at 100:1 voltage ratio.

This is a method that was common years ago, and I still have (and use) a transistor tester that uses this method to provide a constant base current to the device under test. With a supply voltage of 250V feeding the base-emitter junction (0.65V typically) via switched resistances, the current is not affected at all by any variation in the base-emitter voltage under load.

The principle works well, but no-one wants to have to use such high voltages in equipment these days.

So why mention this method at all? Simply because the operation and characteristics of current sources are not well understood by most non-engineers (and quite a few engineers, too). Figure 1 shows a resistive current source that will maintain the set current of 1mA to an accuracy of within than 1% over the range 0-10V.

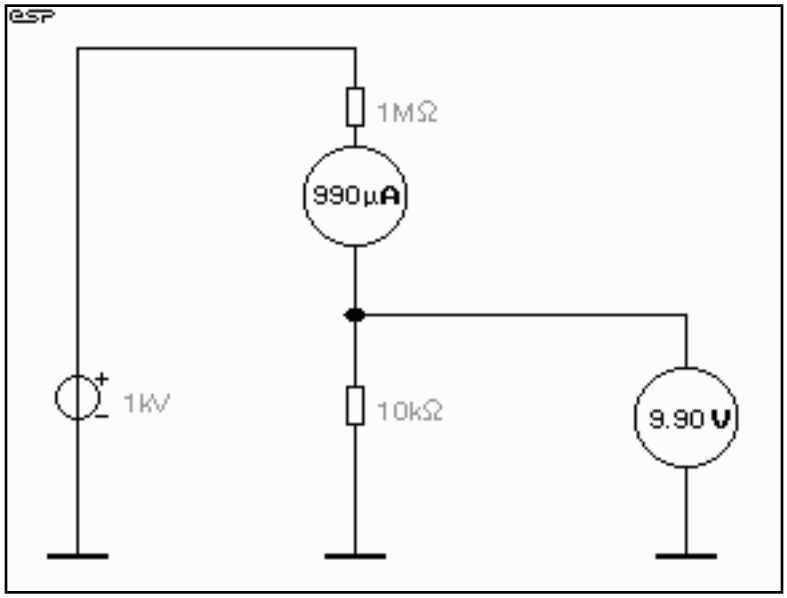

Figure 1 - Simple Resistive Current Source

The first thing that we need to be aware of is that the impedance is very high, and a perfect current source (as described above) does indeed have an infinite impedance. Although this is impossible to achieve in practice, impedances of many, many megohms are quite possible, and are used regularly in many different circuit types.

The Common Emitter Transistor Amplifier

If we look at a simple common emitter transistor amplifier (Figure 2), the output impedance is equal to the collector resistance, and the gain is equal to the collector resistance divided by r_e - the transistor's internal emitter resistance. This is equal to approximately

$$26 / I_e \text{ (mA)}$$

and will naturally vary with the current. Please note that biasing components have been omitted for clarity, but in reality they must be used.

For all examples, a transistor with a current gain of 100 is used and the bias current will be set at exactly 100th of the expected collector current (using a current source, naturally).

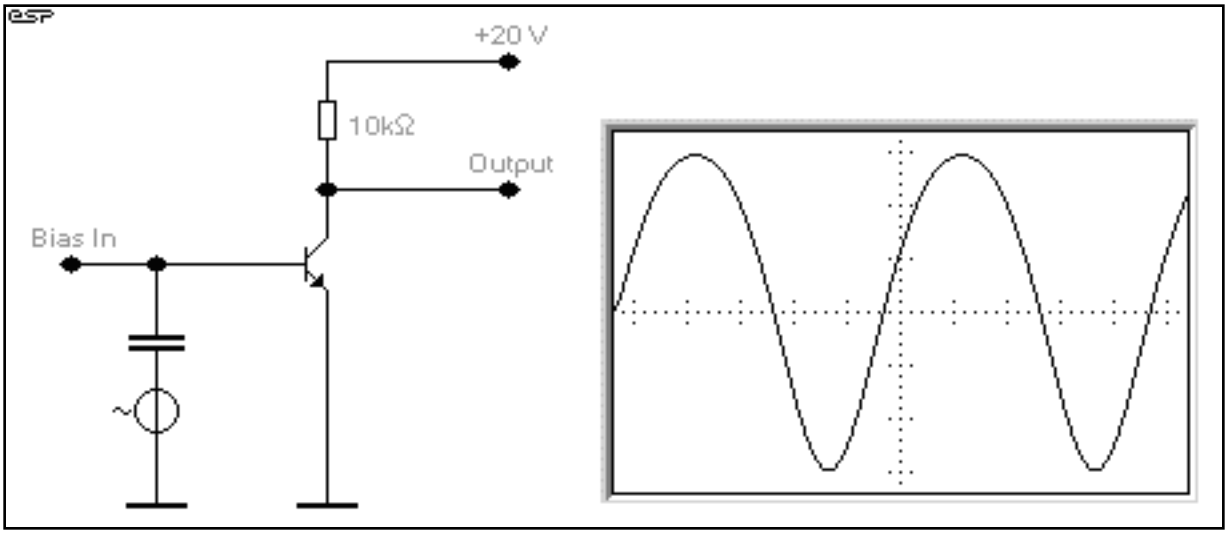

Figure 2 - Simple Common Emitter Transistor Amplifier

At low output levels, the gain should be 385, but as simulated is actually 397. This is well within the degree of accuracy we want to go to in this article, so practice correlates well with theory (one would hope so, or we would all be in trouble).

As the transistors output voltage increases, the available collector current (and hence emitter current) falls, so r_e increases (and vice versa). The higher the output voltage (relative to the supply voltage), the less emitter current flows, and the lower the gain becomes. As the transistor turns on (reducing the output voltage), the exact opposite occurs, and the gain rises. This effect is immediately evident in the output waveform, which is distorted. This is shown in the oscilloscope trace in Figure 2, and the distortion is clearly visible, with the tops of the waveform flattened out, and the bottoms "stretched". This is typical of any transistor amplifier operating without feedback, and is also true of valves and FETs.

Local Feedback

One method of reducing this distortion is to introduce a resistance into the emitter circuit (local feedback) to reduce the gain and swamp the variations in r_e. This works, but we still have a relatively low output impedance, and distortion is still evident - although much reduced. This is shown in Figure 3, where a 100 Ohm emitter resistor has been added.

A commonly held belief is that local emitter feedback reduces the output impedance - this is simply not true - the output impedance of a common emitter amplifier is equal to the collector resistance, regardless of emitter degeneration. To reduce the output impedance, it is necessary to apply feedback around the entire circuit - from the output back to the input. The proof of this is outside the scope of this article, but it is nonetheless a fact.

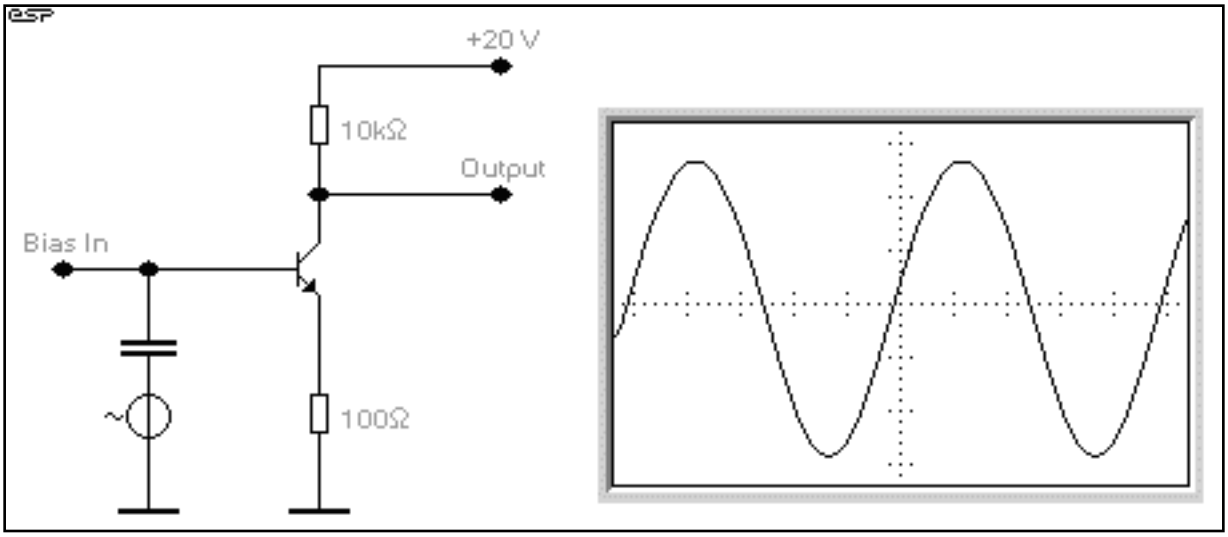

Figure 3 - Common Emitter Stage With Local Feedback

With all this talk of distortion, I can almost hear all the thermionic valve (tube) enthusiasts cheering "I knew it - and here is the proof I have been looking for!"

Sadly, this is not the case. Valves do exactly the same thing, as do FETs of all types - the mechanism is different in each, but the result is the same. Gain varies with current in all known amplifying devices to a greater or lesser degree, so the principles outlined here are valid for any device. I am staying with transistors because they are the most commonly used of all the devices currently available.

In this case, the gain of the stage works out to be just over 78, and theory would predict a gain of 79, so again the correlation is very good. Remember that with an emitter current of 1.001 mA (collector current plus base current), the value of r_e is about 26, and this must be added to the external resistance R_e.

Use of a Current Source Load

Since we have determined that the load resistance affects gain, and that variations of collector current (and hence emitter current) affect linearity, if a current source were to be used instead of the 10k resistor, we should get vastly more gain, and the distortion should be negligible.

In reality, this is exactly what will happen, and Figure 4 shows a theoretical current source as the collector load. The current source is set to provide a current of 10 mA as before. No oscilloscope trace is shown, because the linearity is so good that no distortion is visible, and a trace of a sinewave gets tedious after a while.

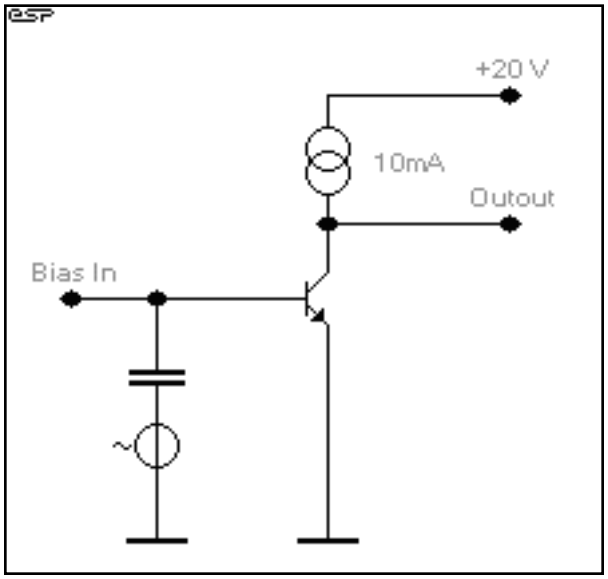

Figure 4 - Use of Current Source as Load

Figure 4 shows the circuit, which (theoretically) has a gain of about 20,000,000 (and no, there are not too many zeros, it really is 20 Million). Naturally, real life will reduce this considerably - even using a 10M Ohm oscilloscope probe will cause a dramatic loss (down to about 390,000 in fact). In reality, the gain of this circuit is actually infinite, but the "meters" I used in the simulation are "only" 1G Ohm each, which reduces the gain.

Figure 5 shows the same circuit with a real current source, and the gain from this (again, the transistors all have an Hfe of 100) is still quite astonishing. We still manage a gain of 19 Million (bearing in mind the meter load, which reduces the gain).

This form of circuit can no longer be biased using a simple current source, because the circuit gain is so high that even the smallest variation in transistor Hfe, or the tiniest variation in a resistor value will cause the output to "go to ground" or sit at the supply voltage. Consequently, an opamp has been added to apply bias, otherwise the circuit is almost impossible to stabilise. The use of a bias servo in this manner is not too common, but I have seen it used in a number of applications. Care needs to be taken to ensure that a low frequency phase shift oscillator is not created if you want to experiment with this idea.

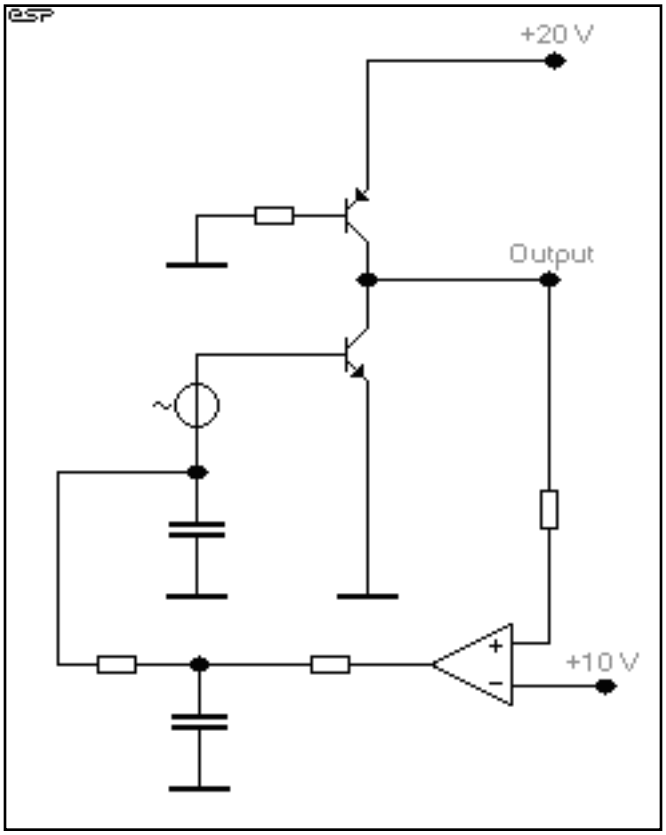

Figure 5 - Real-Life Current Source Load With Bias Servo

For a current source of this type, the current is equal to

```
I = (( V - 0.65 )  / R ) * Hfe
```

The current source shown is workable, but is highly dependent upon the gain of the transistor, and the supply voltage. Now that the basic principles have been examined, we shall look at some real current sources (or sinks, depending on how you look at it).

Where **I** is the current, **V** is the supply voltage, **0.65** is the emitter-base voltage (typical), **R** is the base resistor and **Hfe** is the forward current gain of the transistor.

Real-Life Current Sources

The "classic" current source is shown in Figure 6, and is reasonably stable with transistor gains and temperature. In audio work, absolute stability is not really necessary, since the feedback loop is used to ensure that bias voltages are maintained at the correct value. In some cases a servo circuit may be used (as shown in Figures 6 and 7), but this is not really necessary in the majority of cases.

The circuit shown uses the diode stabilised base voltage to maintain a constant voltage across the emitter resistor. As always, a constant voltage across a resistor means that the current is

also constant. The output current of this source is calculated from

```
I = 0.65 / RE
```

Where **RE** is the total emitter resistance - the internal r_e of the transistor plus the external resistance R_e. The diode current should be a minimum of 10 times the expected base current, but can be up to 100 times as great.

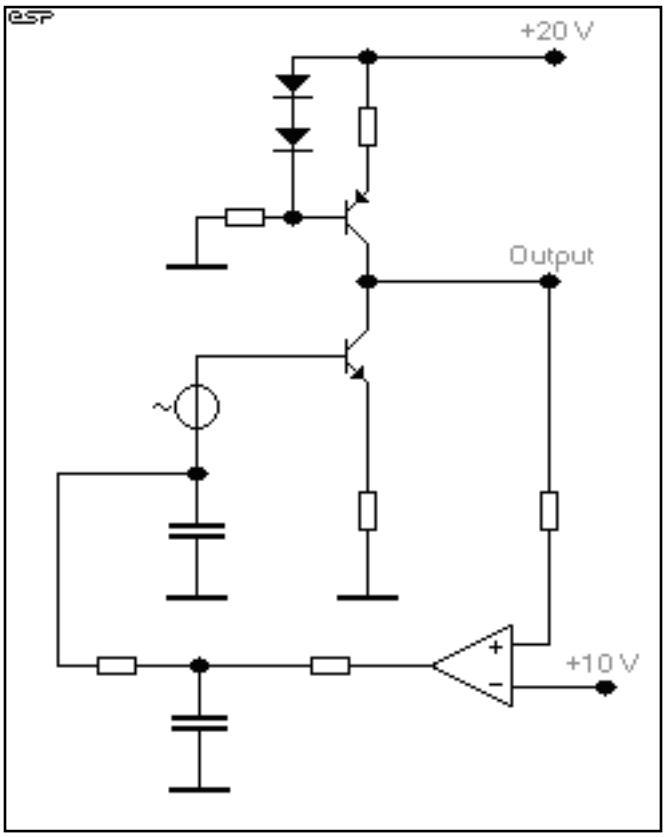

Figure 6 - The "Classic" Current Source

The gain is relatively unaffected by the change in the configuration of the current source, and the next variation (which is preferred by many designers - including me) has no significant effect either.

In any of the above cases, the inclusion of an emitter resistor (100 Ohms - as shown in Figure 6) reduces the gain to about 3.75 Million - this is still an outstanding amount of gain from a single transistor!

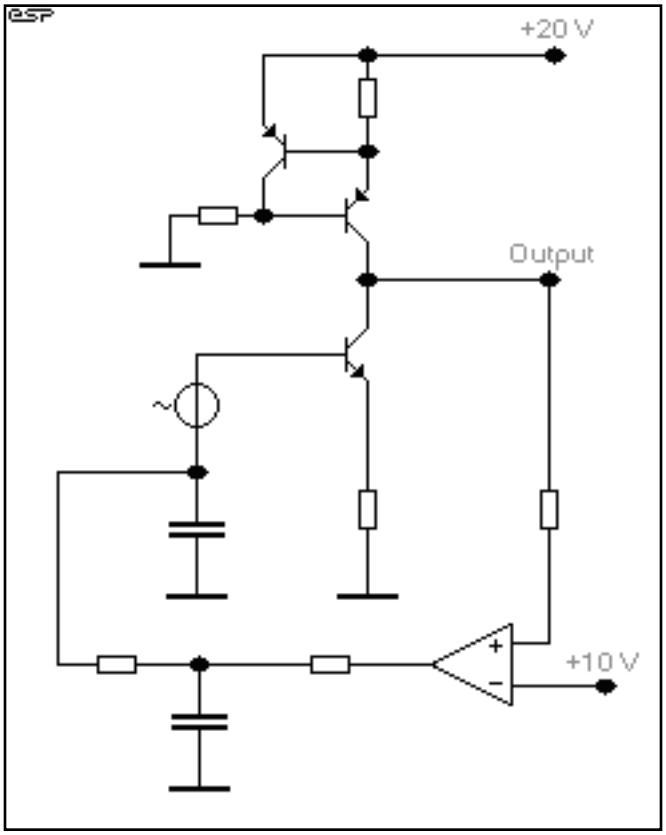

Figure 7 - The Preferred Current Source

This current source is probably one of the most commonly used, and has excellent stability, especially if the two transistors are thermally bonded. This is not needed for most applications, since as mentioned previously, absolute current accuracy / stability is not (or should not) be a requirement for an audio amplifier.

This is a very simple circuit, but will give excellent results wherever it is used. Current is calculated by

$$I = 0.65 / Re$$

In this case, the internal emitter resistance is not an issue, since the second transistor allows only that exact amount of base current for the current source to develop 0.65 Volt across the resistor. Should the current try to increase, the second transistor simply turns on harder, and steals more of the base current. The current through this second transistor should be at least 10 times as great as the expected base current of the current source.

With all the circuits shown, output impedance is very high, and by my tests, is about 500 Megohms (this happens to the the combined resistance of the two meters I used for monitoring, so the actual amplifier output impedance is effectively infinite. Inclusion of the emitter resistor (providing local feedback) has no effect whatsoever on the impedance (contrary to popular belief), but simply reduces the gain.

Bootstrap Current Source

The final (and least understood) of all the current sources is the so-called "bootstrap" amplifier. While not as good as a true current source, its performance is still very good, and in the example shown in Figure 8 manages to provide a gain of 8,860. Bear in mind that this is at a current of only 1mA (the others all used 10mA), so the gain must be reduced somewhat. However, this circuit is not in the same league as the gain of millions from the current source, but in real terms this is more than enough for the Class-A amplifier / driver stage of a power amplifier.

There are some advantages and disadvantages to this circuit, and it is dependent on the application whether it will be suitable. Where a true current source has the same (more or less) impedance at all frequencies right down to DC, the bootstrap circuit has a low frequency cut-off point determined by the resistance and capacitance used. This makes DC biasing easier (since the gain is quite low at DC), but since it reduces gain (and global feedback) at DC, there may be more DC offset at the amplifier's output as a result.

Distortion will also increase at very low frequencies, since the constant voltage across resistor R2 will not be maintained as phase shift (and LF rolloff) start to take their toll.

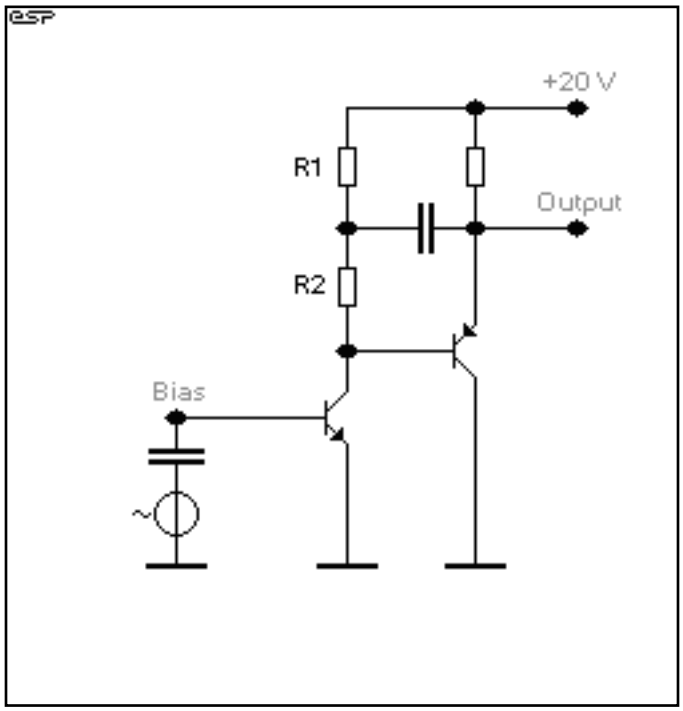

Figure 8 - Bootstrap Current Source

Since it is so misunderstood, it is worth a few words of explanation. R1 and R2 supply a nominal current of 1 mA (resistors are 5k each). Under normal (i.e. quiescent) conditions, there will be 5 Volts across each resistor. As the output varies, the capacitor couples the output signal back to the centre tap of the two resistors, and if the emitter follower were a

perfect buffer amplifier, this would exactly equal the input. As a result, the voltage across R2 is kept constant - if the voltage across a resistor is constant, then it follows that the current through the resistor must also be constant. The current through R1 varies considerably, but R2 maintains a constant current over the full output operating range.

Small differences in voltage (due to the loss through the emitter follower) or in phase (due to the capacitive reactance starting to become significant with decreasing frequency) both cause the bootstrap current source to reduce its effectiveness, so impedance and gain drop, and distortion increases. In a well designed circuit, these effects are minimal at all normal operating frequencies, but cannot be discounted.

Practical Applications

Now that we have looked at the various types of current source (there are many more, but the others will not be examined here), we can examine where they are best used, and why.

I am mainly interested in audio amplification, and will therefore concentrate on this aspect of the use of current sources and mirrors. There are naturally countless other applications, but I will leave it to the reader's imagination to explore the additional uses.

One of the most irksome loads for any amplifier is one that has inherent non-linearities, and the output stage of an audio amp definitely fits this description. Consider the worst case, where there is no forward bias applied to the output devices, which are operating in Class-B. The global feedback in an amplifier is generally considered to the be main saviour, by reducing the distortion components by using the input stage as an error amplifier.

This is actually only a small part of the story - a properly designed Class-A amplifier will have both high gain and high output impedance, both of which are useful in reducing the otherwise inevitable crossover distortion. Consider Figure 9a and 9b, showing the same output stage delivering the same peak output voltage to the same resistance.

The first is using a low impedance amplifier (an opamp) with unity gain as shown, but will normally be adjusted to give the required output, while the second uses a high impedance source having a high gain and impedance, but still providing the same output voltage.

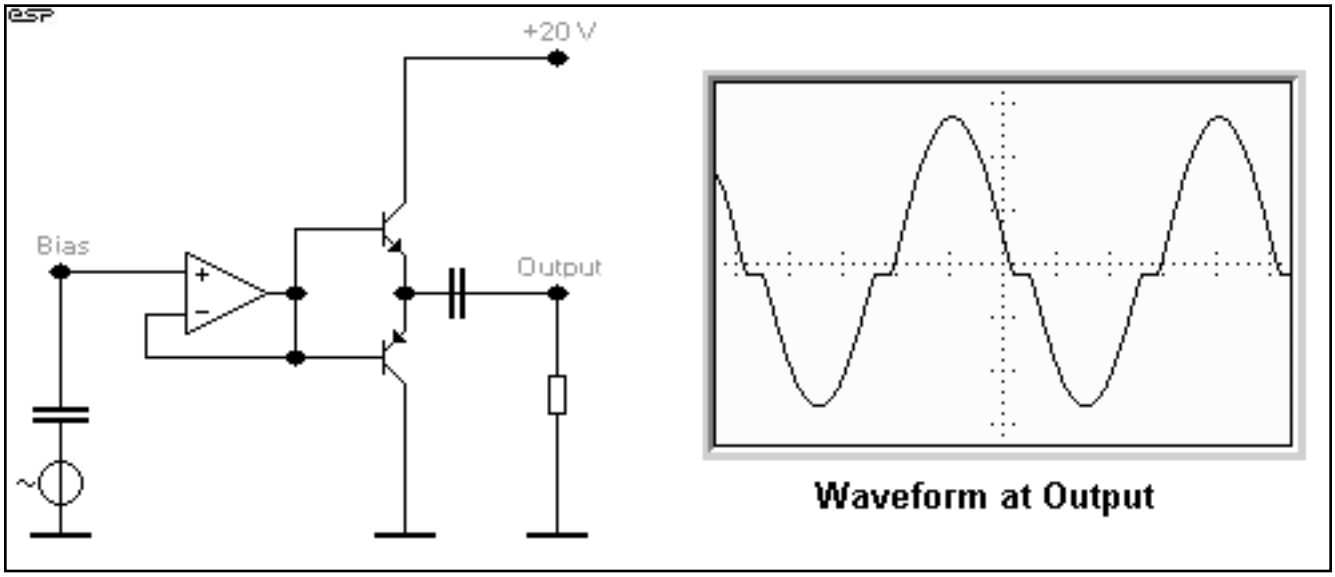

Figure 9a - Use Of A Voltage Source Driving an Unbiased Output Stage

The load for each amplifier is 100 Ohms, and it is clear from the first figure (9a) that crossover distortion is gross. Figure 9b shows how the high impedance drive to the output stage overcomes the crossover distortion - the output waveform is not shown, because there is virtually no distortion visible in the oscilloscope trace, so it looks just like a sinewave.

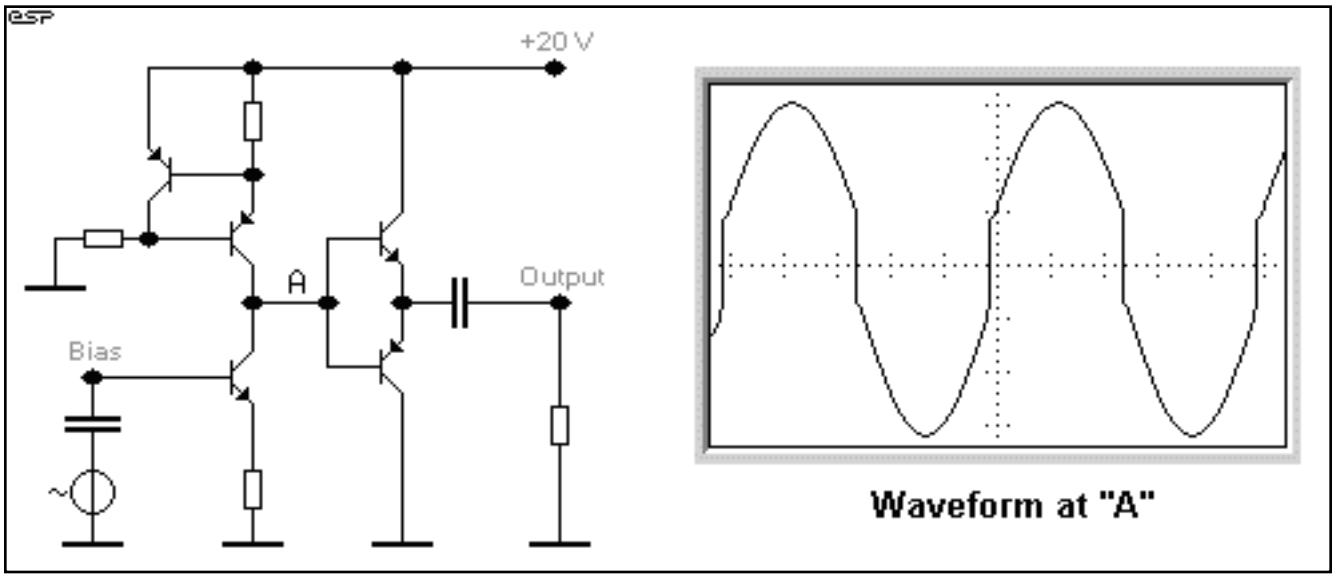

Figure 9b - Use Of A Current Source Driving an Unbiased Output Stage

Remember that this is with no feedback whatsoever - the addition of feedback will reduce the distortion even more - as will some biasing on the output stage - neither of these were included to show the effect more clearly. Note that the settings on the oscilloscope were not changed between these simulations, to ensure that the full effect was not obscured (or accentuated) for each example.

The inescapable conclusion is that the high impedance drive will greatly assist in overcoming non-linearities in the output stage, even those as nasty as a completely unbiased

complementary pair as shown. Naturally other non-linearities are also negated (to some degree) by these techniques, which are pretty much universal in modern amplifier designs.

None of the above should be taken to mean that we no longer need negative feedback - the idea is to make the amplifier as linear as possible before feedback is added. This makes a good amp better - feedback will never make a bad amp good !

Current Mirrors

The next item is current mirrors, another little understood circuit. These are extremely useful in amplifier design, and in this section I will show where they can be used, and the benefits that can be obtained.

The basic current mirror is shown in Figure 10, and it can be seen that whatever current is injected into the left side is mirrored, and the right hand side is a constant current source (sink) reflecting the injected current. Should the input current at change, so will the output current, but it will remain constant, regardless of the actual voltage (provided it remains within the supply limits of course).

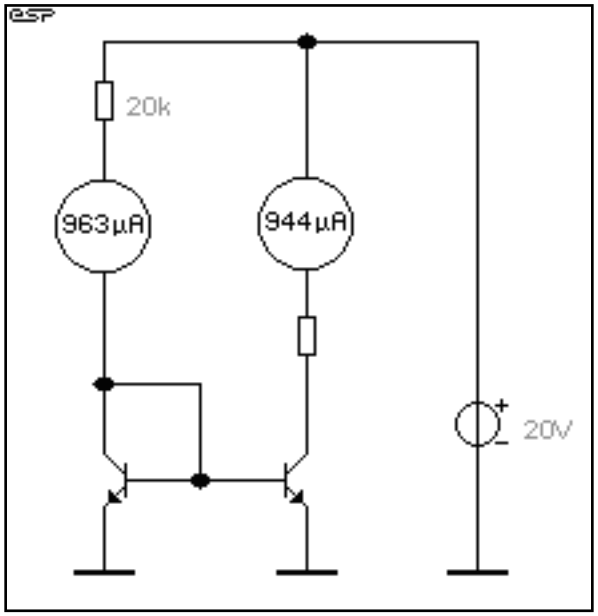

Figure 10 - A Basic Current Mirror

The problem with this circuit is that the current in the two halves is different - the mirrored current is too low, differing by 19 uA (it is actually 20 uA, but the simulator's accuracy is not great enough to show this). If we check, we will find that the emitter currents of both transistors are identical, so the 20 uA that "disappeared" is the base current that must be supplied to each transistor (10 uA each).

Adding emitter resistors does absolutely nothing to alleviate this, but is useful if the transistors

are not matched. Even then the resistors do not really do a lot of good, unless the voltage developed across them is significant (at least 100 mV, and preferably more) but it helps a little bit.

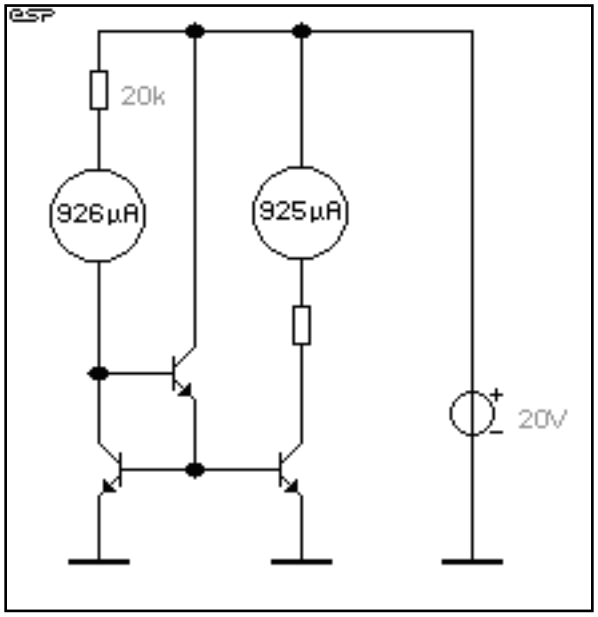

Figure 11 - Buffered Current Mirror

A better solution is to use a buffer as shown in Figure 11. This removes the base current component of the error, and makes the current mirror matching a lot better. This simple addition has reduced the error dramatically, and now all we have to do is find a use for the circuit.

Differential Pair Amplifier

Consider the differential pair (aka long tailed pair or LTP). Most of the time, we are losing half the gain of the circuit, since the output is taken from only one collector as shown in Figure 12. This configuration also suffers from linearity problems, unless the output is current only - as is the case when driving the base of a transistor (this is shown below).

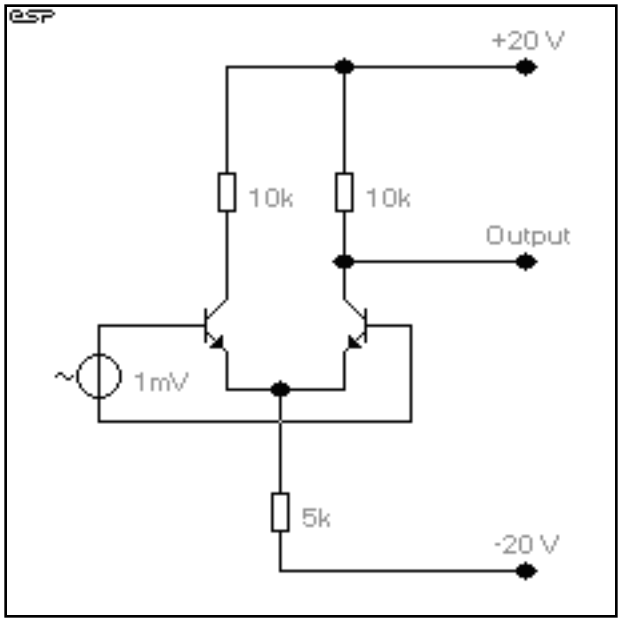

Figure 12 - The Long Tailed Pair As A Voltage Amplifier

The circuit as shown (without the essential biasing components, which were omitted for clarity) has a voltage gain of 315 (again using transistors with a Hfe of 100), and is quite linear at low output voltages. The linearity will suffer badly as the level increases, and even with the +/-20 volt supplies used is not satisfactory as a voltage amp for outputs greater than about 1.5 Volts RMS (this is at an input voltage of 5 mV).

Using a current source / sink in the "tail" is very common in amplifier circuits, and this variant is shown below. It is commonly (but entirely mistakenly) assumed that this increases the gain, but the real purpose is to improve the common mode capability of the circuit. Common mode signals are those that are applied to both inputs in the same polarity, and are generally required to be rejected. Using a simple resistive tail severely limits the common mode voltage that can be accommodated before severe distortion occurs, and indeed renders the common mode rejection of the circuit almost useless.

In the example above, the common mode rejection is only 1.8 dB but with a current sink tail the rejection is so good that the simulator cannot measure it. In reality this will rarely be the case, but in most amplifier circuits common mode signals (of the undesirable kind) are not an issue if the input stage is properly designed.

If a current mirror is used as the load, gain is increased by a very useful amount, and Figure 13 shows the arrangement used. The stage gain is now over 2,000 and the use of a current sink as the tail has only a marginal effect (provided that the current is maintained at 4 mA). This circuit is shown in Figure 13, and although useful in certain applications, it is not suitable to drive the output stage of a power amplifier.

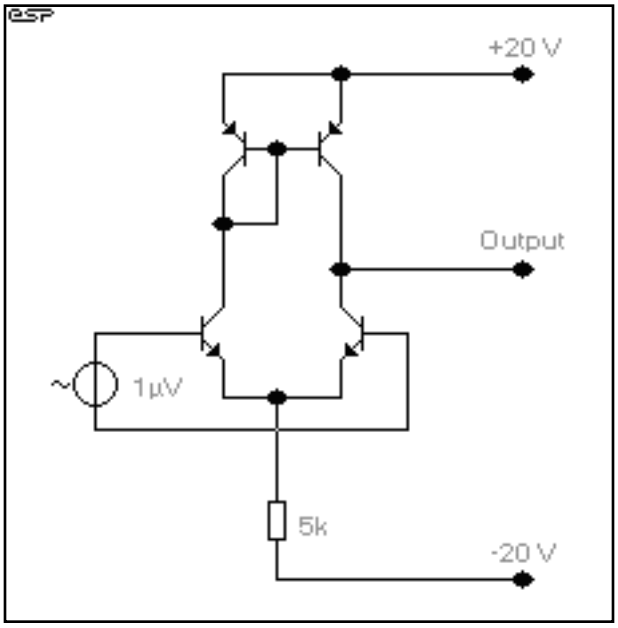

Figure 13 - Using A Current Mirror The LTP Load

If we really wanted to get silly (and I have seen it done), we can put all the bits together in one place, and finish up with an input stage + Class-A driver, with a total gain of a little over 400,000 (based on 100k feedback loading). This will increase dramatically when the output is buffered, but because of the extremely high impedance, suffers when loaded even with 100k. The buffered current mirror does not help the gain, but reduces output offset. The complete circuit is shown in Figure 14, and is a useful example of the techniques discussed in this article.

As we discovered earlier, extremely high output impedance is not a bad thing for this type of application, because the gain can be kept to a manageable level, but still have the necessary reserve to overcome output stage non-linearity before the application of global feedback.

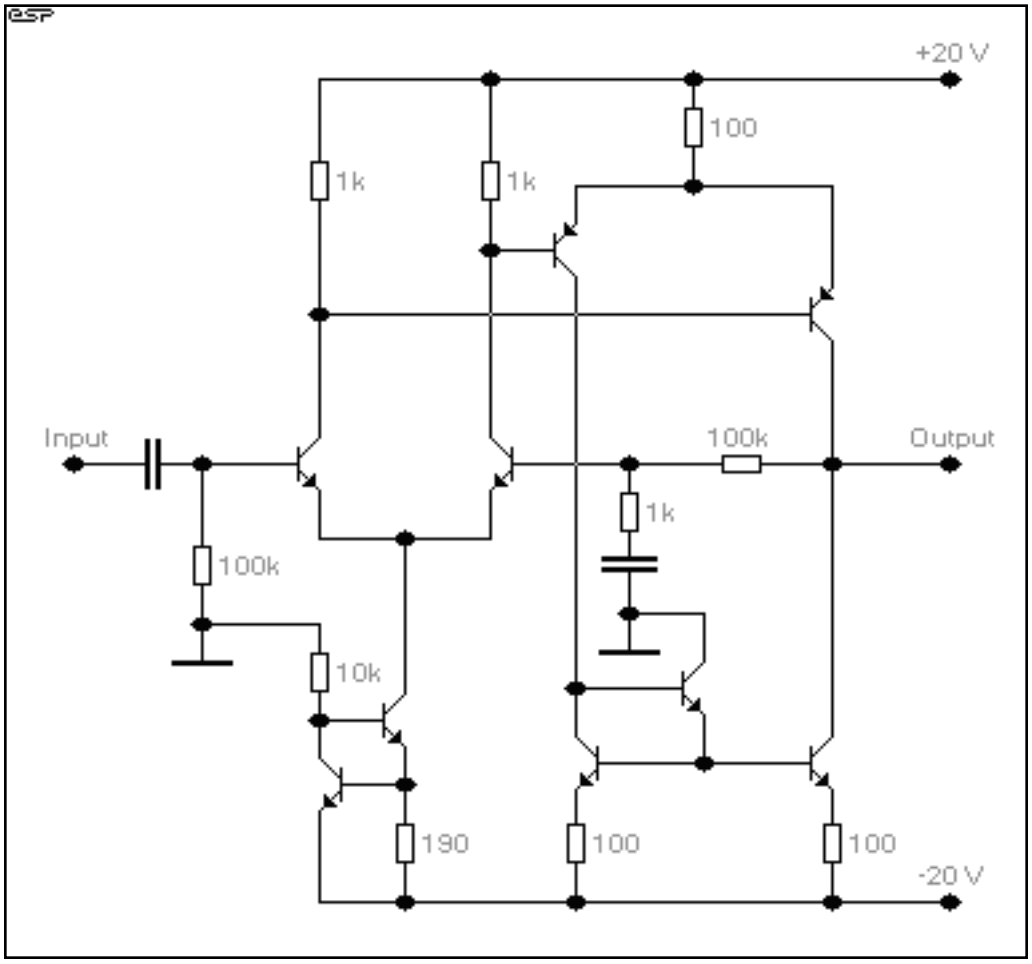

Figure 14 - Combination LTPs and Current Mirror

This circuit uses an input LTP that drives a secondary LTP as the Class-A amplification stage. The load for this second LTP is a current mirror, and this arrangement has excellent linearity. I suspect that it could be a cow to stabilise in a real amplifier circuit, and quite frankly, I do not see any reason to go this far. One amplifier I have seen using this arrangement was a MOSFET type, and given the inherent non-linearities of MOSFETs the additional gain is useful. Initial measurements on the MOSFET amp show that stability is not as good as I would like to see (there are traces of oscillation at some output levels), but overall stability seems to be acceptable. I expect that the wide bandwith of the MOSFET output devices might make this arrangement a little more tractable than would be the case with bipolar transistors.

Conclusion

At this stage, I suspect that I have either cleared up some degree of confusion, or created even more. There are so may choices, and so many reasons to use (or not use) any one of them. This article is meant only to describe and explain - you can see where my own preferences lie from the circuits published in the projects pages. I happen to be a strong supporter of the KIS principle (keep it simple), and in my own designs have not found it necessary to make the circuit any more complex than is needed to make it work and provide

good distortion figures. Listening tests bear this out, and IMHO I do not believe that the difference between a highly complex amp and a simple one (provided that both are well designed) is audible under any listening condition.

This being the case, I cannot think of any good reason to go for the complex solution, especially since it will almost certainly be much harder to stabilise (I happen to think that this is extremely important), and will use more parts. Granted that the additional cost is minimal in the greater scheme of things, but sound for sound, simple and reliable has to win out.

As a final point, with the LTP configuration and current mirrors, it is often beneficial to match the transistors, so they have gains that are approximately equal, and emitter-base voltages that are as closely matched as possible. It is also useful with both of these configurations and two transistor current sources to thermally bond the two transistors to prevent mismatch due to thermal effects.

Remember that the emitter-base voltage of a transistor falls at a rate of 2mV per degree Celcius, so even a small temperature difference will change the DC offset performance quite dramatically.

For more information on the design of amplifier stages, please refer to the Amplifier Design page.

1 - Introduction

This article is essential reading for anyone who uses heatsinks in audio, and the same principles apply for power control, RF and CPU cooling, as well as many other applications in electronics. There are many misunderstandings and misconceptions about transistor mounting. What are the essential requirements? Which things make the biggest difference? These questions may not have occurred to many readers, but they are very important to ensure the long term reliability of your projects.

Please ... read all of this article - not just the bit you think you need. You would be surprised how much I learned while researching and writing this material, and I have had a lot of additional information supplied by readers (you know who you are, and thank you for your input). The material here is the result of a lot of hard work, research, personal experience and (what should be) common knowledge.

The design of heatsinks, or to be more exact for most builders, the selection of a suitable heatsink, is not difficult once the basics have been mastered. Terms such as 'thermal resistance' and 'degrees C / Watt' are a little daunting for the uninitiated, and the purpose of this article is to explain how thermal transfer works, from the transistor die until it is finally dispersed into the atmosphere.

This sort of information seems to be unusually difficult to obtain, either on the web or elsewhere, and I have had great difficulty in getting thermal resistance data from anywhere - although as you shall see as you read on, I have managed it. Not that this article is the "last word" on heatsinks - far from it, but it is a collection of some of the most useful information I have been able to gather thus far.

Note that in this article, the 'transistor' can be a bipolar, MOSFET, TRIAC, CPU or any other semiconductor device (including diodes or ICs of all kinds) that is mounted in a case which must then be mounted on a heatsink of some description.

The reliability and longevity of any semiconductor device is (roughly) inversely proportional to the square of the junction temperature change. Thus halving the junction temperature will result in approximately 4 times the expected life of the component. The converse is also true! A worthwhile increase in reliability and component life can be achieved by a relatively small reduction in operating temperature, since these parameters increase exponentially as temperature is reduced.

The whole process of removing heat from a transistor's active area (the die or 'junction') involves many separate thermal transfers, and we shall examine each in turn. In order to see a meaningful result, we need a heat input value and an ambient air temperature. From these two basic elements, the entire heat flow can be established.

Towards this end, an electrical analogue may be drawn, showing the thermal generator as a current source, thermal resistance as a resistor and the thermal inertia (or transient capacity) of the various materials as a capacitor. The transient capacity is the ability of any material to absorb a quantity of heat for a short time, after which its temperature will rise in the same way as the voltage rises in a capacitor if the supply current is maintained.

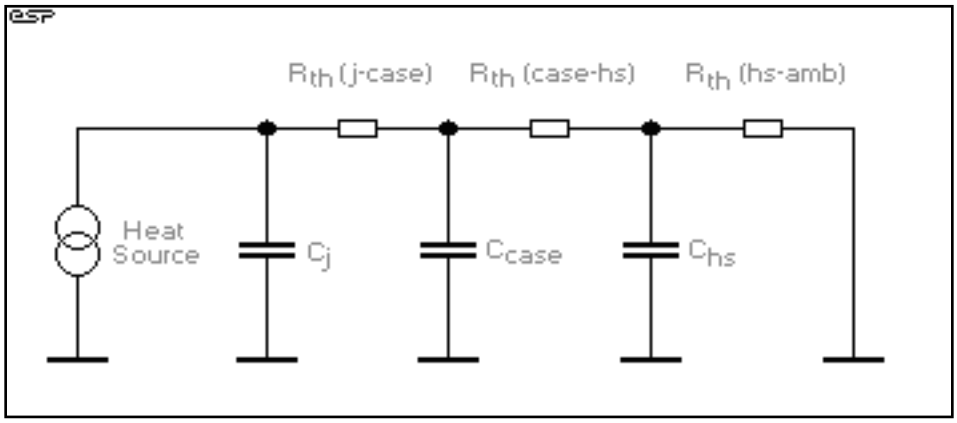

Figure 1 - Heat Flow From Generator To Ambient

From Figure 1, we can see the thermal resistance (Rth) from junction to case, the thermal inertia of the junction (this is very small), the thermal inertia of the case itself (again, not large), the thermal resistance from the case to the heatsink, thermal inertia of the heatsink (this might be very large) and finally the thermal resistance from the heatsink to ambient.

The small thermal inertia values should be ignored, as they will heat up very rapidly, and

the heatsink itself will only absorb so much heat. A state of equilibrium is required where the heat input equals the heat output, but without the junction temperature reaching a dangerous level - even momentarily.

---

2 - Types of Heatsinks

Heat sinks can be classified in terms of manufacturing methods and their final form shapes. The most common types of air-cooled heat sinks include:

- **Stampings** Copper or aluminium sheet metals are stamped into desired shapes. They are used in traditional air cooling of electronic components and offer a low cost solution to low density thermal problems. They are suitable for high volume production, because advanced tooling with high speed stamping lowers costs. Additional labour-saving options, such as clips and dry interface materials, can be factory applied to help to reduce the board assembly costs.
- **Extrusions** These are by far the most common for power amplifiers, and allow the formation of elaborate two-dimensional shapes capable of dissipating large heat loads. They may be cut, machined, and options added. Cross-cutting will produce omni-directional, rectangular pin fin heat sinks, and incorporating serrated fins improves the performance by approximately 10 to 20%. Extrusion limits, such as the fin height-to-gap ratio and fin thickness, usually dictate the flexibility in design options. Typical fin height-to-gap aspect ratio of up to 6:1 and a minimum fin thickness of about 1.3mm are attainable with standard extrusion processes.
- **Bonded / Fabricated Fins** Most air cooled heat sinks are convection limited, and the overall thermal performance of an air cooled heat sink can often be improved significantly if more surface area can be exposed to the air stream. Such high performance heat sinks utilise thermally conductive aluminium-filled epoxy to bond planar fins onto a grooved extrusion base plate. This process allows for a much greater fin height-to-gap aspect ratio of 20 to 40, greatly increasing the cooling capacity without increasing volume requirements.
- **Castings** Sand, lost core and die casting processes are available with or without vacuum assistance, in aluminium or (less frequently for audio applications) copper/ bronze. This technology is used in high density pin fin heat sinks which provide maximum performance when using forced air cooling.
- **Folded Fins** Corrugated sheet metal - either aluminium or copper, increases surface area and, hence the volumetric performance. The heat sink is then attached to either a base plate or directly to the heating surface via epoxying or brazing. It is not suitable for high profile heat sinks, but it allows high performance

heat sinks to be fabricated for specific applications.

---

3 - Sample Calculations

Let us assume that the heat generated in the transistor die is 50W, such as might be the case with a Class-A power amplifier operating from a +/-25V supply, and drawing 2A quiescent current. Only half the total supply voltage of 50V is across the transistor in the quiescent or no signal state when the output is at zero volts, so each of the transistors in the output stage will have a voltage of 25V at 2A, or 50W dissipation.

An ambient temperature of 25°C is a good starting point, and provides a safety margin for most domestic systems, although as we shall see later on, it is important to design for worst case if reliability is to be maintained.

The primary aim of the heatsink designer is to ensure that the total thermal resistance is kept to the minimum possible value, and the entire design process looks at thermal resistance as the primary item to be calculated. Only after this has been determined can the actual temperature of the transistor junction be predicted.

To some extent, this article was prompted by a reader of my pages, who complained that transistors in an amp he built ran very hot (mounted on a bracket), while others seemed to run fairly cool. So I got to thinking, didn't I?

How to actually mount transistors does not seem to have achieved much coverage on the web, but I have seen some absolute drivel spouted by PC types talking about heatsinking Pentium processors - the same principles apply, but the amount of heat and thermal dynamics are a little different.

Throughout this article I will often refer to "aluminium", which in this context means aluminium alloy. Pure aluminium is rarely used, since it is too soft and easily distorted. It is also quite difficult to drill and tap for mounting screws, because it tends to clog the flutes on the drill bit, and will even snap the drill if great care is not taken.

When drilling aluminium (or any of its alloys), the use of methylated spirit (denatured alcohol) or WD40 (or other similar 'water displacement' spray) as a lubricant is recommended. This trick is not well known, but is very effective.

Be warned that 'metho' (as it is commonly known in Australia) is highly flammable, and burns with an almost invisible - but very hot - flame. Extreme care is required, and use only enough to keep the drill bit wet - the last thing we need is one of my readers burning down the house while drilling a heatsink. Needless to say, I can accept no responsibility for any accident caused by the use of this technique.

On the positive side, metho evaporates quickly and leaves no residue. This also means that spontaneous combustion is far less likely than with any oily lubricant. You should *never* just drop oily rags in the dustbin, as it is quite possible for them to burst into flame for no apparent reason.

---

4 - Measuring Heatsink Thermal Resistance

The most accurate way to determine the thermal resistance of an unknown heatsink is to measure it. The exercise is not trivial though, since you will require a large metal clad resistor having a good flat bottom surface (or you can use transistors), a contact thermometer (a conventional alcohol in glass thermometer cannot be used), and a suitable low voltage, high current power supply. If you have a large number of heatsinks to test it may be worthwhile to build a dedicated test unit, however this is unlikely for most home constructors.

It is important that the heatsink under test is set up as closely as possible to the way it will be used. There is no point testing a sink just lying on the workbench (for example), as the results will be way off. If a heavy chassis is planned, then attach the heatsink to the chassis or a reasonable facsimile thereof. Ensure that the heating system is in the best possible thermal contact with the heatsink. Thermal compound is essential, and do not use any insulators.

The test is based on knowing the voltage and current you apply to the heatsink heating system (resistor(s) or transistors), and being able to accurately measure the ambient and heatsink temperatures. First, apply a relatively low power to the heater system of your choice, and wait for the heatsink temperature to stabilise - this could take an hour or more. If the heatsink is too hot or too cold the results will be inaccurate, so slowly (in steps) increase power until the heatsink is at approximately the maximum temperature you feel is reasonable (typically around 50-60°C).

Measure the ambient temperature and the heatsink temperature, preferably using the

same thermometer. A contact thermometer is essential for the heatsink (again, use thermal compound). Determine the temperature difference (temperature rise) between ambient and heatsink.

Next, determine the power applied to your heating system. Thermal resistance may now be established with some very simple maths ...

You will use the following terms -

Tr - Temperature rise
Ta - Ambient temperature (example 22°C)
Th - Heatsink temperature (example 54°C)
Vh - Voltage to heater (example 12V)
Ih - Current to heater (example 3.5A)
Ph - Power applied to heatsink
Rth - Thermal resistance (in °C/W) so ...

Tr = Th - Ta= 54 - 22 = 32°C
Ph = Vh * Ih= 12 * 3.5 = 42W
Rth = Tr / Ph= 32 / 42 = 0.76°C/W

This is as accurate as you need, and as good as you'll get in real life. To get accurate results is time-consuming, and is usually not necessary once you get a reasonable feel for heatsinks. Once you do this a couple of times you will be able to 'guesstimate' the approximate power handling capacity of a heatsink just by looking at it and checking the manufacturer's data. Bear in mind that few heatsink manufacturers supply the all important temperature rise information, so their figures can be off by 25% in either direction.

Thanks to "Scorpion" on the ESP forum for the idea

---

5 - Transistor Case Styles

There is a vast number of different case styles available. I shall only deal with the most common (as shown below), but the information is equally valid for other case styles. In many cases, an educated guess will be needed to determine case to heatsink thermal resistance if the case used by your device is wildly different from those quoted. Generally, this is based on surface area and the evenness (or otherwise) of pressure distribution directly beneath the internal silicon die. This is a wildly variable quantity, and has been known to cause may a constructor grief, not realising the importance of evenly distributed pressure.

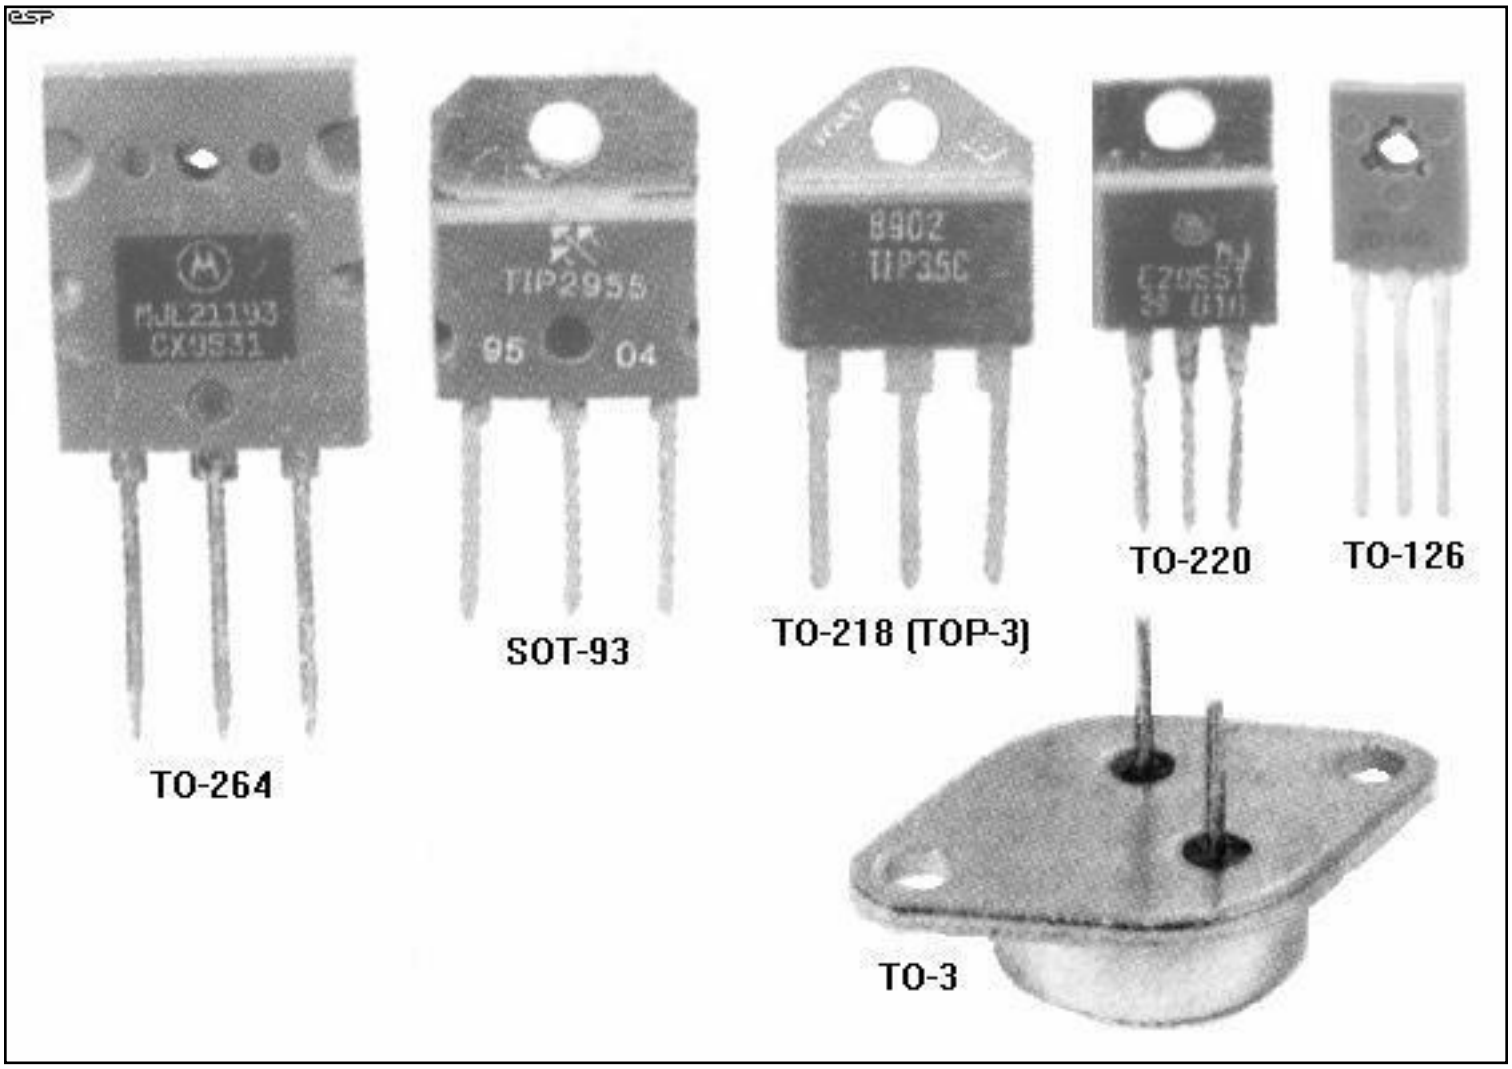

Figure 2 - Common Case Styles

This is only a sample of those currently available (including ICs of various types), but is representative of the most common for transistors, MOSFETs and the like. In most cases, the die can be assumed to be roughly in the middle of the plastic moulding for all plastic encapsulated devices. In the TO-3 package, it is located in the geometric centre of the package (more or less).

---

6 - Junction to Case Thermal Resistance

Although this is always an important consideration, there is nothing the amplifier designer can do to reduce this for any given transistor. Manufacturer's data will sometimes quote this figure, but it is more common to refer to the device case temperature - this is easier to deal with, since the data sheets have already taken die to case thermal resistance into consideration when the temperature derating graph was produced.

Derating is commonly applied to semiconductor devices, and typically the maximum power dissipation claimed for most devices will be at or below 25 degrees C. At any temperature above this, less power is available from the transistor with increasing temperature, until at some figure (typically around 150°) the permissible power dissipation is zero.

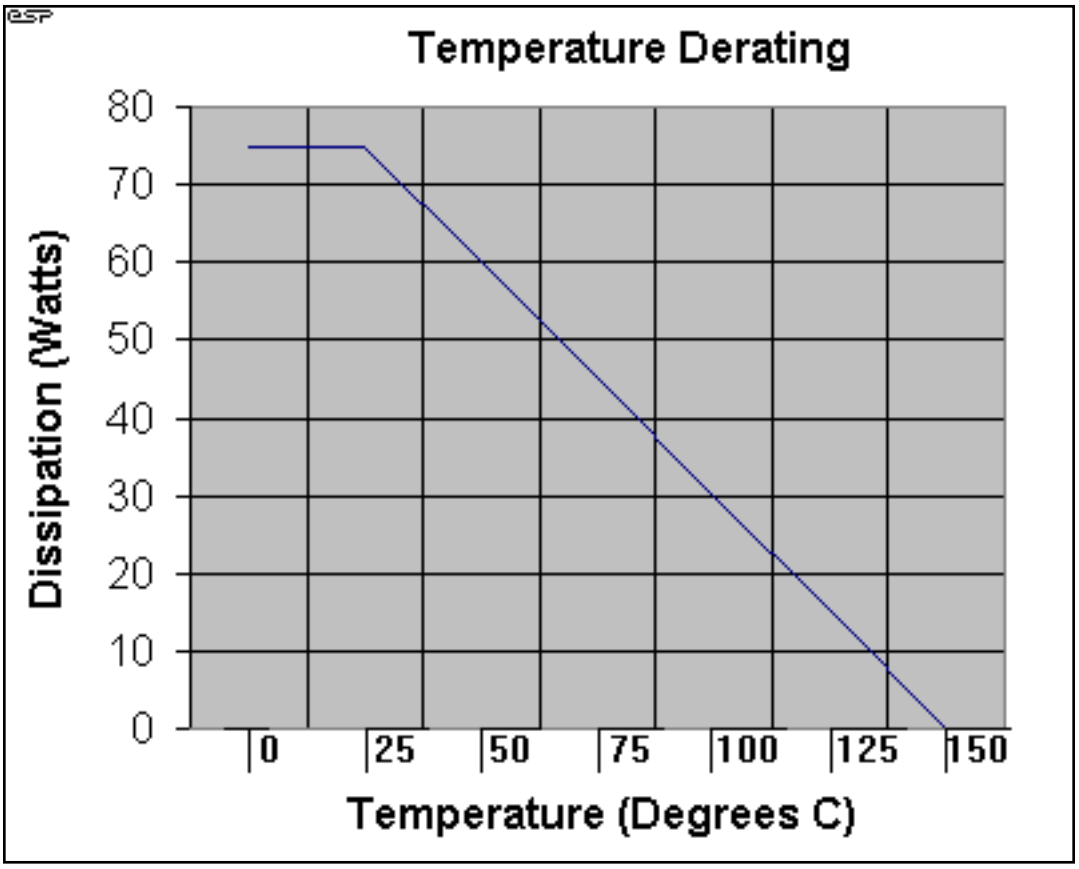

Figure 3 - Case Temperature Derating For MJE3055

Figure 3 shows the case temperature derating curve for an MJE3055 (TO-220) power transistor as an example. As can be seen, at 25 degrees and below, the device is rated at 75W dissipation, but at 100 degrees, 30W is the maximum permissible. At 150 degrees, no power may be dissipated at all.

This device has a 1.67°C thermal resistance from junction (die) to case (Motorola specification sheet for the MJE2955/3055), so the actual junction temperature will be somewhat higher than the case temperature until 150 degrees, at which no power may be dissipated, so case and junction will be at the same temperature.

Our first calculation shall be to see what the junction temperature will be at 75W device dissipation, with the case at 25 degrees (Celsius):

Thermal resistance = 1.67
Power = 75W
Therefore junction temperature rise = 1.67 x 75 = 125 degrees

If the junction is 125 degrees above ambient (25 degrees) then the total is 125 + 25 = 150°. This is a seriously high temperature, and if you were to do the same calculation for all the temperatures on the scale above you will quickly see that the junction temperature is 150° at maximum dissipation for any given case temperature. The thermal derating curve simply limits the allowed power dissipation to ensure that the junction never operates at above 150 degrees.

The information above is obtainable from all device manufacturers, and is essential reading to ensure that transistors are not damaged by excess temperature. The maximum quoted temperature should never be exceeded, as the device will have a considerably lower life expectancy if overheated. Instantaneous failure is not uncommon if a device at an already elevated temperature is called upon to suddenly do some work.

Using our theoretical amplifier above, we know that the dissipation will be 50W per transistor (or a total of 100W), and from the derating curve we see that for this power, the maximum case temperature is 65° C. The goal of this exercise is to determine the size of heatsink needed to ensure that the transistors ratings are not exceeded. We can also see if it is possible to operate them at a lower temperature, thus prolonging their operating life.

The junction to case thermal resistance varies widely, but will rarely be less than about 0.5 degrees C/W, depending (of course) on the manufacturer, the case style, and the type of device. A few examples:

- IRF540 MOSFET - 1.0°C/W
- MJL21193/4 BJT - 0.7°C/W
- MJE3055/2955 BJT - 1.67°C/W (our demonstration model)

Also remember that in use, the base-emitter voltage of transistors falls at 2mV / degree C, and leakage current increases exponentially (leakage current doubles for every 8 to 10 degree C increase in temperature). These are two very good reasons to try to keep the operating temperature as low as possible.

---

7 - Case to Heatsink Thermal Resistance

This is where the whole process often falls down, since semiconductor devices are nearly always electrically insulated from the heatsink. This means that some material (typically mica or Kapton - the latter is sadly hard to get now for some reason) must be used between the case of the device and the heatsink surface. This will invariably increase the thermal resistance - there is no known material which is a perfect electrical insulator and thermal conductor. Sad but true.

There are actually a number of alternatives for electrically insulating the transistor from the heatsink while still allowing heat transfer. Two were mentioned above, but there are others too. The basic list:

Material	Thermal	Electrical	Thermal Resistance	Other Properties
mica	Good	Excellent	~ 0.75 - 1.0	Fragile
Kapton	Good	Excellent	~ 0.9 - 1.5	Very robust
aluminium oxide	Excellent	Fair	~ 0.4	Fragile - easily damaged
beryllia (beryllium oxide)	Excellent	Excellent	~ 0.25	Toxic
Sil-Pads	Fair +	Excellent	~ 1.0 - 1.5	Convenient

Table 1 - Thermal Resistance of Various Mounting Methods (TO-220 Case)

The above table shows the approximate thermal resistance for various materials, and (except for the Sil-Pads) assumes that a good quality thermal compound has been used. Despite the claims made by some manufacturers, most thermal compounds are much of a muchness, since their primary purpose is to exclude air from the mating surfaces, and provide a modicum of heat transfer themselves. Air is a most excellent thermal insulator, and even the tiny air gaps that exist between the transistor case, insulating washer and the heatsink will increase thermal resistance dramatically.

Mica is probably the most commonly used insulator, but it has limitations. The worst of these is quality control, which results in mica washers being whatever thickness they happen to be (i.e. unpredictable). With infinite care and patience it is possible to shave mica down to a thickness of perhaps 0.05mm (0.002"), but few of have the time to fiddle about at this level. A micrometer is essential if you really want to do this. See the section on mica (below) for more information on this topic.

Kapton is an excellent material in this respect. Predictable thickness and very tough (try ripping one of these guys apart), but generally not quite as good as mica thermally. For reasons which remain entirely obscure, Kapton transistor washers do not seem to be as

readily available as they once were, which I find a real shame since they have always been a favourite of mine. However, Kapton tape can be made into very acceptable washers with a pair of scissors and a hole punch.

Aluminium oxide (anodised aluminium or 'anodized aluminum' if that makes you feel better) is an excellent electrical insulator, and provides very good heat transfer, but is fragile and easily damaged. Even a small scratch will generally allow an electrical short circuit, and obtaining a consistently thick (relatively speaking) layer of oxide is difficult in the extreme in mass produced heatsink extrusions. Anodised aluminium washers are available from some electronics suppliers, but are generally expensive and you will probably find that they are not available for all transistor case styles.

Beryllium oxide was quite popular a few years ago, until someone discovered that it is toxic. Consequently, such mounting washers have vanished (at least as far as the DIY fraternity is concerned). A pity, since most people I know have never eaten a transistor washer in their lives, but governments do so like to protect us from ourselves. In fact, it is inhalation of the beryllium oxide dust that causes problems (respiratory disease) rather than ingestion, and it turns out that they are still available, as are many other parts made from this unique and versatile ceramic. Because it *is* toxic, special precautions are needed during manufacture, and this makes it rather expensive.

> Thanks to Robert K. for providing me with some additional info on beryllium oxide and its continued use.

Sil-Pads are only comparatively recent additions to the mounting hardware options, and are very convenient to use. The down side is that they are not as good (thermally) as mica or Kapton, but they require no silicone grease or other thermal compound. There has been some comment made about the re-usability of Sil-Pads, with the claim being made (I do not remember by whom) that the deformations caused by prolonged heat and pressure will cause increased thermal resistance if they are re-used.

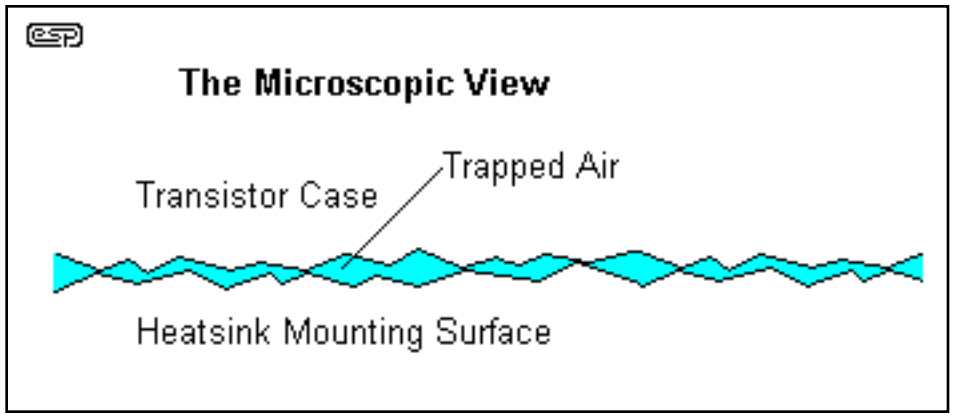
I have tested and verified this, and it makes perfect sense, since the thickness of the pad will not be even after it has been used, due to uneven pressure and mating surfaces (at a microscopic level). Even if the new device is located in exactly the same place on the pad, thermal resistance will be impaired. I suggest that Sil-Pads be used where maximum thermal conductivity is relatively unimportant, as their thermal resistance is generally not as low as claimed. The figure shown in Table 2 for the TO-3 and TOP-3 case styles is (IMHO) highly optimistic, and is unlikely to be achieved in practice.

Package	Direct Contact (Dry)	Direct Contact + Thermal Compound	Mica Insulator + Thermal Compound	Sil-Pad™
TO-3	0.5 - 0.7	0.3 - 0.5	0.4 - 0.6	0.4
TOP-3 (est)	0.8 - 1.1	0.5 - 0.7	0.6 - 0.9	0.65
TO-126	1.5 - 2.0	0.9 - 1.2	1.2 - 1.7	NA
TO-220	1.1 - 1.3	0.9 - 1.1	1.0 - 1.6	1.5

Table 2 - Comparison of Case Types

The information in Table 2 shows the variations expected with various transistor cases and mounting techniques. It should come as no surprise that these figures are different from those in Table 1, since this info is from a different source. I prefer to err on the side of caution when it comes to thermal resistance, because it is always better to have the devices run a little bit too cool than a lot too hot. I would suggest that Table 1 is more realistic (if not all that accurate).

The TOP-3 (TO-3 Plastic) package will have a case to heatsink thermal resistance (estimated) at about 1/2 way between TO-3 and TO-220 packages. I could find no information on this package for the above table, and the estimate is mine.



The importance of a thermal compound cannot be overstated. The drawing shows the surface of the transistor and heatsink (or mica washer) at a microscopic level. OK, so I just drew it, but this is exactly what you would see under a powerful microscope. The blue area represents air, and the surfaces only touch in a few places. This is why the thermal resistance is so much higher without the use of any thermal compound.

In some cases the situation is worse - I wonder how many readers have come across (especially) TO-220 transistors that look as if they had been machined with a chainsaw. A flat file, or fine wet/dry abrasive paper and water (no, it won't hurt the transistor) should be used to make sure that the surface is as flat and smooth as you can make it.

Never hold the transistor in a vice and file it! Hold the file still, and gently slide the

transistor on the file (or wet/dry paper on a sheet of glass) until it is smooth. There is no point having it nice and smooth if it is rounded - this *will* happen if you rigidly mount the transistor and hand-hold the file.

When you are finished, you should be able to lay the transistor on the heatsink and see no light between the two surfaces. This little bit of extra effort may mean the difference between the success or failure of your project - at least in the long term.

---

8 - Mica

What is Mica? Mica is transparent, and can be split into a very thin film along its cleavage. Electrically, it has the unique combination of high dielectric strength, endurance, uniform dielectric constant, low dielectric loss (or high Q), and extremely good insulating properties. Mica is moisture-proof and has low heat conductivity. It is infusible and may be exposed to high temperatures (in excess of 700°C) without any noticeable effect. If you want more info - try a web search :-)

So much for the descriptions, but why would mica get a section all of its own? Simply because the quality control is virtually non-existent (from what I have seen lately). The overall shape is fine, but the thickness is generally too great - commonly by a huge margin. I have used mica washers that were so thick that I was able to separate them with a (very) sharp knife, and obtained four washers for the price of one (plus some scrap from the splitting operation).

Splitting a mica washer is not hard, but requires a steady hand, a good magnifier, and the sharpest knife you can find (or a new razor blade). The thickness should ideally be in the order of 0.025 to 0.05 mm for normal use, but you will probably find that up to 0.1 mm is quite acceptable. It is possible to make it much thinner than this, which decreases thermal resistance but makes the washer fragile and easily damaged.

The electrical characteristics of mica are such that even the thinnest possible washer will be more than adequate for typical amplifier voltages. The dielectric strength allows mica to withstand 1,000 - 1,500 volts per mil (1/1000 inch), or about 0.025 mm (25 micrometres) of thickness without puncturing or arcing.

This being the case, I am unsure why commercially available transistor washers are anything up to 0.25mm thick (and no, I am not kidding - I have even found some thicker than that!). This is capable of withstanding over 10kV in theory, let alone a measly 200V or so, and will introduce considerable thermal resistance. If one had a steady enough

hand, just one of these would yield 10 washers of acceptable thickness (thinness?), with each still capable of at least 1kV insulation breakdown.

I am even tempted to make a mica splitter, that can be adjusted to a suitable thickness. One of these days ...

---

9 - Thermal Compounds

One of the most common mistakes made by hobby electronics enthusiasts (and quite a few professionals too), is to assume that if a little thermal compound is good, a lot must be better. Absolutely not so! The amount of thermal compound should be exactly that amount which ensures that an air-free join is made between the mating surfaces. If too much is applied it will cause an increase in thermal resistance, since it is not really that good at conducting heat. Generally speaking, any electrical insulator is also a thermal insulator, so the thinner the final composite insulation - including thermal "grease" - the better.

Having said that, one must ensure that the electrical insulation is sufficient for the applied voltage or disaster will surely follow - usually in a spectacular fashion - especially if high voltages or currents are available.

A quick note on the application of thermal compounds is in order. This is the method I generally use, and it works very well once you have a copious supply of workshop rags to clean the mess from your fingers.

Apply a small quantity of the thermal compound to one finger, then gently rub with your thumb to create an approximately even coating on finger and thumb. Now rub the thermal compound onto a washer, held between thumb and finger, ensuring that the coating is just thick enough to be opaque, but thin (and even) enough to ensure that the contact will be absolute on both surfaces (transistor and heatsink). Test your skill until with moderate pressure, you can leave a perfectly formed outline of the transistor, with no blobs or gaps, on the heatsink surface.

---

10 - Thermal Inertia

Since any heatsink has some mass, it will also posses thermal inertia, which is to say that it takes time for the body of heatsink material to heat up. Naturally, the larger the heatsink (and the more aluminium it has in it), the longer it will take to heat. This can

easily lead one to believe that the heatsink is large enough for the job, but only by running an amp for an extended period will the truth reveal itself.

Thermal inertia is a good thing, because it allows the heatsink to absorb transient power "surges", and will dissipate the heat again during low power operation. Because of the dynamics of music, this tends to work well, but for professional use (where heavy compression is often used), the average power into the heatsink can be very high for prolonged periods, so either massive bulk material must be used, or a combination of reasonable bulk and lots of surface area. Fan cooling is almost mandatory for professional use at high continuous power levels.

Even if one were to obtain an infinitely large block of aluminium, if a bracket or other mounting arrangement directly underneath the heat source (the transistors) is not thick enough, it will have significant thermal resistance, and the transistors may just overheat anyway, so we do need to look at all the resistances in the thermal circuit, not just the heatsink itself.

It is not uncommon to have transistors operating at well in excess of their ratings, but a casual "finger" test of temperature on the surface of the heatsink will appear to indicate that all is well.

---

11 - Minimising Thermal Resistance

The key to obtaining maximum power from any transistor is minimising the thermal resistance from junction to free air, and as can be seen from the above information, one of the worst offenders is the transistor itself.

11.1 - Mounting The Transistors

The most common way to mount the transistors is to use metal thread screws, either with nuts on the back of the heatsink, or with a thread tapped into the heatsink itself. In production environments, spring clips are often used, and even rivets are sometimes used for mounting. The latter is a *very* bad idea, as the following tale describes ...

> Transistors, especially the TO-220 are sensitive to mechanical shocks. The T0-220 for example should never be attached to its heatsink by means of a rivet, either conventional or pop rivet. I was building replacement voltage regulators for a large automotive manufacturer, where the original device was riveted to a metal base with a mica insulator in between. Our version of this worked okay for a while until one day the manufacturing setup guy over adjusted the rivet force

> and the was some deformation of the tab. The parts kept passing the 100% electrical test and the manufacturing group kept making them over my objections. This too worked okay for awhile until we started getting field failures. When we investigated, we found that the power Darlingtons inside were suffering "earthquake" damage due primarily to the shock of the rivet machine. Often it was the outer edges of the device that would crack, leaving the device functioning but affecting V_{ce} Sat. With the higher saturation voltages (not measured on our tester of the time) the devices overheated and failed.
>
> It took 7 tractor trailer loads to haul all of the inventory back from our warehouse. We had to rework over 100K voltage regulators.
>
> Having seen the problem once, you would be amazed at how often I have seen it since. One guy was using a pop rivet gun. There was no damage to the tab but the shock from the pop of the rivet sent its message through the tab to the silicon. I saw another guy who was cutting the tab off the device in order to package it in the available space. I saw a piece of home brew equipment where the tab was being held by a nut and bolt that had been over tightened distorting the tab. Your comment about not holding the device in a vice and not filing on it with a hand file basically speak to the same issue: Silicon is thin and brittle. Do not alter the package or subject it to shock

My thanks to Mike for that story. I have seen transistors riveted to heatsinks as well, but that was many years ago, and I don't know if it caused any problems. The main issue is that riveting is at best unpredictable, and also creates considerable shock when the mandrel breaks (for pop rivets at least).

The key to mounting is pressure - it must be just right. Too much, and you distort the device case and possibly damage the thread or cause protrusions in the soft aluminium heatsink. Too little, and the thermal resistance will be too high. High reliability applications (Mil-Spec) will demand that a torque driver is used, to ensure that every device is tightened to exactly the right pressure. I don't suggest for an instant that this is needed in your project (torque drivers tend to be rather expensive), but it is essential that you develop a feel for tightening the screws to get consistent and reliable results.

Once the transistor mounting technique is perfected, we can generally assume that the thermal resistance will be about 1° C/W. This may be bettered, but again, a safety margin is always useful. At a continuous dissipation of 50W, this means a temperature rise of 50° C due to mounting and insulation requirements. Since we already worked out from the derating graph that the absolute maximum case temperature is 65° for 50W dissipation, we are faced with a problem - the maximum heatsink temperature is only 15° C. If this were to be the (somewhat chilly) ambient temperature, a 0° C/W heatsink is needed!

Perhaps I have been looking in the wrong places, but I have not been able to find a heatsink which can manage 0° C/W, and if the ambient temperature were to rise to (say) 20° , the heatsink now needs a negative thermal resistance - this is called a heat pump, and the most common example is an air conditioner or refrigerator. This approach, although quite feasible, can become somewhat expensive. Peltier devices (hot/cold junction semiconductors) can be used, but tend to be expensive, and require a fairly heavy current. In order for the cold junction to work at a suitably low temperature, the maximum temperature of the hot junction must be kept as low as possible - this requires (only one guess!) ... a heatsink.

For the above example, because there must always be a thermal gradient (temperature difference) to allow heat to flow from one device to another, this means that ambient temperature must be -10° C to be able to use a 0.5° C/W heatsink! We have just designed an impossible output stage, which cannot be made to work in real life without considerable additional cost.

11.2 - Further Reductions of Thermal Resistance

It is generally far cheaper to reduce the thermal resistance of the devices and their mountings than it is to use the largest heatsink you can possibly find, or go to all the bother of water cooling (which works extremely well, but is difficult to implement in the listening room), or using fans which are noisy and spoil the signal to noise ratio of your equipment. There is no point ensuring that the S/N ratio is 100dB or more, only to have a background noise of perhaps 55dB SPL created by cooling fans. Remember that even if the heatsink stays at ambient temperature (an infinite amount of air will be needed :-), from the above example, the absolute maximum ambient temperature is 15° C.

One technique used to reduce thermal resistance is simple - use two (or more) transistors in parallel in place of a single device. Although the thermal resistances for each of the transistors remain the same, the resultant thermal resistances for a "parallel pair" are effectively halved. This is due to the fact that each transistor is only dissipating half the total power.

Heatsink calculations for the parallel pair are best carried out by considering each transistor individually. In this example, each transistor of a parallel pair has a power dissipation of 25W.

From Figure 3, the maximum case temperature must not exceed 105° C. With a case to heatsink thermal resistance of 1.0° C/W, there will be a 25° C temperature difference

between the two. The maximum heatsink temperature is therefore 80° C (at this temperature, protection would need to be provided to prevent accidental contact, but this *must not* affect airflow across the heatsink). If we assume an ambient temperature of 30° C, each transistor requires a heatsink with thermal rating of 2° C/W. The parallel pair will require a heatsink of twice this size, i.e. 1.0° C/W. The calculation in the preceding paragraph does not allow for any safety margin (other than that built-in to the case to heatsink thermal resistance assumptions) and it would be better to design using a higher ambient temperature. For an ambient temperature of 40° C, the heatsink for the parallel pair would need to have a rating of 0.8° C/W and for an ambient of 50° C, 0.6° C/W. If we are going to mount all the transistors for a single amp on the one heatsink (which is the most common approach), then the heatsink must have a rating of 0.5° C/W (assuming a conventional output stage) for an ambient temperature of 30° C and no safety margin. The ratings at 40° C and 50° C would be 0.4° C/W and 0.3° C/W respectively. Similar calculations can be carried out for any number of paralleled transistors.

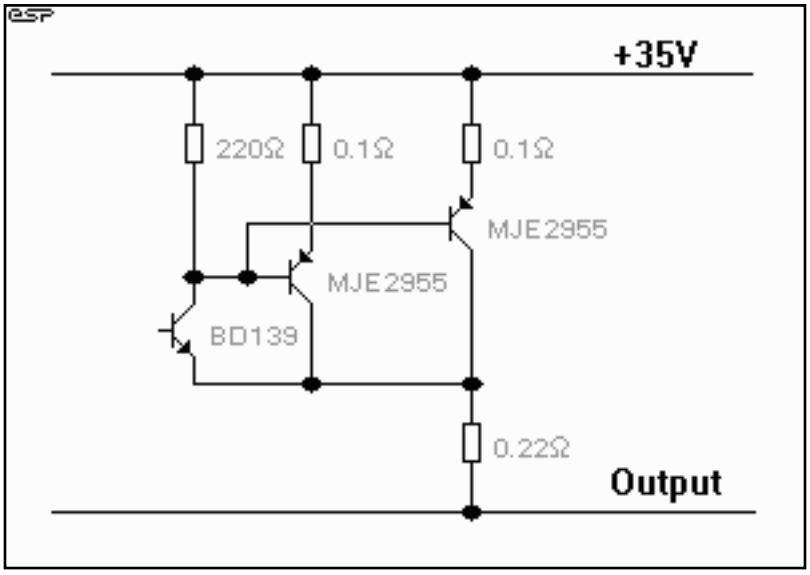


Figure 4 - Connecting Transistors in Parallel

The 0.1 Ohm resistors shown in Figure 4 ensure that each transistor carries the same (or at least roughly equal) current. Without them, the transistor with the higher gain (or the lower emitter-base voltage V_{be}) will take the majority of the current. This will cause it to get hotter than the 'lesser' transistor, which in turn increases its gain further and lowers V_{be} even further, which means it will get hotter, and so on. Note that the use of 0.1 ohm resistors is restricted to transistors with fairly closely matched V_{be}. Higher values are recommended where matching is impractical. This is all standard stuff in amplifier design. The 0.22 ohm resistor is used to stabilise bias current and introduce local feedback. These must not be omitted.

There are other ways in which thermal resistance can be reduced. For example, we are assuming that the transistors will all be on the same heatsink, which will probably be earthed to the chassis. If the NPN and PNP transistors were to be mounted on separate heatsinks, and were not earthed, but connected to the power supply (or output - depending on the topology of the output stage), we can reduce the case to heatsink thermal resistance even more.

This approach is generally considered too much of a nuisance though, because of the risk with high supply voltages, and the difficulty of mounting the heatsinks using insulating bushes, nylon screws etc. Also, it will be necessary to provide some form of shield, such as perforated steel mesh, to protect the heatsinks from becoming shorted to each other or the chassis should some object be dropped. Even the end of a lead swinging about could destroy the amplifier - not a happy thought.

11.3 - Additional Thoughts On Reducing Thermal Resistance

Some other methods also exist for reducing the thermal resistance, with one of the simplest being to use a higher power transistor, or even a simple change of case type. Use a TO-3 case or large footprint plastic package instead of a standard TOP-3 for example. A few real examples ...

TO3 package	**Watts**	**Max Temp.**	
2N3055	115W	200° C	1.5° C/W
MJ802	200W	200° C	0.875° C/W

TO3P package	**Watts**	**Max Temp.**	
TIP3055	90W	150° C	1.39° C/W (standard footprint 16x20)
2SA5358	150W	150° C	0.83° C/W (standard footprint 16x20)
MJL21193	200W	150° C	0.7° C/W (large footprint 20.5x26) (Actually TO-264 case)

The figures quoted above are typical, and will vary (sometimes significantly) depending on the manufacturer and the fabrication method used.

As you can see, simply selecting a higher power device in the same case style, the thermal resistance is lowered, since the manufacturer must make allowance for the junction to case thermal resistance to allow the higher power. In many instances, this will

probably be "automatic", since the silicon die must be larger to allow more power, and thus has greater surface area and better heat transfer.

(Thanks to Geoff Moss - my defacto editor for this information)

---

12 - Introduced Thermal Resistances

It is not uncommon for amplifier designs to use a bracket of some sort to connect the transistors to the heatsink. Where this is done, it is imperative that the minimum additional thermal resistance possible is created. I have seen designs where a simple aluminium bracket is simply bolted onto the heatsink, and everyone hopes that this will be enough. Generally, it is not. Transistors must be mounted as close as possible to the heatsink side of the bracket, since the aluminium is not a perfect conductor, and the smaller the distance the heat has to travel the better.

Any bracket used must be of the thickest material possible, and be mated to the heatsink with the greatest care. Otherwise, one is simply adding an unknown (possibly quite large) thermal resistance between the transistor's junction and the ambient air. I have heard, and seen in magazine readers' letters, complaints from amplifier builders that the transistors keep blowing for "no reason". Other more experienced (or careful) constructors have no such problems with the same design, and it is quite rare that the designers of magazine construction projects will suggest that the bracket to heatsink mounting could well be the problem.

If brackets must be used, ensure that the mating surface with the heatsink is completely flat, and free of burrs or other anomalies which will prevent the "perfect" contact. There should be no less than 1 screw (or aluminium rivet) for each square 25mm of surface area, and screws should be tightened from the centre outwards, much as one tightens the cylinder head bolts on a car engine. A thin film of thermal compound is a must, and the mating should be tested with firm pressure then inspection to ensure that the contact surface is even. If it is not, then fine valve grinding paste (available from automotive parts stores) can be used to ensure that the surfaces are matched to each other.

Simply place a small quantity on the bracket, and distribute it with your finger. Rub the two components together (bracket and heatsink) in small circular patterns, until inspection shows that the two surfaces are evenly polished. It will not hurt one little bit to use a metal polish to shine the surfaces when you are satisfied that they mate properly - the smoother the surfaces, the better the thermal contact, since surface irregularities are minimised. Thermal compound should be used sparingly - once the surfaces are mated,

the smallest amount only should provide coverage of the entire surface.

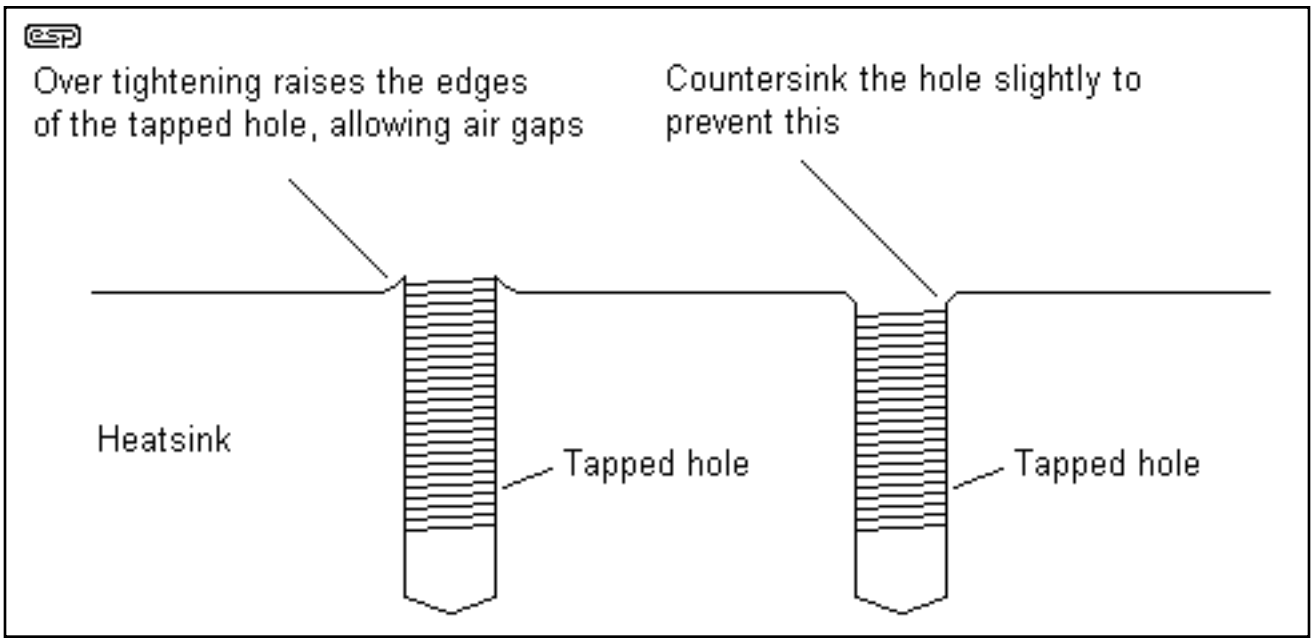

Figure 4a - Raised Edges Due to Aluminium "Stretching"

A short word about the mounting holes and screws is also called for. When a screw is tightened into a soft metal such as aluminium, it will tend to distort (or stretch) where the screw exerts pressure. On the heatsink, this will cause the metal to distort outwards, preventing the proper mating of the surfaces. After all your hard work ensuring that the surfaces were as good as you could get them, this will instantly negate your efforts. *Small* recesses in the underside of the bracket's screw holes will allow the distortion to occur, but will not lift the bracket off the heatsink. Likewise, a *very slight* recess in the surface of the heatsink will prevent the distortion from projecting above the surface - I tend to use both methods at once just to be sure. It is vitally important that any recess or countersinking is only large enough to prevent metal "stretch" - overly large recesses will do more harm than good, either by reducing the available surface area, and/ or allowing the transistor flange to be distorted.

Do **not** be tempted to tighten the screws as much as you can. They need to be tight enough so that there is good contact, but over tightening will distort the metal and will generally make the thermal resistance higher. The use of at least two washers is recommended, as this will help to distribute the pressure more evenly, and a spring washer is essential to stop the screws from loosening. If you can obtain them, 'cup' or compression washers are highly recommended, as they will maintain a consistent pressure, despite any movement ('flow') of the heatsink material. This is especially important with extruded aluminium heatsinks (i.e. most of those available) for long term thermal stability. Cast heatsinks are a completely different alloy, and distortion does not seem to be an issue.

If you use a mounting bracket, and can feel any difference in temperature between the main heatsink and the bracket, there is thermal resistance present, and more work might be needed to ensure that it is reduced to the minimum.

Remember too, that aluminium is a soft metal, and will tend to 'flow' when a consistent pressure is exerted. Over time, this may lead to the thermal resistance increasing, possibly to the point where the transistors overheat and are destroyed. For this reason, excessive tightening is never recommended, and the better the contact between bracket and heatsink, the less pressure is needed to ensure thermal resistance is kept to the minimum. Aluminium pop rivets can also be used, since they have the same rate of expansion as the heatsink and bracket (which are also aluminium), and will exert a consistent pressure which is not excessive. Care must be taken to ensure that the rivets are long enough to penetrate the heatsink, or the holding power is reduced to slightly less than useless.

Note that if you are using rivets, the bracket must be attached to the heatsink *before* the transistors are mounted. The shock from the riveter may cause damage to the transistor die.

---

13 - Flat-Pack Transistors

The TO-220, TOP-3 and other flat plastic packages have some real problems with thermal resistance, and their mounting arrangement does nothing to alleviate this - in fact the reverse is true. The problem is that the transistor junction is physically located more or less in the middle of the plastic encapsulated section, and the mounting is by a single tab, separated from the die by perhaps 10mm or so. This does not sound like very much, but the thickness of the tab is such that a significant heat difference can be measured between the two points.

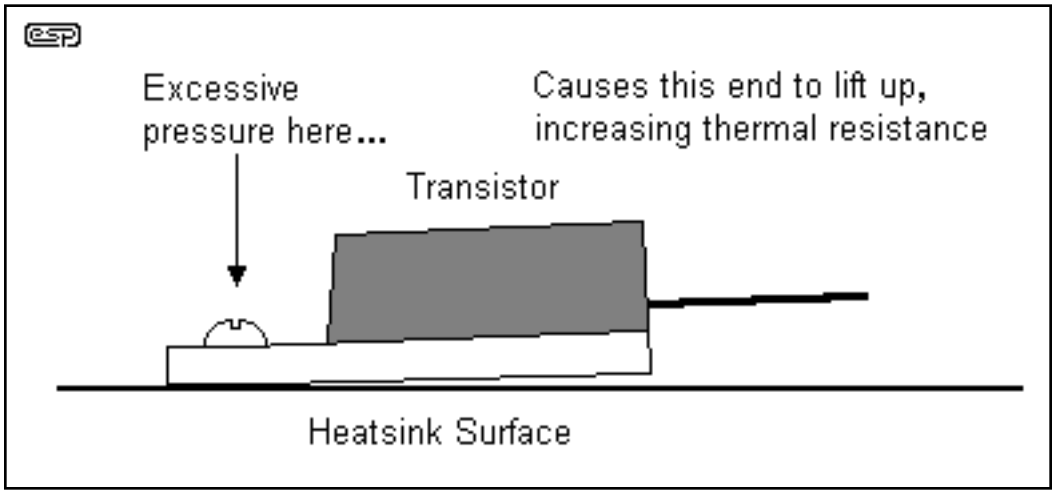

Figure 4b - One Result of Excessive Pressure

When the device is mounted, the pressure of the mounting screw is concentrated in one spot, and may even cause the remainder of the transistor case to lift up from the heatsink slightly. When maximum heat transfer is required (which is most of the time), a very worthwhile improvement can be obtained by clamping the transistor to the heatsink with a section of flat aluminium bar (or even better, a channel or u-section). This should be thick enough to not bend when the screws are tightened, and also alleviates the requirement for insulating bushes and the like, since the normal mounting screws are not needed (the insulating washer is naturally still needed). Because of the pressure exerted directly above the transistor junction, thermal resistance is reduced by a worthwhile margin, but care must be taken to ensure that the screws holding the pressure bar are tightened evenly to ensure that all devices are firmly clamped. This method has the additional advantage that any deformation of the heatsink surface due to the pressure of the screw thread will be away from the device itself, enhancing long-term reliability.

A smear of thermal compound on the top of each transistor allows the pressure bar to become a part of the heatsink - not to the degree that a smaller sink can be used, but any reduction in thermal resistance is worthwhile, however slight.

Excessive pressure is a definite no-no, as you might be strong enough to crack the transistor case if you are not careful. This is one for those with some skill with machines and the like, since we are attempting to provide the absolute maximum allowable pressure on the cases, without the risk of damage - mechanical engineering stuff, basically.

The other advantage of this technique is that it allows the use of larger screws than would normally be possible, since they no longer have to be able to fit through the little hole in the insulating bush. This means more pressure and less thermal resistance, but

only if the screws are tightened to a uniform torque so all devices have the same pressure exerted upon their cases.

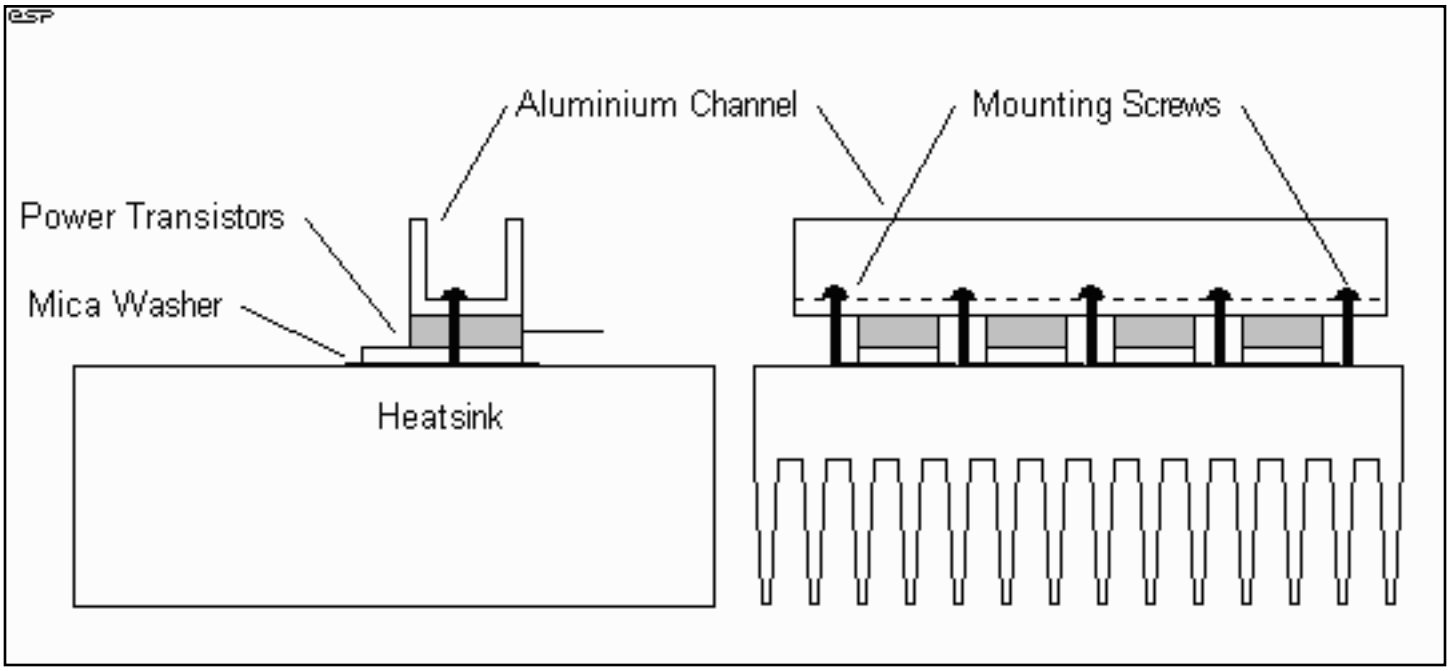

Figure 5 - Suggested Method For Mounting Flat-Packs

Figure 5 shows the general idea, with four transistors mounted on the heatsink. On the left is a side view, with an 'end-on' view of the transistors on the right. This method requires that there is some free area on the PCB, since the transistor leads will normally be mounted directly into the board. The aluminium channel section can then perform another very useful function - supporting the circuit board, so excessive vibration or flexing does not fracture the transistor leads.

In addition, some amps need a heatsink for the driver transistors, and - there it is! I am surprised that this method is not more widely used in production amps (but then again, I only thought of it a couple of years ago, so maybe they just haven't thought of it yet). If this is the case, just remember where you saw it first .

If you are a little wary, thinking that the mica washers might slip during assembly, use nylon screws to hold the transistors down loosely during assembly (don't tighten them too much, or they just snap off). These will hold everything in place while you go about the business of carefully tightening down the channel section screws. Remember that they should be all fairly even, and it is best to start from the centre, then work out towards each end to prevent any possibility of the channel section developing a buckle (however slight). If available, a torque wrench is very useful for tightening the screws (no, not the one you use for the car's cylinder head bolts :-)

14 - Where To Mount Transistors

Since heat rises by convection, one might think that mounting the transistors on the bottom of the heatsink might improve thermal performance. This is incorrect, and will actually cause the devices to run hotter. Aluminium is an excellent conductor of heat, and the idea is to ensure that the transistors are mounted in such a way that each has sufficient clearance from the others, and they are close to the geometric centre of the sink.

This method ensures that the heat from each transistor has a similar mass of aluminium to disperse its heat into, ensuring that all devices have a similar and equal chance of dispersing the heat generated.

Convection (as we normally think of it) does not apply in a solid, since it requires molecular movement on a grand scale. In a solid, the molecules merely jiggle about more, but stay in the same place.

15 - Heatsink Surface Area

There is only one thing on a heatsink that actually gets rid of heat to the surrounding air - surface area. The higher the surface area, the more heat will be disposed of. However, this is only the start, since fluid dynamics (in this case the fluid is air) also plays an important part. Make sure that you read the sections below on fin density and altitude effect - these are very important considerations in the overall design.

Heat is lost to the air by two mechanisms, and both should be maximised for best performance:

- Conduction / Convection
- Radiation

Conduction (and / or convection) requires that there is a continuous stream of air flowing past the fins of the heatsink, which means that the fins should be vertical if at all possible. Horizontally oriented fins will lose a vast amount of thermal transfer, since the air cannot flow through to the body of the heatsink. A fan solves this problem immediately, since air being blown onto the face of the heatsink has considerable turbulence, ensuring that there is always plenty of cool air at the surface of the heatsink.

Simple convection is not as effective (even for the same rate of flow of air), because of the "laminar" flow of air (where the air at the surface of the heatsink moves slower than that further away). This effect can be easily seen on a windy day. If you stay close to a wall or other large area (lying on the ground works too), it will be noticed that it is less windy than out in the open. Exactly the same thing happens with heatsinks (but on a somewhat reduced scale). Creating turbulence is an excellent way to defeat this process, but this requires fans, and fans are noisy.

Radiation requires that the surface has the maximum emissivity of heat, and this means that its colour is important. Shiny gold anodised heatsinks might look great (if you like that sort of thing), but are hopeless at radiating heat. It's no accident that the radiator in a car, or the condenser on the back of a refrigerator is matte black - not chrome plated and shiny. Matte black heatsinks are the best for radiation, and will have a significantly better thermal resistance than any other. Use of paint is to be avoided however, unless kept thin and even, as a thick layer of paint acts as an insulator, reducing the ability of all those unwanted therms to get out into the air.

This is one of the reasons that aluminium is so popular as a heatsink material - it can be anodised, and black dye is then introduced into the porous layer of aluminium oxide. This is far thinner than any coat of paint, and is very effective. Copper is actually a far better conductor of heat, but cannot be anodised, and its colour is such that it is a naturally terrible radiator. Such is life. Oxidised copper (kinda, sorta like anodising) is passably effective, but rarely used due to its cost. Table 3 shows the "emissivity" of various surfaces. This is a measure of their ability to emit infra-red radiation (heat), and a figure of 1 is as good as it gets for a passive heatsink (i.e. no heat pumps or the like). This list is not exhaustive, but is a fair indicator for the most common surface treatments.

Surface	**Emissivity**
Polished aluminium	0.05
Polished copper	0.07
Rolled sheet steel	0.66
Oxidised copper	0.70
Black anodised aluminium	0.70 - 0.90
Black air-drying enamel	0.85 - 0.91
Dark varnish	0.89 - 0.93
Black oil paint	0.92 - 0.96

Table 3 - Emissivity of Various Surface Treatments

Emissivity refers to radiation, which is only a relatively minor (typically 25% or less) but still important means of dissipating the heat. Most heat is conducted to the air at the surface boundary, and although black oil paint has excellent emissivity, it will also insulate the fins from the air. Overall, as discussed above, about the best treatment is black anodising, but matte black automotive type lacquer is also very good (IMO) - provided it is applied as *thinly as possible*.

Most high performance heatsinks have the surface of the fins ribbed, which further increases the surface area, so even a relatively small heatsink will have a radiating surface far greater that its moderate size would indicate, after all the individual fins, and the ribbing on the fins, is taken into account. Heavy application of black paint (for example) could fill the ribs, and reduce performance dramatically!

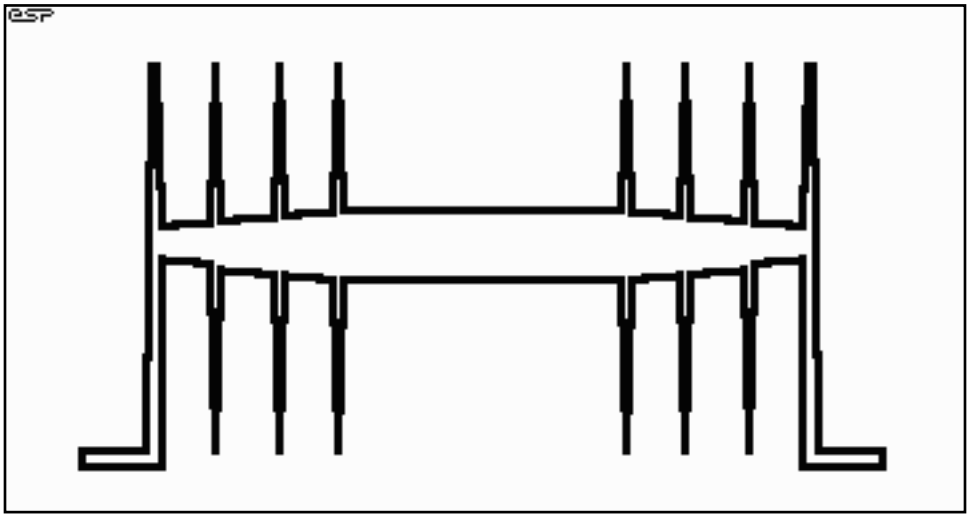

Figure 6 - A Typical Heatsink Section

The simple heatsink in Figure 6, (100 x 100 x 50mm high), has a base surface area of 200 square cm, and when the fins are added, this increases to 1000 square cm. Note the way the base tapers away from the centre - this saves metal, but also provides maximum thermal inertia where the transistors mount, and matches the heat carrying capacity at the extremities to the expected heat flow. In reality, such a heatsink would have more fins, and if they were ribbed, the resultant final unit could have a total surface area of perhaps 1500 square cm. This is the equivalent of a single plate over 270mm square, but will have far better performance because the thermal resistances are kept to a minimum by reduced distances. (Remember that both sides of the metal are in contact with the air, so the total surface area is double that expected.)

Note that when dealing with heatsink temperature, it is almost always referred to as temperature rise - the number of degrees above ambient that the heatsink will reach. If ambient temperature is lower than the "standard" 25°C, so too will be the heatsink temperature (and vice versa, of course). Temperature rise is a constant in the equations - this is where we must be careful when the ambient temperature is high. A car in the sun can have an internal temperature of 50°C quite easily, so a temperature rise of 25° will see the heatsink at 75°C.

The thermal resistance of a heatsink is determined by :-

- Its size
- The number of fins
- The total surface area - a ribbed fin design will be smaller than one using flat fins for the same thermal resistance
- Thermal resistance within the aluminium itself - the actual alloy used, its thickness, etc
- The colour - matte black is best, and other colours are all worse
- The orientation of the fins - vertical is best, any horizontal position is worse
- Availability of unrestricted air flow
- Its temperature!

According to the 'quick and dirty' formula on Harry's Homebrew Homepage (see link below), the thermal resistance is approximately equal to

$$\text{Thermal Resistance} = 50 / \sqrt{A}$$ Where A is the total surface area in cm^2

Using this formula on the above heatsink (without ribbed fins), gives a thermal resistance of about 1.58° C/W or 1.29° C/W with the ribbed fins. This is not an insignificant difference.

The same heatsink used in my heatsink calculator (see Downloads page) gave a thermal resistance of 1.12° C/W, assuming flat fins. I used a fin height of 50mm, depth of 100mm, and told it the heatsink has 8 fins. This assumed an ambient temperature of 25° C, and a maximum heatsink temperature of 40° C. This seems more or less realistic compared to manufacturer's data for similar heatsinks.

Manufacturers' ratings are not usually very specific, but we can safely assume that a given thermal resistance is the best obtainable, and probably assumes that the heatsink is in free air (no nearby casings, optimal fin orientation, etc). In most cases, a heatsink

has to be used in a real-life situation, which means that you might need to add anything from 10% to 50% to the quoted figure, so a 1° C/W unit could end up as anything from 1.1° to 2° C/W, depending upon its mounting and other impediments to airflow.

Where possible, make sure that the heatsink is firmly attached to the case, which can make a reasonably thick aluminium chassis (for example) a significant part of the heatsink. This can improve performance markedly if good thermal bonding is used between case and sink. I do not recommend that you include the case in any calculations unless it is large compared to the heatsink, but if you do, do *not* count the inside of the case as part of the surface area. This is sealed (or semi-sealed), and the air will not have the free movement needed to remove the heat from the inner surfaces.

The last point is likely to cause some confusion - after all, thermal resistance is a constant based on the other factors, right? Wrong.

Let's imagine a heatsink with a heat load of 10W. After careful measurement, we determine that the temperature rise is 10° C (i.e. 10° above ambient), so the heatsink has a thermal resistance of 1° C/W. We will almost certainly decide that a 10° rise is probably a bit restrained, and in fact we can allow a temperature rise of 20° C, and we may decide to allow for a maximum 25° ambient (not much use in outback Australia during summer, but it will do for this exercise).

Allowing an additional 10° brings the thermal resistance down to 0.89° C/W, and if we decided that even a 35° rise were acceptable (80° C heatsink temperature referred to a 25° ambient), the thermal resistance drops further, to 0.73° C/W.

This apparently anomalous behaviour is actually all completely normal, and the heatsink is actually obeying the Second Law of Thermodynamics perfectly (feel free to look that up if you don't know it already).

In fact, the term 'thermal runaway' - where a transistor gets hotter so conducts more current, so gets hotter, so ... - is a misnomer in terms of physics. At some point, the system will stabilise, as it must. Unfortunately, this will probably involve temperatures in excess of what the transistor junction can tolerate, so it (or they) will be destroyed.

The heatsink discussed above has a thermal resistance of only about 0.45° C/W if a temperature rise of 200° C were acceptable (which it absolutely is *not*).

This is no different from any other situation where there is a difference in potential, pressure, or anything else. The greater the difference, the greater the flow rate. Now you

know that the thermal resistance is *not* a constant - it is inversely proportional to the temperature difference between heatsink and ambient (this is a gross simplification, but will suffice for the time being). If heatsink and ambient temperatures are the same, the heatsink has an infinite thermal resistance!

---

16 - Altitude

Since the density of air varies with altitude, so does the efficiency of a heatsink. I wonder how many consumer equipment makers take this into consideration? As can be seen from the table below, the effects are not insignificant.

Altitude (Metres)	Altitude (Feet)	Derating Factor
0 (sea level)	0	1.00
1,000	3,000	0.95
1,500	5,000	0.90
2,000	7,000	0.86
3,000	10,000	0.80
3,500	12,000	0.75

Altitude Derating Factors

The altitude effect should be considered in all cases, as can be seen. While the air temperature of an indoor environment is normally controlled and is not affected by the altitude change, the indoor air pressure does change with the altitude. Since many electronic systems are installed at an elevated altitude, it is necessary to derate the heat sink performance mainly due to the lower air density caused by the lower air pressure at higher altitude. The table shows the performance derating factors for typical heat sinks at high altitudes. For example, in order to determine the actual thermal performance of a heat sink at altitudes other than sea level, the thermal resistance values read off from the performance graphs should be divided by the derating factor before the values are compared with the required thermal resistance.

Example: A 1° C/W heatsink would become 1.16° C/W at an altitude of 2,000 metres, or 1.25° C/W at 3,000 metres.

---

17 - Fin Density

Although it would seem reasonable to assume that the more fins per unit area the better, this is not always the case. Closely spaced fins will not be able to dispose of the heat well in a standard convection (i.e. not fan forced) heatsink. This is partly because of the airflow that will actually be able to establish itself within a confined space, and partly because the fins will tend to radiate much of the heat to adjoining fins, which helps to stabilise the temperature, but does little to dispose of the heat.

The maximum distance between fins is dependent on the depth or height of the fins - deep finned heatsinks will need more space between adjacent fins than a shallow design unless fan cooling is used. As shown in the following table, the minimum spacing is determined by fin depth and airflow.

Fin length (millimetres)	**75**	**150**	**225**	**300**
Airflow (metres / sec)	**Fin Spacing (mm)**			
Natural convection	6.5	7.5	10	13
1.0	4.0	5.0	6.0	7.0
2.5	2.5	3.3	4.0	5.0
5.0	2.0	2.5	3.0	3.5

Fin spacing (in mm) versus flow and fin length

The average performance of a typical heat sink is linearly proportional to the width of a heat sink in the direction perpendicular to the airflow, and approximately proportional to the square root of the fin length in the direction parallel to the flow. For example, an increase in the width of a heat sink by a factor of two would increase the heat dissipation capability by a factor of two, whereas doubling the depth or height will only increase the heat dissipation capability by a factor of 1.4. Therefore, if the choice is available, it is beneficial to increase the width of a heat sink rather than the length of the heat sink fins. Also, the effect of radiation heat transfer is very important in natural convection, as it can be responsible of up to 25% of the total heat dissipation. Unless the heatsink is facing a hotter surface nearby, it is imperative to have the heat sink surfaces painted or anodised to enhance radiation.

The reason for the difference is simply that as the height is increased, the air at the top of the heatsink is hotter than that entering at the bottom. If the fin depth is increased, there is more mutual radiation between fins, and as the spacing is reduced, mutual radiation increases again. Airflow is also restricted because of the smaller physical area

for air to pass, since more of the available space is occupied by the heatsink itself.

---

18 - Water Cooling

I was going to stay away from this completely, but it is worth a small paragraph at least. Water just happens to be the best heat removal medium known, with a specific heat of 1, it requires more energy to raise a gram of water by one degree C than any other material.

If extremely high power is the goal (and a bit of plumbing is Ok), a water cooled heatsink is the ideal. Provided the thermal resistance from junction to heatsink is minimised, a minuscule heatsink with only a moderate water flow will remove prodigious amounts of heat. Although uncommon for audio amplifiers, water cooling has been used for many years for cooling high power radio transmitters and the like.

However, it must be admitted that few audiophiles will go to the trouble of installing special plumbing to cool their amplifiers - it would be cheaper to put them in another room and use fan cooling, and a lot more convenient.

Having said that, the use of water cooling is gaining in popularity, and quite a few commercial H_20 cooling systems are available for microprocessors. As component density increases in the ICs, it becomes harder to get the heat out efficiently, so expect to see that side of the market expand in the next few years. While it must be admitted that water cooled heatsinks are the best possible choice for amplifiers, this is not an area that can be expected to grow, since it is just too expensive and unwieldy to implement. Finding a silent running pump is another hurdle, and although the plumbing is not at all difficult (low pressure systems are all that's needed), it still has considerable nuisance value - the cables in a typical system are bad enough, let alone having a plumbing system that must be 100% watertight. Of course, then there is the radiator, pump and fan to be considered - they have to live somewhere, and can be expected to have a SAF (Spouse Acceptance Factor) of perhaps -20dB ("I don't know what you're planning to do with *that* horrible looking thing, but if it comes in here, I'm moving out!" - a fairly typical response, I would suggest).

Still, I may do a water cooled heatsink project at some time, just for the fun of it ;-)

---

19 - Heat Pipes

Heat pipes are not common, and will not be discussed at any length in this article. They are expensive, and are most commonly used where a hot component must be cooled in a confined space. The heat pipe is actually two heatsinks, joined by a pipe containing a refrigerant. Natural convection is used to move the refrigerant from the hot area (the component to be cooled) and the main heatsink, which may be mounted some distance away.

For those who are interested in this technology, there are quite a few articles on the web that discuss heat pipes, and I suggest a web search to locate them.

There are some newer versions of the same basic principle now available. These make use of "micro-channels" to dramatically increase the surface area at the hot end, and allow the use of more environmentally friendly coolants. However, it is to be expected that these will be expensive, and outside the budget of most home constructors.

---

20 - The Bottom Line

As can be seen from the above, for a given heatsink, the most critical part of the whole thermal resistance equation is actually the transistor itself. If the thermal resistance of the active devices can be reduced, the heatsink requirements are lessened, resulting in a pleasing increase in reliability, and an equally pleasing reduction in the cost of the necessary heatsink.

The thermal resistance from transistor case to heatsink is also very important, and proper mounting technique can result in a significant improvement over the "just slop some grease on and bolt it down" approach.

If these two thermal resistances can be reduced enough, the heatsink itself can be quite a bit smaller than would otherwise be the case for the same (or even lower) transistor operating temperatures.

Always remember that manufacturers' data on heatsinks is under ideal conditions, and is usually measured at a temperature of up to 50 to 75°C above ambient - although this is rarely stated.

---

21 - Other Heatsink Information

I have included a heatsink calculator spreadsheet, which appears to work quite well. Go

to the Downloads page to get a copy, or you can just click here for a download.

A very useful link for those who are put off by the cost of large heatsinks:

HeatSinks Very good drawings, showing the complete process for building a heatsink. All measurements were in imperial - i.e. inches, but now include metric.

Harry's Homebrew Homepage has some good info on estimating the thermal resistance of a heatsink (such as the one you make yourself), and for determining how big a heatsink needs to be for a given thermal resistance.

A most excellent document has found it's way into my clutches! It is an application note from International Rectifier (irf.com) and I have linked it here for your convenience. Although it refers to a specific case style, the information is generic enough to ensure that you have a better all-round understanding of the subject.

Another excellent document that describes mounting methods and techniques can be found at the On Semiconductor website. This describes the subject in considerable detail. This document was only recently pointed out to me, and was not used as a reference for this article.

Please Note: With all articles of this nature, there will be some information that appears to be in conflict with other data you will see, either in this article, or other application notes or publications. This is perfectly normal, as no two engineers will ever be in complete agreement, but the basic data correlates very well, with only a few minor points of difference.

Introduction

It is the purpose of this article to give the reader an introduction to understanding noise in electronic circuits, why it happens, and how to read noise specifications. The latter are not usually explained in a way that makes sense to the uninitiated, so it is hoped that this article will assist those trying to make some sense of it all.

Noise has enormous nuisance value with sensitive (i.e. high gain) circuits, but the information provided by most IC and transistor makers does not always make the choice of the most suitable device easy. Certainly, there is copious information, but explanations of what it means and how to apply it are few and far between.

This short article will hopefully clear up some of the confusion. By nature, it is rather more technical than I generally prefer, but this is unavoidable for a passably thorough understanding of the subject.

In this context, noise refers only to circuit noise, and not hum, buzz or other extraneous outside influences. These are usually the result of bad (or misguided) earthing practices, or signal wiring running close to magnetic field or harmonic generating items such as transformers and bridge rectifiers. Also to blame can be radio frequency interference, which will often cause problems if adequate (and appropriate) precautionary measures are ignored.

Noise Figure

Noise is inherent in all electronic circuitry, and comes in three basic flavours:

- Thermal noise
- Shot noise
- Flicker (l/f) noise

Thermal noise is "white" in character (has a constant energy per unit bandwidth) and is generated by the thermal agitation of electrons in a conductor. The typical sound is hiss, hopefully at a low level so that it does not intrude on the programme material. It is calculated using Nyquist's relation:

$V^2R = 4k * T * R * f$

Where ...

V^2R = mean square noise voltage
k = Boltzmann constant (1.38×10^{-23})
T = Absolute temperature (Kelvin)
R = Resistance in ohms
f = Noise bandwidth in Hertz

Without even performing any calculations, we can see that the noise from a resistor is proportional to its resistance and temperature. Operating resistors at elevated temperatures in input stages is obviously undesirable, as are high resistance values. This also applies to any other resistive device, such as the voice coil of a dynamic (magnetic) microphone, the coils of a guitar pickup, or a vinyl disc pickup cartridge.

Shot noise is also white, and is inherent in semiconductor devices. It is primarily caused by the changes in molecular energy levels as a semiconductor device conducts.

Flicker noise is a low frequency effect, and as such is not so much of a problem with audio circuits. It becomes worse as frequency is reduced, and this can be seen in some data sheets. At the lower frequency extremes, the noise level increases.

Explanations

Before we continue, there are a couple of terms that need explanation.

Firstly, the term 'dBv' refers to decibels relative to 1V RMS, and 'dBu' means decibels

relative to 775mV. This is also known as dBm, and relates to the old convention of 1mW into a 600 Ohm load. This was common in telephony (and still is in some cases), but is of little relevance to audio applications. However, we are stuck with it. 0dBv is equivalent to +2.2dBu.

Secondly, noise is commonly referred to the input of an amplifier circuit. This allows the instant calculation of output noise by simply subtracting the dB figures. So an amplifier with an 'Equivalent Input Noise' (EIN) of -120dBu having a gain of 40dB will have an output noise of -80dBu (120 - 40). This is the equivalent of 80dB Signal to Noise ratio (S/N) relative to 0dBu. Many equipment manufacturers will state S/N relative to maximum output, thereby gaining perhaps 10dB better figures. This is actually meaningless, since no-one will operate equipment at the maximum level, and the average will be considerably less.

Thirdly, it is commonly accepted that the minimum theoretical input noise (EIN) for any amplifier is -129dBu. Although not explicitly stated, this implies that the input will be terminated with a resistance. Typically, a 200 ohm source resistor will give this figure at 25°C. Sometimes, a short circuit is used instead, and this gives better apparent noise performance. A short circuit is actually meaningless though, since no real-world signal sources have zero impedance. Some do come close though, so the amplifier should always be terminated with an impedance that matches (as closely as possible) the output impedance of the signal source. This should be stated in any specification.

This means that a perfect (as noiseless as it is possible to be) amplifier with a gain of 40dB and a 600 ohm source impedance will have an output noise level of -89dBu, and if the gain were to be increased to 60dB, then output noise will be -69dBu.

It is the nature of noise that it does not add in the same way as two equal frequencies. Because of its random nature, two equal noise voltages will increase the output by only 3dB, not 6dB as might be expected. As a result, we can be reasonably sure that it is the input noise of the most sensitive section of a preamp that will set the final limit to the signal to noise ratio of the entire unit.

The way the noise figure of an opamp is commonly described is something else that needs a little explanation, since it is hardly specified in terms that most constructors will be able to relate to. The data sheet telling you that the "noise figure is 5nV/√Hz" is not very friendly. To get this into something we can understand, first we need to take the 'square root of Hz' and make some sense of it. The audio bandwidth is taken as 20Hz to 20kHz, so the square root of this is ...

√20,000 = 141 (it is not worth the effort of subtracting the 20Hz, so 141 is close enough)

With a noise figure of 5nV / √Hz, the equivalent input noise (EIN) is therefore ...

5nV x 141 = 707nV

If we assume a typical gain of a sensitive microphone stage (for example) as 100 (40dB) and an output level of 1V (0dBv), this means that the output noise equals the input noise, multiplied by gain. Signal to noise ratio can then be calculated ...

707nV x 100 = 70.7uV (EIN = -120.8dBu)
Signal to noise (dB) = 20 x log (1V / 70.7uV) = 20 x log (14144) = 83dB

We can also calculate this using dB alone.

EIN = -120.8dBu
Gain = 40dB
S/N = 120.8 - 40 = 80.8 (ref 0dBu), or 80.8 + 2.2 = 83dB (ref 0dBv)

For low level preamps (such as microphone or moving coil phono pre-amplifiers), it is common to specify the EIN only, allowing the user to calculate the noise for any gain setting, since it changes as the gain is varied. The same amplifier as above with unity gain will have a theoretical signal to noise ratio of 123dB (relative to 1V). All of this assumes that the passive components (especially resistors) do not contribute any noise. This is false, as any device operating at a temperature above 0K (zero Kelvin, absolute zero, or about -273° Celsius) generates noise, however the contributions of passive components are relatively small with quality devices provided resistance is kept as low as possible, and voltages minimised.

Remember that a 'perfect' amplifier (contributing noise at the theoretical minimum possible), will have an equivalent input noise of -129dBu .This means that with a gain of 60dB, the best possible signal to noise ratio will be 69dB relative to 775mV (or 71.2 ref 0dBv).

As an experiment, I built a three opamp precision microphone preamp using 1458 opamps (equivalent to a dual uA741). These have a noise input figure of about 4uV - this translates to about 30 to 35nV / √Hz, or nearly 20dB worse than the NE5534A. With a gain of 46dB (200), the circuit managed a signal to noise ratio of 65dB, referred to 0dBv (1 Volt RMS). The apparently better than expected S/N ratio is because the

bandwidth was so limited because of the opamps I used for this test.

I measured a S/N ratio of better than 80dB (about 82dB) again at a gain of 46dB using LM833 opamps (dual version of the NE5534). When I say that I measured this, it was with extreme difficulty. Because of the low noise, my test instruments were at their limits, so I had to guess a bit. The theoretical 'best possible' at this gain is 85.2dB referred to 0dBv, or -83dB ref. 0dBu.

Search carefully for devices with low noise for sensitive circuitry, and make sure they also have the bandwidth needed to achieve high gains. LM833 or NE5532 dual opamps are an excellent choice for low noise, but they also have wide bandwidth and can be troublesome to keep stable. Do not be tempted to use lesser devices, since their bandwidth is too limited - the 1458 was 3dB down at only 8kHz, and died rapidly after that.

In some cases, it will be found that better noise performance can be obtained using discrete opamps - built using individual components. A common technique for low noise is to select transistors based on their noise data, which will indicate the optimum collector current for a given source impedance.

Then, by using multiple devices in parallel, the noise is reduced further. Two transistors in parallel will have a noise level 3dB better than a single device. Using four will reduce this by another 3dB, and eight will give a further 3dB reduction. This is the theory behind it, but of course it will never be as good as ideal theory might indicate. It is generally considered (based on the many such designs I have seen) that between 2 and a maximum of six devices in parallel will achieve the best overall compromise. Project 25 shows a couple of designs using this method, and has some descriptive text explaining the two (very different) techniques. Project 66 gives the circuit diagram for a microphone preamplifier that uses a discrete front end to obtain low noise. No devices are paralleled as such, although the two sections appear in parallel to the following opamp.

Other Stuff

For all resistors in low noise input circuits, you absolutely, positively, must use 1% tolerance resistors, which will be metal film for lowest noise.

Many noise tests are performed using A-weighting, which introduces a filter prior to measurement. The theory of this is that it compensates for the ear's natural rolloff at low and high frequencies, and makes the measurement 'meaningful'. While the idea is quite sound in principle, I do not believe that this should be done, as not everyone is scrupulous about stating that this technique has been used, so results can be very

misleading. An A-weighting filter is described in the ESP Project Pages (Project 17), along with an extensive description of the theory behind this practice.

Noise In Digital Equipment

For each digital bit, the relative noise floor is lowered by 6dB. A 1 bit system is of little use, and it is necessary to go to a minimum of 8 bits before even ordinary speech is intelligible - not acceptable, but intelligible. This gives a noise floor of 48dB - about what you would expect from the modern telephone system. Even there, speech is digitised at 16 bits (using an 8kHz sampling rate), and then compressed digitally to 8 bits.

(BTW, Worldwide, there are two different digital compression systems used - A-Law, used by all European countries, much of South America, Australia and New Zealand etc. u-Law (as in mu, the Greek letter) is used in the US, Canada and Japan. Prior to digital to analogue conversion, the signal is returned to the 16 bit format. This has nothing to do with noise, I just thought I'd mention it.)

Some digital answering machines use 8 bit digitisation, which explains why they sound so disgusting. Even though the noise floor is (barely) low enough, there is an insufficient number of discrete levels to faithfully reproduce speech. 8 bits only provides 256 discrete levels, and it has been generally accepted that anything less than 12 bits is unacceptable (4096 discrete levels). This is easily verified by recording something on your PC at the various available bit rates and making a comparison.

$$\text{Minimum Digital Noise} = 20 * \text{Log}_{10}(\text{number of discrete levels})$$

When professional digital recording systems were first introduced they were 16 bit. Although this gives a theoretical noise floor 96dB below the maximum level, in reality 90dB was more likely. If maximum level corresponds to +4dBu, this indicates a noise level for each digital channel output of -86dBu.

$$\text{Noise} = 20 * \text{Log}_{10}65535 = -96.33\text{dB}$$

In the sound recording industry, the relative differences between analogue tape and digital recording must be considered. In an analogue machine, it is the tape that clips, which it does in a 'soft' manner, introducing predominantly low order harmonics. These are relatively inaudible, provided the duration is kept short (1ms or so), such as on transients.

A digital system by comparison clips suddenly and with great clarity, and it is essential to leave sufficient headroom to prevent this. If 10dB of headroom is left below maximum level to allow for transients (I would suggest this as a workable minimum), then this implies that the noise level actually present at the output of the digital playback system is -80dBu, relative to nominal (average) playback level.

Many digital systems now have 20 bit or greater resolution, although generally only 20 bits is achieved in practice. This reduces the theoretical noise floor by a further 4 bits, or 24dB. Therefore the noise level at the output of such a machine should be -110dB. Allowing the same 10dB headroom rule as above, this gives a final output noise figure of about -100dB. It is possible in many cases that the associated analogue circuitry within the digital system will be worse than this figure, so the final noise figure is somewhat unpredictable.

1.0 - Introduction

In the field of audio, there are many people who, for one reason or another, dislike

opamps. In some cases this is almost a passionate hatred, despite the vast number of extraordinary opamps available. Some have been around for a long time, and although they replaced the circuits described in this article in 99% of all equipment, it is worth looking at the circuits that were used in the pre-opamp (but post valve/ tube) years.

Of these circuits, Philips was responsible for many of the two transistor feedback amplifiers that were commonplace in high end equipment of the day. There is no denying that the performance of some of these circuits is/ was very good indeed, but it is exceeded (in many respects) by even mediocre opamps.

This article cannot even hope to show all the variations, but the most common circuits are examined. This is an excellent way to learn more about transistors, how they work, and what you can do with them, and as such is recommended reading for anyone who is learning electronics or wants to brush up on what is now an 'ancient technology'.

For all examples, an output voltage of 2V RMS will be used - this is for no other reason than to be able to show the difference between the circuits and to give a reasonably good idea of their relative performance. For the same reason, a supply voltage of 18V was chosen for all circuits that follow (and including the audio stage in Figure 1). Likewise, the gain has been set to 10 (or as close as standard value resistors will allow). This is a voltage gain of 20dB. All circuits are loaded by 10k, again for repeatable results. This is also a reasonably representative load - perhaps a little on the low side, but chosen to give the most realistic result available from the SIMetrix [1] simulator (or any simulator for that matter).

2.0 - Single Transistor Amplifiers

The simplest of all transistor amplifiers, these were used commonly in the very early days of transistor applications. They are very limited even today, and were much more limited when only germanium transistors were available. Unlike a valve (vacuum tube), input impedance is relatively low - this caused many of the early designs some grief because so many of the sources were high impedance.

There are ways around anything, but noise performance was usually rather ordinary - in many cases worse than that obtained from valve circuits. However, the overall convenience of equipment that could be operated from a single (low voltage) battery was just too overwhelming, and the days of the valve were numbered when Sony released one of the first all transistor portable radios. This early radio was reliable, and had surprisingly good performance (germanium transistors, remember). Yes, I did have

one

The circuit in Figure 1 became the standard for single transistor amplification stages. There are other variants, but they either have poor thermal stability or poor tolerance for different transistor gains (or both).

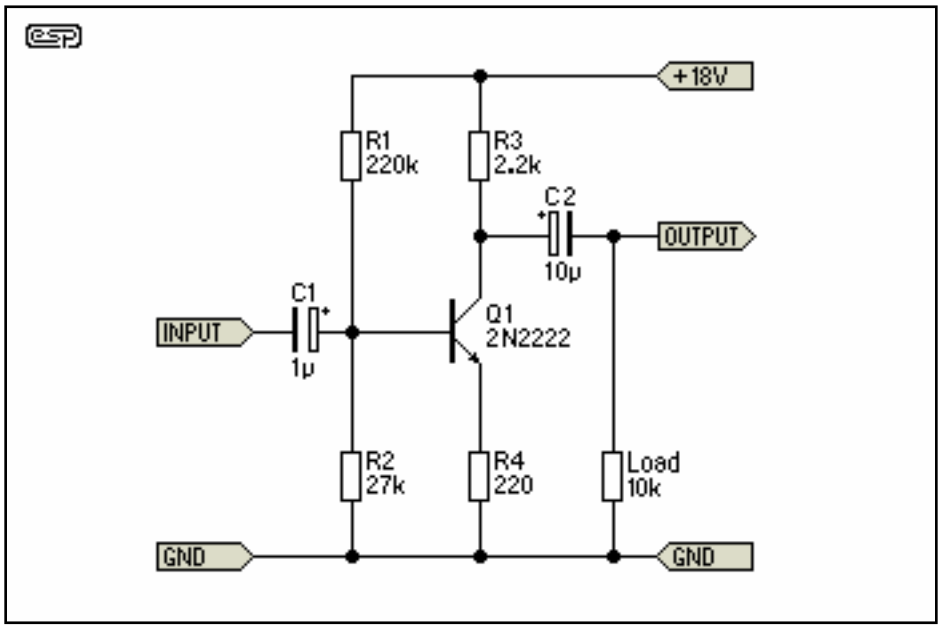

Figure 1 - Single Transistor Amplifier

The drawing above shows a capacitor coupled AF (audio frequency) stage. Although transformer coupling was also used on occasion this was usually restricted to RF circuits. There were some instances where transformer coupling was used for audio, but the demands for lower cost and better performance saw the demise of transformers in this application. Transformer coupled audio stages will not be covered.

As always, these 'simple' amplifiers are almost always biased so that the collector voltage is about ½ the supply voltage, so in the example above (AF only) the collector voltage is set to about 9V.

With the standard load of 10k, the Fig 1 amp has a total harmonic distortion of 0.218% - not too shabby, but several orders of magnitude worse than even an 'ordinary' opamp. The output FFT spectrum is shown in Figure 2 - low order harmonics predominate, and it is worth noting that 1uV referred to 2V peak output is -126dB. This is well below the noise floor that can be expected for this type of circuit.

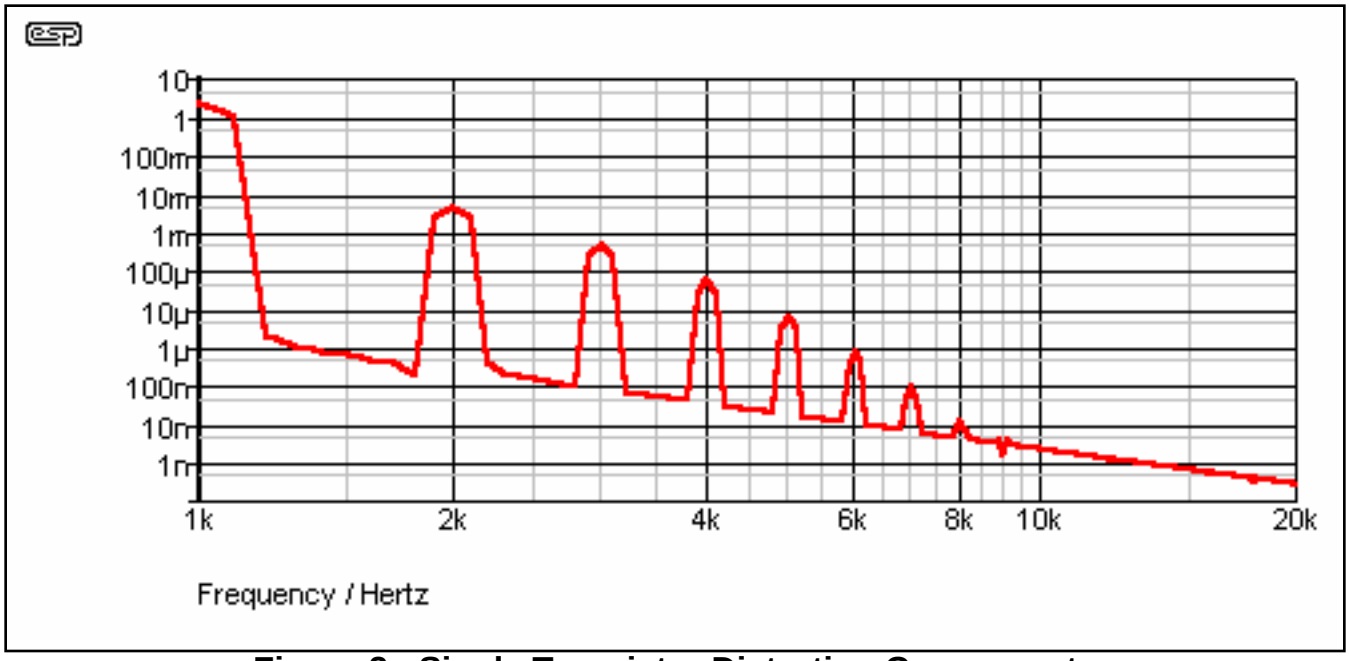

Figure 2 - Single Transistor Distortion Components

The basic amplifier has many disadvantages. Input impedance is rather low, and is only 16k for the circuit as shown. Output impedance is equal to the value of the collector resistance (2.2k in this case), and the local feedback provided by the emitter resistor does not affect this. Stage gain is (approximately) equal to the collector resistance divided by the emitter resistance. For the example shown the gain is actually only 7.95 - somewhat less than expected.

Two small traps for the unwary -

- in nearly all simple transistor amplifier designs, the effective collector load resistance is actually the value of the physical collector resistor in parallel with the external load impedance - in the case of the Fig 1 amp, this works out to about 1.8k when it is loaded with 10k as shown.
- The stage is inverting - a positive going input produces a negative going output (and vice versa, of course). Unless an inverted signal is acceptable, all such designs must be used in even numbers to provide a non-inverted output.

2.1 - How the Circuit is Designed

The design process for this amp is simple enough to explain (unlike most of the others shown below), and it gives a good insight into the way to approach analogue design. The key factor is the value of the collector resistance and the design voltage that will be across it under quiescent conditions. In this case, the resistor is 2.2k and it will have 9V across it, so ...

I = E / R = 9 / 2.2k = 4.09mA (4mA close enough).

The next step is to decide on the gain - in this case I chose a gain of 10. The gain is (in theory) determined by the ratio of the collector load (RL - resistor R3) to RE (the emitter resistor R4), so ...

Av = R3 / R4 = 2.2k / 220 = 10

As we saw though, the gain is less than this, so what went wrong? Two things - firstly (as noted above), the collector resistance (RL) is equal to the parallel combination of the actual resistance used, and the load resistor. Secondly, there is an intrinsic resistor inside the transistor - commonly referred to as re (literally 'little r e'), and its value is inversely proportional to the emitter current (IE) determined by

re = 26 / IE (mA) = 26 / 4 = 6.5

Recalculating the collector load resistance (the 10k load in parallel with the 2.2k collector resistor) ...

$RL = R3 * R_{load} / (R3 + R_{load}) = 1.8k$

Now we can recalculate the gain using the proper load resistance and the total emitter resistance ...

Av = RL / RE + re = 1.8k / 220 + 6.5 = 7.96

That is almost exactly what was measured, so the design process actually does work

Although the gain is less than the original target of 10, we shall accept that anyway for the purposes of this exercise. The next task is to determine the value of the bias resistors (R1 and R2). The first stage is to find out the lowest current gain for the selected transistor - let's assume that to be 200. The base current is equal to the collector current divided by the transistor gain. That works out to ...

$Ib = Ic / h_{FE} = 4 / 200 = 0.02mA$ (20uA)

The general rule is that the bias circuit should carry between 2 and 5 times the base current, so we are looking for somewhere between 40 to 100uA through the bias

network (this may go as high as 10 times if greater predictability is needed). Before we can start on that, we need to know the base voltage. Again, we need only Ohm's law and a simple addition to determine this. Knowing that the emitter current is 4mA (plus the base current of 0.04mA which can be ignored for high gain transistors), the emitter voltage will be ...

$$Ve = Re * Ie = 220 * 4mA = 880mV$$

The base voltage is therefore the sum of the emitter voltage and the base to emitter voltage (typically taken as between 600 and 700mV). Assuming 600mV, the base voltage should therefore be ...

$$Vb = Ve + Vbe = 880 + 600 = 1480mV\ (1.48V)$$

R1 can now be found. The voltage across it is the supply voltage less the base voltage, the current through it is worked out using Ohm's law (again). We shall start with a value that is 10 times the collector resistance (always a good starting value), so let's try 220k ...

$$I_{R1} = V_{R1} / R1 = (18 - 1.48) / 220k = 75uA$$

That's 3.75 times more than the base current, so should be fine. Now, we only need to work out the value for R2 ...

$$R2 = Vb / (I_{R1} - Ib) = 1.48 / (75 - 20) = 26.9k\ (27k)$$

And that's it. The exercise is rather tedious (much more so before the advent of the calculator), and has to be re-calculated each time you change the supply voltage or the stage gain. The impedances are fixed by the component values and there is little you can do about it. It is possible to bypass R4 with a large value cap to get more gain (which can be very high even for a single stage), but then distortion goes through the roof.

Output impedance is set by the value of the collector resistance (2.2k in this case), and input impedance is determined by the parallel combination of R1, R2 and Zb (the input impedance of the transistor's base). We need to know this so we know how much this circuit will load the source ...

$$Zb = (RE + re) * h_{FE} = (220 + 6.5) * 200 = 45.3k$$

The total input impedance is the parallel combination of all three impedances ...

$$Zin = 1 / (1 / R1 + 1 / R2 + 1 / Zb) = 1 / (1 /220k + 1 / 27k + 1 / 45.3k) = 15.7k$$

Since we measured (well, I did anyway) the input impedance at about 16k, it looks like everything has fallen into place nicely.

It is worth noting that 'little re' can be ignored if its value is less than one tenth that of RE (the external resistance). For what it's worth, when RE is bypassed by a cap re becomes significant. I used a value of 2,200uF, and the circuit gain becomes roughly 220, but distortion rises rapidly - try 8.25% at 2V RMS output! The vast majority of that distortion is the result of the modulation of re as the collector voltage varies - as must the current through the load resistance and hence the emitter. This is explained for interest value - feel free to examine this yourselves, you will learn a great deal in the process.

You may have noticed that the vast majority of the design process involved only Ohm's law. It is commonly (but mistakenly) believed that all sorts of intricate maths are needed to design basic circuits. This is not the case at all.

2.2 - Single Transistor Summary

For many years, the single transistor stage was the fundamental building block of 'solid state' audio, and it must be admitted that these circuits did not compare particularly favourably (in some areas) to valves. Although the gain was more predictable, distortion was about equal for low levels, but the valve circuit with its much higher voltage had much greater headroom as well.

The advantages of the circuit were that it consumed almost no power (by comparison to valve circuits), was not microphonic, and had an indefinite life. Added to this was the fact that it also occupied very little space (again compared to valves), and it used a single supply voltage (no heater) that was a nice safe low voltage.

Compare the angst of having to perform all those calculations (and we didn't even consider noise contour curves or anything even remotely esoteric), with the ease of an opamp. There is no comparison. During the reign of germanium transistors things were even worse, because the leakage of germanium devices is so high (compared to silicon). Although the distortion is at a tolerable level, intermodulation products are higher than is desirable - 1kHz + 9kHz at 200mV input voltage each generates

intermodulation at -53dB relative to the 1kHz signal level. This will almost certainly be audible.

There is no reason to use circuitry of this type for any reason any more, as there are no benefits whatsoever.

3.0 - Two Transistor Feedback Pair

The increasing demands of customers and the need for circuits whose characteristics were fixed by resistors rather than device characteristics led to the design of better circuits. Device dependency was an issue that plagued valve equipment designers - if you wanted a different gain you often had to use a different valve. The ability to break away from that dependency was almost a miracle, and the improved circuits gained rapid acceptance.

All of these amplifiers are pure Class-A (as is the single transistor version), but the addition of feedback allowed much higher performance than was ever achieved with *any* preceding (affordable) technology. It was these circuits that essentially brought hi-fi to the masses - people were no longer satisfied with the 'mantel radio' (so-called because it fit neatly on the mantelpiece over the fireplace), and wanted better reproduction for prices that were not out of reach.

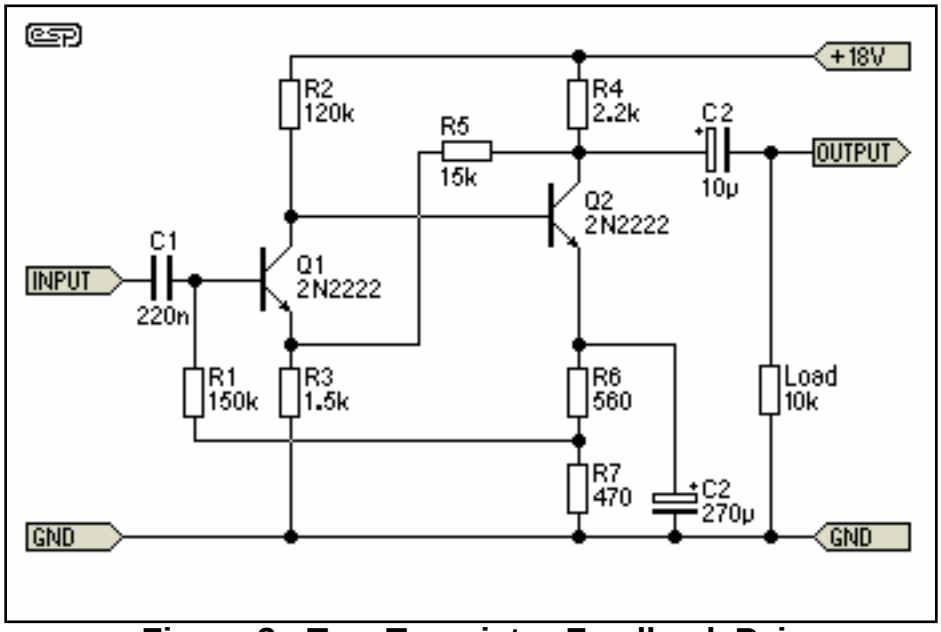

Figure 3 - Two Transistor Feedback Pair

Under exactly the same drive conditions, this circuit has a distortion of 0.065%. The spectrum is shown below, using the same axes as Fig 2. It is very apparent that it has

greatly reduced distortion. Although the harmonics do extend a little further than the first example, they are all well below the noise floor. This extension of the harmonics is obviously typical of feedback circuits, but when they are at such a low level it is of no consequence.

More interesting is intermodulation performance. Using the same criteria as in the first example, primary intermodulation products are at -63dB, 10dB lower than the simple amp above. Since intermod is by far more irritating and obtrusive than harmonic distortion, it is important to minimise this wherever possible.

It is worth pointing out at this stage that a simulated TL072 (not regarded as an audiophile opamp by any means) will give intermodulation figures under identical operating conditions that are **96dB** below the 1kHz or 9kHz levels. This is so much better than you will obtain with any of these circuits that it's just not worth considering them (IMHO). However, I have started this article, and will continue to the bitter end

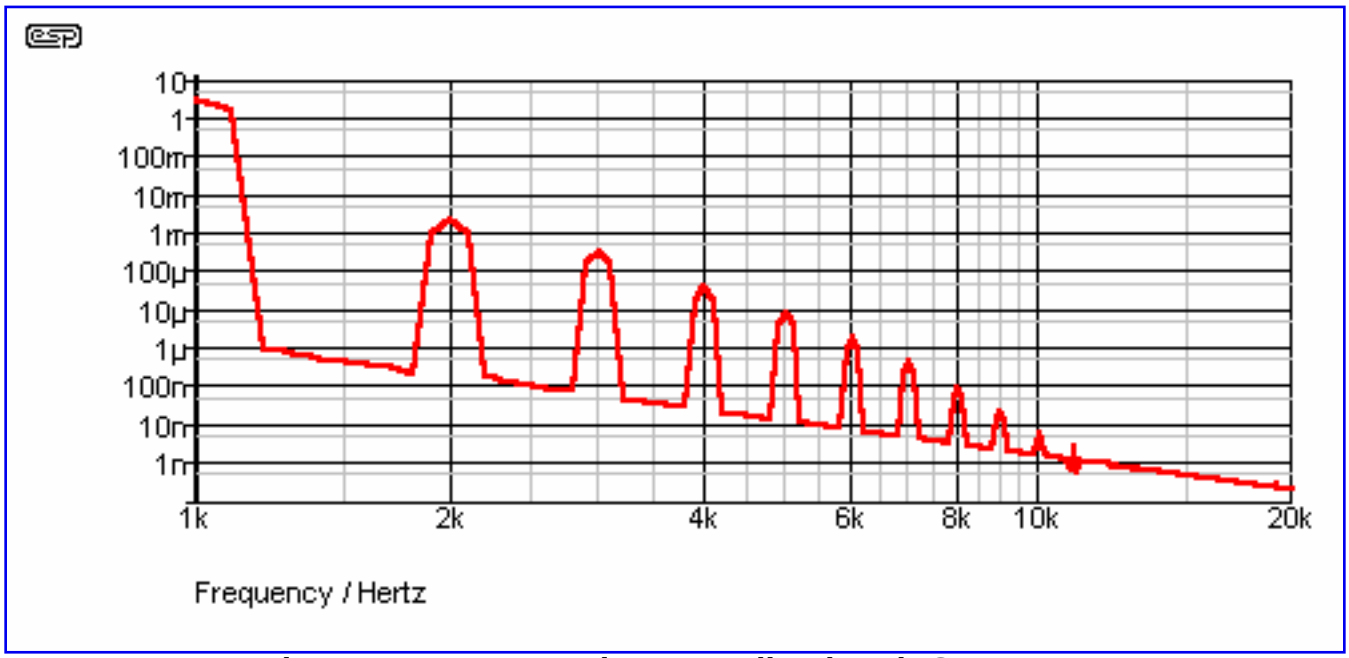

Figure 4 - Two Transistor Feedback Pair Spectrum

The distortion components are reduced, and to make comparison easier, click on the above image to open it in a new window. Now, you can go back to Figure 2 and compare the two. Not so readily apparent is the fact that input impedance is much higher and output impedance much lower than a simple amplifier stage.

These are important parameters for audio (and indeed for all amplification circuits). The input impedance of the Fig 3 amp is around 145k - not much less than the value of the bias resistor (R1). The input impedance of the base of Q1 is about 4.6Meg with the circuit shown, and this is almost entirely due to the feedback (applied via R5 to the

emitter of Q1). This feedback also defines the gain of the circuit, which is much closer to the design value (10 times, or 20dB). In theory, gain should be 11 - it can be worked out from ...

$$Av = (R5 + R3) / R3) = (15k + 1.5k) / 1.5k = 11$$

While it is easy to tweak the values to get the gain to exactly 10, in all cases in this examination we will be satisfied if it is within 3dB of the target. The circuit shown is a direct translation from the circuits presented in Reference 1 below.

Output impedance is harder to calculate than gain or input impedance, because you need to know the open loop gain of the amplifier. It was measured at about 82 ohms, a vast improvement, and this means that sensible load impedances will not change the gain of the amplifier. It is very important to understand that the output impedance of any amplifier does *not* mean that it can drive that impedance.

I measured the open loop gain of the simulated circuit at 1,220, so (in theory) the output impedance is equal to ...

$$Zout = R_{load} / Av_{open\ loop} = 1.8k / 2,220 = 81\ Ohms$$

Note that the effective load resistance is *always* equal to the collector resistance in parallel with the external load resistance. This applies for all transistor topologies, and is independent of feedback or anything else you may imagine.

Particularly with resistor loaded circuits, the peak current available is determined by the output resistor - for the Fig 3 circuit, this means that it cannot supply more than 4mA peak into any load, and it is important that this is not exceeded. In fact, the current demanded by the load (be it a following amplifier stage, a volume control or external equipment) should be no more than ½ the peak current available to maintain linearity. Ideally, it will always be much less than this. For the circuit shown, the minimum suggested load is around 10k, although it will tolerate less if the peak output voltage swing is restricted to no more than (say) ±3-4V.

It is impractical to try to describe the design process for this circuit - not because it is hard, but because it is just time-consuming. Anyone who is interested enough can use the principles used in 2.2 to analyse the circuit. Despite the additional complexity, the basic analysis methods are the same.

3.1 - Dual Transistor Feedback Pair Summary

This class of circuit pretty much sealed the fate of simple stages, and also entrenched the use of feedback as an indispensable tool to obtain improved performance with predictable results despite device parameter spread. Variations on these feedback amps were used for equalisers (especially RIAA phono and tape head preamps), microphone preamps, and a great many others.

Because of the tedious design process, Philips published a table of component values for different gains for the circuit of Fig. 3, although they probably could have saved themselves some trouble with a fairly simple design modification. By partially bypassing R3 (using a resistor and capacitor in series) the gain is easily modified, however, I have elected to reproduce the table below ...

Component	10dB Gain	20dB Gain	30dB Gain	40dB Gain
R1	150k	150k	150k	150k
R2	120k	120k	120k	120k
R3	4.7k	1.5k	1.5k	1k
R4	1.8k	2.2k	2.2k	2.2k
R5	12k	15k	56k	180k
R6	470R	560R	330R	680R
R7	1.2k	470R	270R	220R

Table 1 - Component Values for Different Gains (Figure 3)

It is recommended that a 10pF cap be wired in parallel with R5 for the 40dB gain version.

It is worth noting that there are two feedback loops in this design. One is DC only, and uses the voltage divider formed by R6 and R7. This biases the input transistor. The second feedback loop is via R5 and R3 - this is both AC and DC, so stabilises the DC operating conditions as well as the AC circuit gain.

All in all, this circuit was a breakthrough in the early days of transistor circuits, and I learned a great deal about the design process by analysing circuits such as this when I first became serious about electronics. That circuits such as this will never be the equal of one of today's opamps is readily apparent, but given the resurgence of people wanting to use discrete circuitry someone will hopefully find this information interesting. Even today (after so many years of electronics) it is still fascinating to see the ways that

were used to solve the problems that are inherent in all basic circuits.

4.0 - Buffers

Buffers were always a tricky issue before opamps, but the emitter follower is probably one of the best known single transistor circuit known. It is still used to this day in some cases, and is perfectly ok where extreme precision is not needed.

4.1 - Non-Inverting Buffers

The emitter follower is non-inverting, has very good linearity for a simple circuit, but does not have unity gain. Typically, the gain is quoted as being between about 0.90 to 0.99.

Figure 5 should be easily recognisable - this is a classic emitter follower. Gain is 0.98 and the circuit has very low distortion at 0.059%. The highest intermodulation product is at -65dB (using the same parameters as before). While not as good as an opamp, these figures are fairly respectable, and the circuit is very cheap and almost infinitely reliable. The distortion spectrum is not shown, but is almost identical to that in Figure 4.

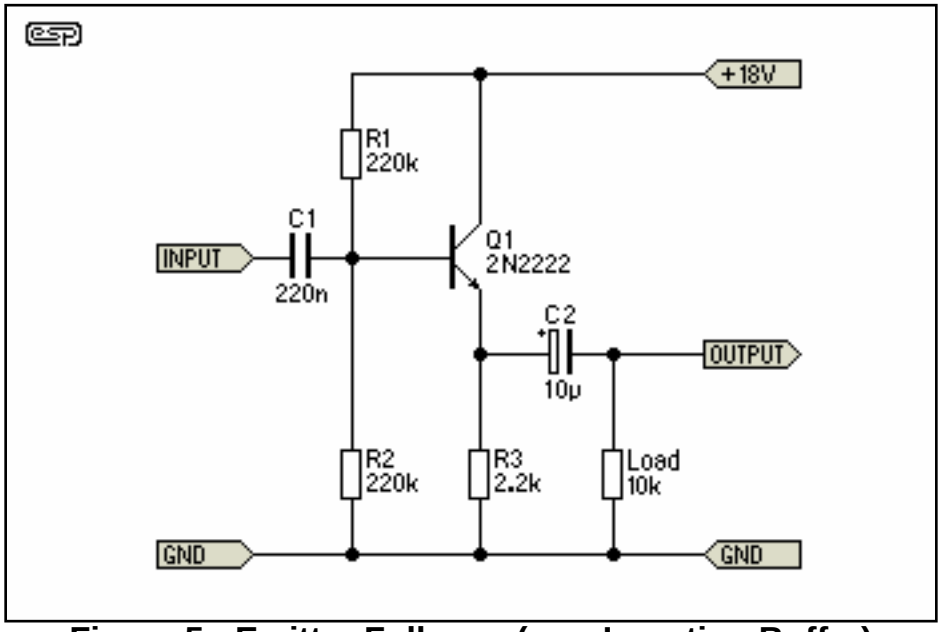

Figure 5 - Emitter Follower (non-Inverting Buffer)

The emitter follower is the easiest transistor circuit to design, requiring the absolute minimum of maths to get a working circuit. Indeed, in most cases you can simply grab a handful of resistors, a transistor and a couple of caps and be in business. It is important to make sure that the emitter resistor is capable of supplying the current needed by the

load, but this is usually as simple as making its value equal to around one fifth of the expected load impedance. For a load of 10k, that means a 2.2k resistor is fine.

Measurements of the Fig 5 circuit show that the input impedance at the base of Q1 is 390k. The calculation for this is simply (and roughly) ...

$$Zb = (Ze + re) * h_{FE} = 1.8k * 200 = 360k$$

Remember that re can be ignored if it is less than one tenth the value of the external load in parallel with the transistor's load resistance (now in the emitter circuit). Calculated and measured values are close enough. As before, total input impedance is

$$Zin = 1 / (1 / R1 + 1 / R2 + 1 / Zb) = 1 / (1 / 220k + 1 / 220k + 1 / 360k) = 84k$$

Output impedance is (approximately) equal to the total impedance seen by the base divided by the transistor's gain. This means that output impedance depends on the source impedance. This level of dependency affects all simple transistor circuits, where inputs are dependent on outputs or vice versa.

There is so little to the emitter follower that I have completely run out of things to say ... except that it must be remembered that an emitter follower operates with 100% local feedback, and the circuit will become unstable if a reactive load (such as a capacitor) is connected to the output. I always recommend that a series resistor be used at the output of any emitter follower that will drive a cable that is more than 100mm long.

Despite my claim that I've run out of things to say, there actually are many more things that could be said about emitter followers, but this article is intended to cover the basics - if every variation were to be discussed it would become a book.

4.0 - Inverting Buffers

Inverting buffers are harder with discrete transistors without excessive circuit complexity. This rather paradoxical state of affairs occurs because of the very nature of the transistor and how it works. While a simple amp is inverting, a simple buffer (emitter follower) is non-inverting. It is possible to create an inverting buffer using the two circuits in tandem, as shown in Figure 6.

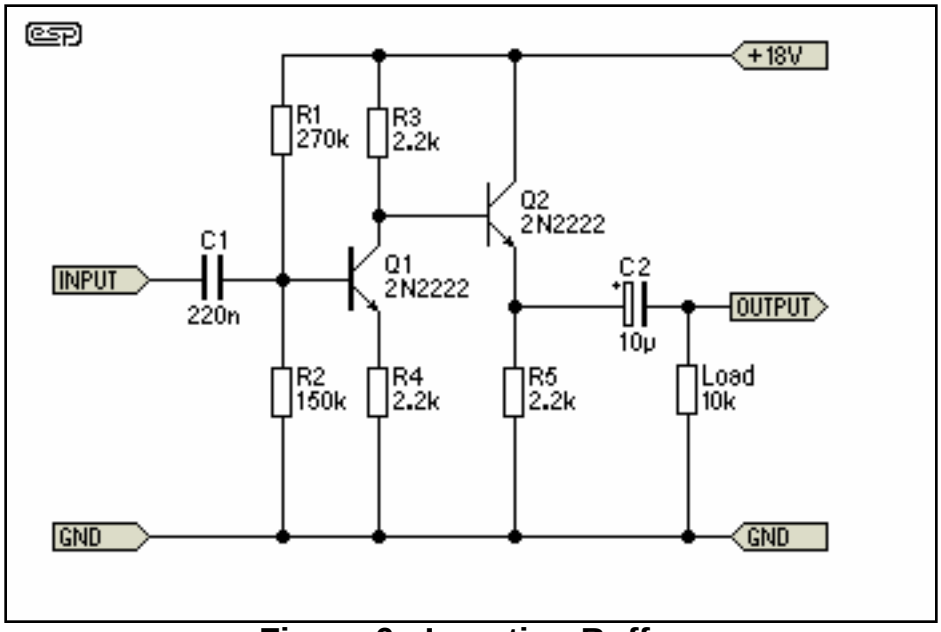

Figure 6 - Inverting Buffer

This circuit has many limitations, the main one being that voltage swing is rather limited. The absolute best that you can expect is about two thirds of the supply voltage (peak to peak), so for the circuit shown, about 12V P-P or about 4V RMS. Assume that you will actually get less than this - the circuit above will manage 3V RMS before clipping.

Because Q1 has the same resistor value for both collector and emitter, the voltages on each are essentially equal and opposite. The first stage therefore has unity gain, but inverted at the collector, while the emitter follower also has unity gain, but non-inverting.

4.3 - Buffers Summary

Simple transistor buffers are acceptable where one needs to provide a low output impedance with the minimum of fuss. The emitter follower is not good enough to use in accurate filters, as its gain of less than unity produces filters with a Q that is lower than expected, changing the filter characteristics.

The inverting buffer is a travesty - IMO it is next to useless. Given the limitations and complexity of the circuit, it is difficult to think of a single area where it might be used to advantage.

By comparison, even a cheap opamp will outperform either of these circuits in almost every respect, and with fewer components.

5.0 - Tone Control

The original Baxandall feedback tone control was based on a simple amplification stage. It was used with both valve and transistor circuits, and although it certainly works, it also has some bad habits when used this way. Again, the problem is mainly one of distortion - with only a limited amount of gain available, there is inevitably more distortion than is usually considered acceptable.

Figure 7 shows the basic arrangement, but it must be admitted that there were a great many alternatives that performed far better than the circuit shown here. Again, it is impossible to give all the variants (or even a subset) because there are so many. *All* of the discrete versions have worse distortion characteristics than a similar circuit made using an opamp of reasonable specification.

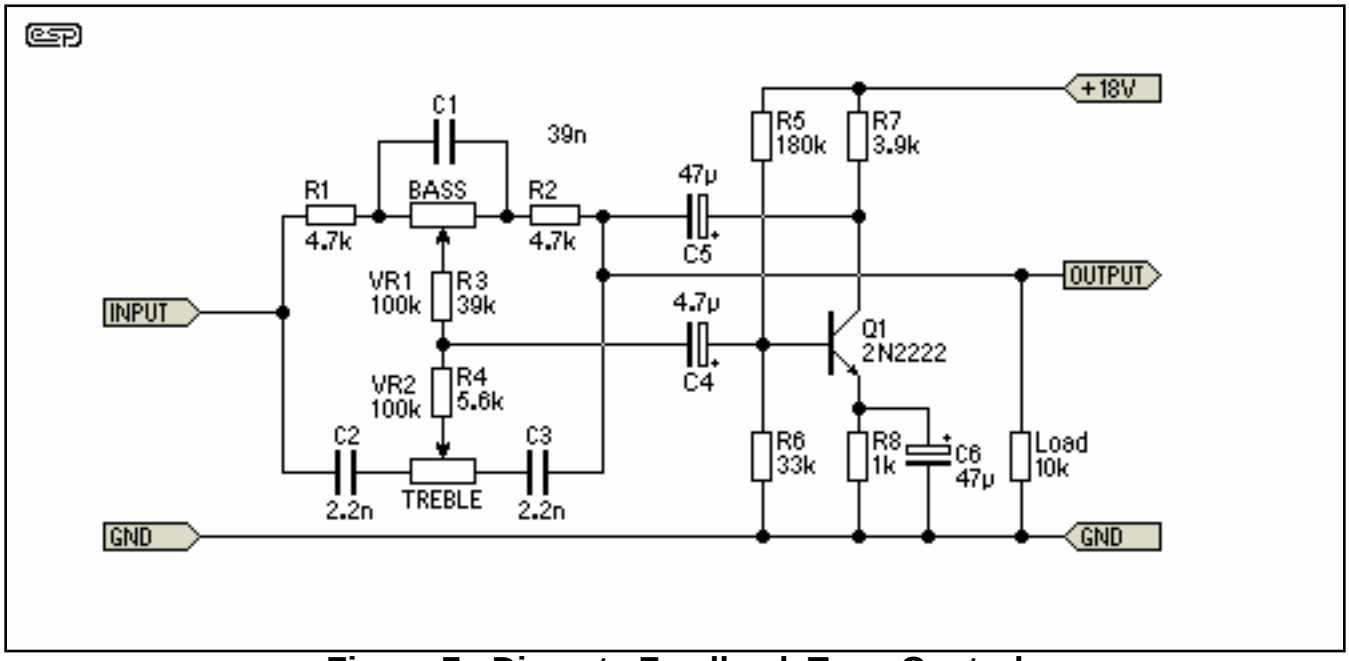

Figure 7 - Discrete Feedback Tone Control

Distortion is only around 0.03% with the controls centred, and it manages to stay reasonably constant at 1kHz regardless of setting. At either frequency extreme things change radically though. Intermodulation rises dramatically at maximum treble cut or boost, with the first intermodulation products at -32dB below the 9kHz tone at either extreme. It must be considered that if the system has to be used with maximum treble boost or cut, then intermodulation is probably the least of your problems.

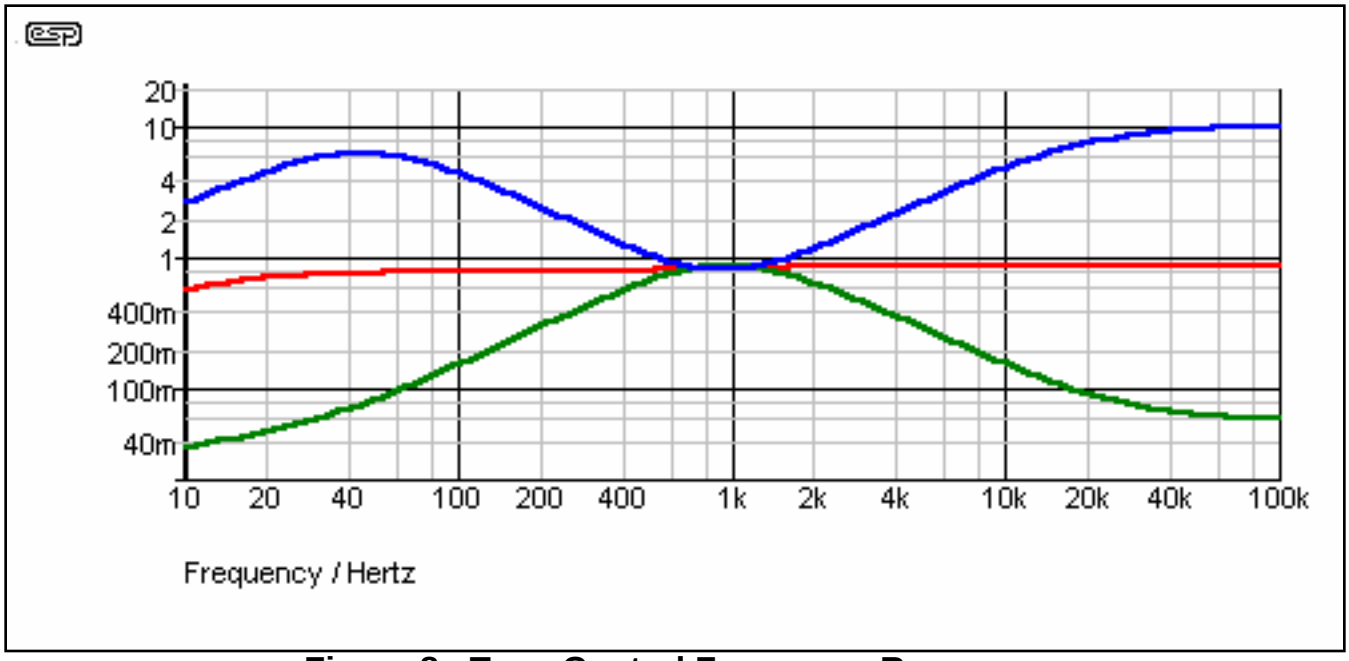

Figure 8 - Tone Control Frequency Response

The response is shown above. It is quite obvious that there is much more treble boost (especially) than you will ever need (or hear), with the boosted signal extending to 100kHz and well beyond. Bass is reasonably well behaved, but with the peak boost at 42Hz, it needs to be extended to work with a system with a subwoofer.

6.0 - Other Solutions

There is a lot to be said for discrete opamps - or at least circuits that have better performance than those looked at earlier in this article. With 0.024% THD and a very clean spectrum, the Project 37 amplifier is better than all of the alternatives shown previously. The main reason is the use of a current source (Q2) as the transistor load. Simply replacing Q2 with a 2.2k resistor increases THD to 0.25%.

To obtain the required gain (20dB), R5 had to be reduced to 1.5k - with 2.2k (theoretical gain of 11), the gain was well down from what it should have been. As we saw in previous examples, this is quite normal where the open loop gain is not high enough.

Although the circuit looks much more complex, it is only marginally worse in this respect than the circuit of Fig 3. The simple fact of the matter is that this level of performance is just not available from less complex circuits. As Einstein said, "All things should be as simple as possible, but no simpler". This is very true when it comes to circuits of this type, and in the author's opinion, far too many 'hi-fi' amplifiers are much simpler than they should be.

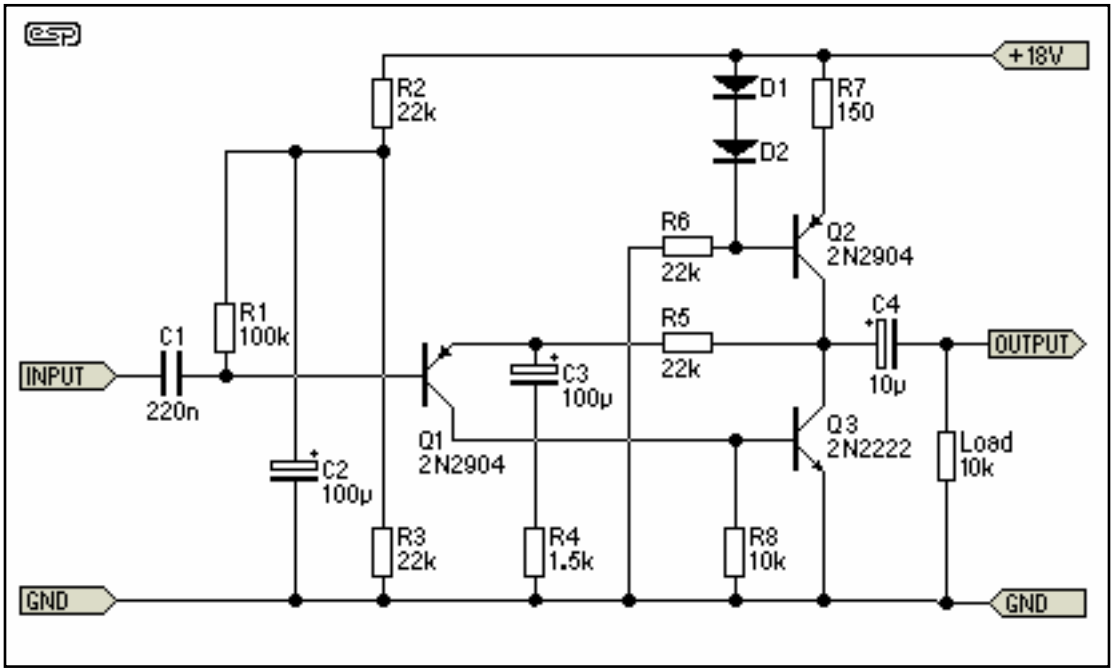

Figure 9 - Discrete Amp (as used in Project 37)

The spectrum is shown below. This shows that the harmonic structure is almost entirely second and third harmonic, and even the third is at -98dB. This is negligible, so it is not unreasonable to claim that distortion is almost entirely second harmonic. The intermodulation results are even better - the first intermodulation product is at -72dB, almost 10dB better than the Fig 3 circuit, and nearly 20dB better than the simple amp in Fig 1.

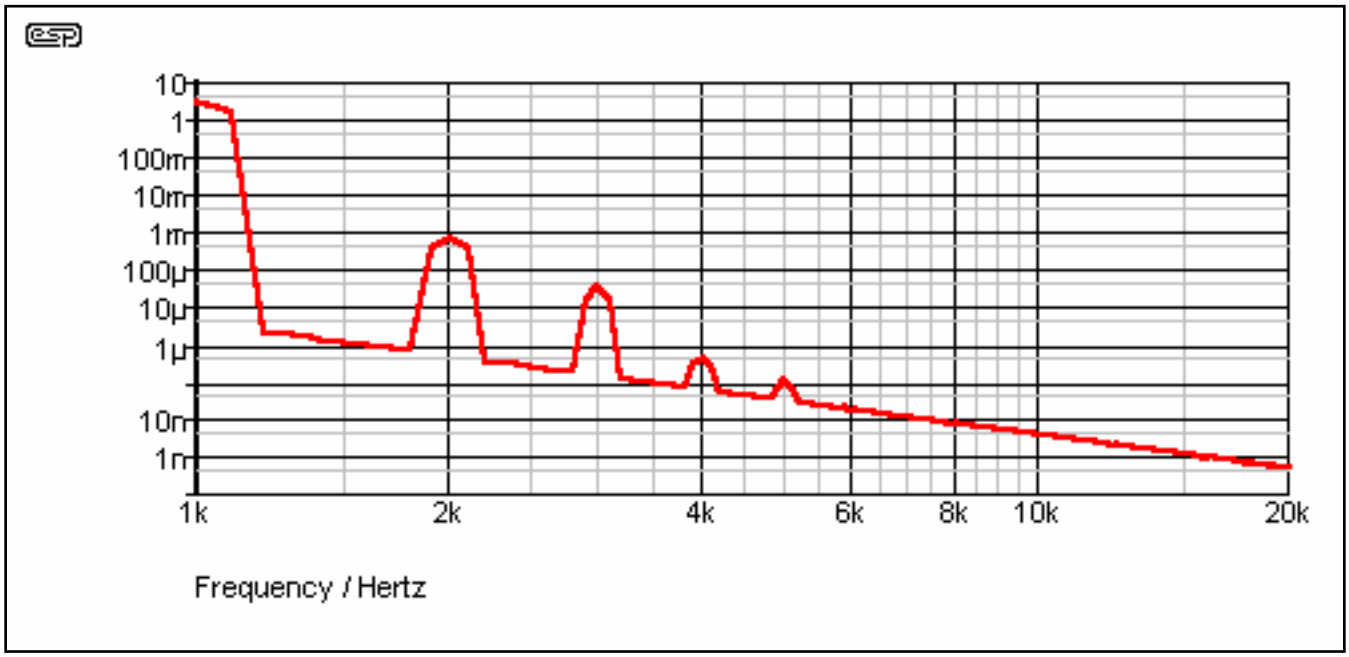

Figure 10 - Distortion Spectrum

The input impedance is about 96k - note the biasing arrangement, which is designed to minimise noise and maximise input impedance. C2 decouples any supply noise, and

bias current is applied via R1. Q1's base input impedance is greater than 2.8 Meg, so R1 could be increased if desired.

It is fairly obvious that the small increase in complexity has yielded a large benefit - much lower distortion being the major improvement. This is particularly important for intermodulation distortion, and this is markedly improved from any of the alternatives.

7.0 - Conclusion

From the details here, it is easy to see that it it not easy to obtain good performance from simple discrete circuits. While improved versions (such as the P37 preamp we looked at in section 6) do perform very well, in general the 'old' circuits do not.

They were certainly an enormous improvement in their day, but that day has passed. Modern opamps are so superior that there is no reason to look elsewhere, unless you wish to experiment and learn more about the design processes involved. While there is certainly some historical value in the circuits shown, they are no longer to the standard expected of true high fidelity.

Where the simulator shows that the first intermodulation product using a TL072 is 109dB below the 9kHz tone, none of the circuits shown come even close to this. The P37 amp is certainly better than any of the others, but it is still significantly worse then the opamp. It is probable that the intermod from P37 is inaudible (after all, many people have commented on just how good it sounds), and it is equally probable that the simulator over-estimated the TL072's quality - it *is* a simulator, after all. I ran a new intermodulation test using an LM324 opamp (hardly a reknowned device for audio), and SIMetrix said that intermod was at -68dB. From that, we can deduce that the models are reasonable so the simulated results will not be too far from reality.

There is no doubt that devices such as the OPA2134 or the venerable NE5534 (or the dual version, NE5532) will be much better than anything shown here, but will they *sound* as good, better or worse? This is something that can only be determined with a proper blind AB test. Logically, it probably should not be possible to hear the difference between either opamp, or the P37 circuit. As for the others ... I don't know, but if you ever find out, be sure to let me know.

Introduction

Having searched the Web for reference material (and found very little!), this would appear to be the definitive article on the design of a 'simple' linear power supply for a power amplifier. Power supplies are needed for every type of amplifier we will ever use. I do not intend to deal with "esoteric" designs with interesting names, but the simple, linear power supply that is still the mainstay of audio.

These supplies should not create any problems for anyone, because they are so simple, right? *Wrong!* They appear simple, but there are many inter-related factors that should be considered before just embarking on your next masterpiece. The purpose of this article is to explain the terminology used, traps and pitfalls, and give some insight by way of a few practical examples.

Power Amplifier Definitions

Power supplies themselves require several definitions (these are discussed later in this article), but the requirements of the amplifier that is to be connected need to be understood before we start. This makes a very big difference to the way the supply performs.

Poor earthing practices, such as connecting components to the nearest available ground reference can (and do) also create problems, and these can introduce hum, or more usually a "buzz" into the signal circuits. This applies equally to Class-AB and Class-A amplifiers, but is usually more apparent with Class-A since the maximum current is drawn on a continuous basis.

Class-AB Amplifiers

I shall refer to the standard power amplifier as Class-AB - of all the amplifier types, these are the most common. Any amp that draws a quiescent current through the output devices is by definition, Class-AB. For true Class-B, there is no quiescent at all, and the output devices will conduct for exactly 180 degrees - this is rare.

Class-AB amps have a very widely varying current drain, which may be only 100mA or less with no signal, but rising to many amps when driven. The main problem is the revolting waveshape of the current on each supply lead, typically half-wave pulses, in sympathy with the program content.

These waveforms - this is current, not voltage - have sharply defined transitions, and as such will generate a magnetic field which varies with the current. Since a sharp transition equates to high order harmonics, care must be taken to ensure that voltages are not induced into the input stages of the amp from the supply lines. Because of the low inductance of the wiring of an amp, these problems are going to create distortion components which will tend to be worse at higher frequencies.

It is not only the amplifier which creates current pulses, but the rectifier/ filter capacitor combination as well. The power supply rectifier diodes usually conduct for only a short time during each AC cycle - this may be as little as 3 or 4 degrees at idle, but both the angle of conduction and the amplitude of the current pulse will increase as more power is drawn from the supply.

Class-A Amplifiers

The other common amplifier type is Class-A. These amps draw a large current on a continuous basis, and place a completely different loading on the supply. The current pulses are gone from the supply leads, but the rectifier and filter now must handle the maximum current on a continuous basis.

The continuous load creates a new set of constraints on the design of a power supply, and the use of a Class-A amp implies that the builder already wants the very lowest noise. Although the noise of the power supply DC output (hum/ ripple) will normally be low because of extensive filtering, regulation or a capacitance multiplier, the switching noise of the diodes in the rectifier can become more than a nuisance if proper care is not taken.

Power Supply Requirements

Somewhat surprisingly perhaps, the fundamental requirements of the final design are not greatly influenced by the different loading presented by the two amp types described above. The continuous rating of a Class-A amp means that you must design the supply for a continuous (rather than transient) current, but since we are discussing properly designed, quality power supplies, the final result will often be quite similar.

When a power supply is used with an amplifier, the basic things we need to know before starting are as follows

- Power output and minimum impedance, or ...
- Peak / average current

Acceptable power supply ripple voltage

With only these three criteria, it is possible to design a suitable supply for almost any amplifier. I shall not be describing high current regulators or capacitance multipliers in this article - only the basic elements of the supply itself. These other devices are complete designs in themselves, and rely on the rectifier/ filter combination to provide them with DC of suitable voltage and current.

Transformers

The first component of the power supply is the transformer. Using magnetic coupling between windings, the transformer is used to isolate the amplifier (and the users) from the mains voltage, and to reduce (for solid state equipment at least) the voltage to something the amplifier can tolerate. The primary winding will be rated at 240, 220 or 120V AC depending on where you live, and the secondary will be a more user friendly (or less user hostile) voltage to suit the amplifier.

DC Output: The DC output is approximately equal to the secondary voltage multiplied by 1.414, but as we shall see, this is a rather simplistic calculation, and does not take the many variables into consideration. At light loading, this rule can be applied without fear, and it will be accurate enough for most applications. When an appreciable current is drawn, this simple approach falls flat on its face.

Mains variations: These occur in all situations, and the mains voltage at any point in time will usually be somewhat different from the nominal voltage quoted by the supplier. Any variation of 10% or less can be considered "normal", and greater variations are not at all uncommon. In nearly all cases, an amplifier is rated at a certain power output into a specified load impedance, and at the nominal mains voltage. For those who live close to a sub-station or pole transformer, expect the voltage (and power output) to be higher than quoted - the rest of us can expect a lower mains voltage and less power, especially during peak electricity usage times.

Losses: Since all transformers have losses, these cannot be ignored in the design phase. Magnetising loss (AKA iron loss) is the current that is required to maintain the design value of magnetic flux in the transformer core. There is nothing you can do to affect this loss, as it is dependent on the size of the core and the design criteria of the manufacturer. Large transformers will have a larger magnetising loss than small ones, but will be less affected by it due to the larger surface area which allows the transformer to remain cool at no load. Small transformers have a greater loss per VA than bigger

ones, and this is one of the reasons that small transformers run quite warm even when unloaded.

The iron losses are greatest at no-load and fall as more current is drawn from the transformer. Copper losses are caused by the resistance of the winding, and are negligible at no load, and rise with increasing output current. There is a fine balance between iron and copper losses during transformer design. A relatively high iron loss means that copper losses will be reduced (thus improving regulation), but if too high, the transformer will overheat with no load. A full description of the magnetising current and its effect on regulation is outside the scope of this article, and since there is little you can do about it, it shall be discussed no further.

Mains noise: Noise can easily get through a transformer, both in transverse and common modes. Transverse noise is any noise or waveform distortion that is effectively superimposed on the incoming AC waveform, and this is coupled through the transformer along with the wanted signal - the mains.

Common mode noise is any noise signal that is common to both the active (hot) and neutral mains leads. This is not coupled through the transformer magnetically, but capacitively. The higher the capacitance between primary and secondary windings, the more common mode noise will get through to the amplifier. The much loved toroidal transformer is much worse than conventional "EI" (Ee-Eye) lamination transformers in this respect because of the large inter-winding capacitance. An electrostatic shield will help, but these are uncommon in mass produced toroidal transformers. The conventional transformer is usually better, and by using side-by-side windings instead of the more common (and cheaper) concentric windings, common mode noise can be reduced by an order of magnitude.

Input mains filters can remove either form of high frequency noise component to some degree, and large spikes can be removed using Metal Oxide Varistors (MOVs) that effectively short circuit the noise pulse, reducing it to a level that is (hopefully) inaudible. Contrary to the beliefs of some, there is no panacea for noise, and it is best attacked in the equipment, rather than the now popular (but mainly misconceived) notion that an expensive mains lead will cure all.

Regulation: The "regulation" of typical power transformers seems to be rather poor when some measurements are taken on a complete power supply. When specified, regulation is based upon a resistive load over the full cycle, but when used in a capacitor input filter (99.9% of all amplifier power supplies), the quoted and measured figures will never match.

Since the applied AC spends so much of its time at a voltage lower than that of the capacitor, there is no diode conduction. During the brief periods when the diode conducts, the transformer has to replace all energy drained from the capacitor in the intervening 7 to 8ms or so (assuming 50Hz and full wave rectification).

Consider a power supply as shown in Figure 1. This is a completely conventional full-wave capacitor input filter (it is shown as single polarity for convenience). The circuit is assumed to have a total effective series resistance of 1 Ohm - this includes transformer winding resistances (primary and secondary) and diode losses. The capacitor C1 has an initial value of 4,700uF.

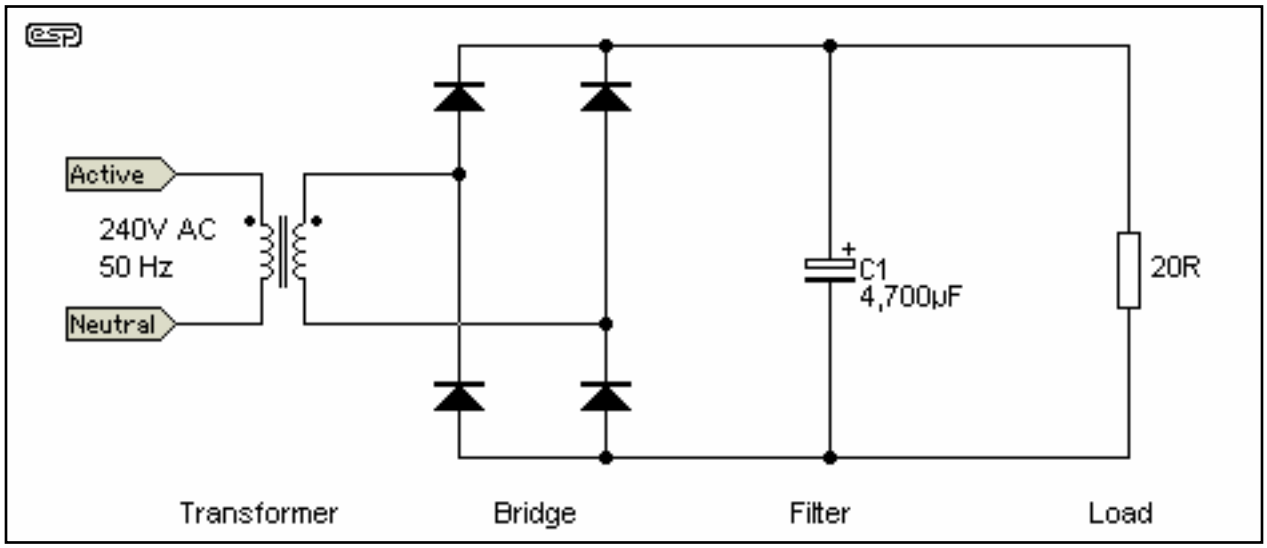

Figure 1 - Full Wave, Capacitor Input Filter Rectifier

The transformer is rated at 60VA and has a primary resistance of 15 Ohms, and a secondary resistance of 0.5 Ohms. This calculates to an internal "copper loss" of 0.75 Ohm.

With a 20 Ohm load as shown, and at an output current of about 1.7 amps (1.69A actually), diode conduction is about 2.8ms, and the peak value of the current flowing into the capacitor is 6A - 100 times per second (10ms interval). Diode conduction is therefore 28% of the cycle. (To check that these figures are valid, we can take the peak capacitor current and the duty cycle, and calculate the average ...

$I_a = (I_p / 100) * \text{duty cycle}$ so, $I_a = (6 / 100) * 28 = 1.68$

(close enough for our purposes)

Ripple across the load is 2.4V peak-peak (or about 740mV RMS), and is the traditional

sawtooth waveform. Average DC load voltage is 33.8V. The no-load voltage of this supply is 41V, so at a mere 1.7A load, the regulation is ...

$$\text{Reg (\%)} = ((V_n - V_l) / Vn) * 100 = 17.5\%$$

Where V_n is the no-load voltage, and V_l is the loaded voltage.

For this example, this works out to 17.5% which is terrible. By comparison, the actual transformer regulation would be in the order of 5% for a load current of 2A at 30V. Note that the RMS current in the secondary of the transformer will be just over 3 amps AC for a load current of 1.7A DC - this must be so, since otherwise we would be getting something for nothing - a practice frowned upon by physics and the taxman.

Output power is 33.8V * 1.7A = 57.46W, and input power is 240V * 0.25A = 60VA. The losses are caused by the diode voltage drop and winding resistance of the transformer.

Transformer Series Resistance

As described above, I assumed a total equivalent series resistance for the transformer of 0.75 Ohm, which is about typical for a 60VA transformer as used here. Larger transformers will have lower series resistance (and vice versa), and the equivalent may be calculated - this is easier than actually measuring it under load.

If the secondary resistance is (say) 0.5 Ohm for a 240V to 30V transformer, it will be found that the primary resistance is (or should be) in the order of 15 Ohms. The actual figure will vary from one transformer type to another (e.g. "conventional" EI (ee-eye) laminations versus toroidal).

The effective primary series resistance is calculated (approximately) by ...

$$R_e = R_p / (T_r)^2$$

Where R_e is equivalent primary resistance, R_p is measured primary resistance, and T_r is the turns ratio (in this case, 240 / 30 = 8

Therefore ...

$$R_e = 15 / 64 = .234 \text{ Ohm}$$

This value is now added to the secondary resistance to calculate total series resistance. Please don't bother to e-mail to tell me that these figures are not correct - this is intended as a rough approximation - calculating actual values for transformers is worthy of an article in itself (which I am not about to write! :-)

The sad truth is that accuracy here is completely unimportant, as there is also series resistance in the mains power wiring from the power generation plant all the way to the power transformer primary winding. This is going to vary from one outlet to another and from one house to the next. Although it can be measured, this is a completely pointless exercise since it will only be relevant for one household. Other factors are the actual supply voltage (nominal 115V, 220V, 240V, etc.) which varies widely from day to day and hour to hour. (For what its worth, the actual supply voltage was 233V when I measured the mains impedance at approximately 0.8 Ohms at my workbench - does this help?). We shall now do what everyone else does, and ignore it completely.

However - again for what its worth - your 100W / 8 Ohm amplifier will be reduced to just over 90W, simply by connecting a 2400W heater to an adjacent power outlet, based on 0.8 Ohms mains wiring impedance and a genuine 240V supply voltage (before connection of the heater). The situation is likely to be slightly worse in the US, because the much lower AC supply voltage means that all currents are doubled for the same power.

VA Versus Watts

An important distinction must be made between power (Watts) and VA. Power is a measure of work, and it is quite possible (common, actually) to have a situation where there is voltage and current, but little or no work. The product of voltage and current is Volts * Amps, or VA, and there is commonly a wide variance between VA and Watts.

Various loads (capacitive or inductive) will draw current from the output of a transformer, amplifier or the mains supply. If the load is purely inductive or capacitive, there is no power (work) at all, even though the current may be quite high. Fluorescent lighting fixtures are renowned for this, where the current can be several times what was expected based on the power rating of the tubes.

This phenomenon is called "power factor", and a power factor of 1 means that there are no power losses due to inductance or capacitance. Likewise, a power factor (PF) of 0 means that there is lots of voltage and current, but no power. In the case of fluorescent

lighting, power factor correction capacitors are used to try to maintain the PF at as close to unity as possible. If this were not done, the wiring to the fittings (especially in large commercial buildings) will overheat, and a much greater load than necessary is placed on the local power sub-station, and indeed on the entire power grid. Electricity supply companies worldwide have the same problems, and in most countries, there is legislation that determines the minimum acceptable power factor for any installation.

The switch mode power supplies used in computers have a very poor PF, and there are many new designs that improve this. These can be expected to become mandatory in the not too distant future, as a poor power factor makes electricity more expensive to supply, and therefore more expensive for the consumer.

Note that I do not propose to cover the topic of power factor in depth (in fact that was it!), but a basic understanding is useful, and will make some of the following information more sensible.

A power transformer does not care if work is being done at the output or not. It has internal resistance and inductive losses, and cares only about the output voltage and current. A power transformer can be overloaded and destroyed by a large capacitance directly across the output terminals. The capacitor does not even get warm, since it dissipates no power and does no work. The transformer "sees" only the load current, and heats up proportionally - if the VA rating is exceeded consistently, the transformer will eventually overheat and die. Equally, a transformer may be operated at 500% of its ratings for a short period, and as long as it has enough time to cool down between overloads, will be unaffected by the ordeal. Unfortunately, this otherwise useful characteristic is pointless in audio, since the voltage will fall too far with the load, and amplifier power output suffers badly. Having said this, most "mainstream" power amps will economise on the transformer, and rely on the duty cycle of typical programme material to provide an adequate supply voltage for normal music signals. The continuous (erroneously called "RMS") power will be lower, sometimes significantly.

The term "dynamic headroom" used to be used to describe the difference between continuous and peak output power. A large figure (2dB or more) indicates that the transformer is too small for the job, since the supply voltage collapses under a sustained load.

Because we are going to use the transformer in an unfriendly manner, with a rectifier and large capacitance as the load, the VA rating is much higher than the power rating of the amplifier may indicate. There are some basic rules of thumb for the most common rectifier types, and these are shown below.

Further Analysis

To properly see the effects of the losses and currents involved, a simpler circuit will be used from this point. This consists of a 25V RMS "ideal" generator, and the copper losses are simulated by a resistance. Since the full-wave bridge rectifier is a very common configuration, this is what shall be used for the detailed analyses that follow. There are variations and exceptions to everything, but simulations and real-life testing on these simple circuits are very close, so this is what shall be used.

A simple resistance is the load, and we shall see the vast differences in peak AC current, capacitor ripple current and output voltage as the various parameters are changed. A solid understanding of the behaviour of the transformer, rectifier and filter capacitor is essential if worthwhile power supplies are to be designed.

Voltages and Currents

Figure 2 shows the voltages and currents present in a typical supply. The waveforms will be examined shortly - for now we are interested in the average current and voltage in each section of the supply. The generator voltage is 25V RMS, and for this supply I have used a winding resistance of 0.75 Ohm - roughly equivalent to a 120VA transformer. The voltages and currents are all RMS - although in practice very few RMS meters can give an accurate reading of the spiky current waveform.

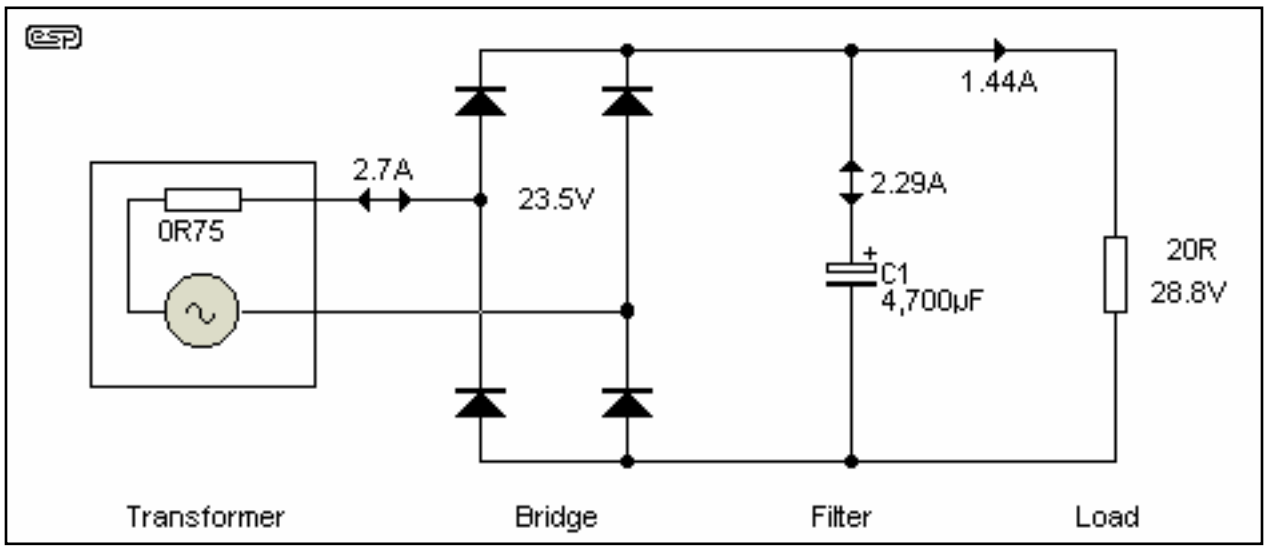

Figure 2 - Basic Bridge Rectifier - Voltages and Currents

Note the big difference between DC output current, capacitor ripple current and AC input

current. The important parameters are listed in the table below ...

Parameter	RMS	Peak
AC Voltage	23.6 V	31 V
AC Current	2.70 A	6.25 A
DC Voltage	28.8 V	-
DC Current	1.44 A	-
Ripple Current	2.29 A	4.8 A **
Ripple Voltage	650 mV	2 V (P-P)

Table 1 - Supply Voltages and Currents

** This figure is somewhat misleading, since there is both a charge and discharge cycle. During the discharge, there is a relatively constant current of -1.44A (the negative means the current is flowing out of the capacitor). During the charge period, the rectifier takes over the supply of current to the load, then re-charges the capacitor at the peak current shown.

Input power is 25V * 2.7A, or 67 VA, and output power is 41W, so in all, over 26W has been lost in the rectification and filtering process. About 2.6W is lost as copper losses in the transformer (dissipated in the 0.75 ohm resistor that simulates the winding resistances). Attempting to quantify each individual loss is a relatively pointless exercise, since the end result is to make a power supply that works - we can do nothing about the losses. In reality, many of the losses are very different from those calculated, since the RMS values are somewhat dubious (although quite OK for the purpose of this article).

About 0.9V is lost across each diode during conduction, but this will vary in practice, based on the current capacity of the rectifier diodes. Since this is a bridge rectifier, there are two diodes conducting at the +ve and -ve peaks of the waveform, so the total voltage loss is 1.8V - so the output DC should be around 32V. The measured values of 23.6V AC and 28.8V DC is a direct result of the measurement inaccuracy! Because current is drawn only at the peak of the AC waveform, the input to the rectifiers is not a sinewave. The voltage and current waveforms are shown below, and it can be seen that the voltage waveform has been "flattened" at the peaks. This is due to the high peak current drawn during this time, and no voltmeter will give the correct value - you must use an oscilloscope to be able to measure the peak-to-peak value of the waveform.

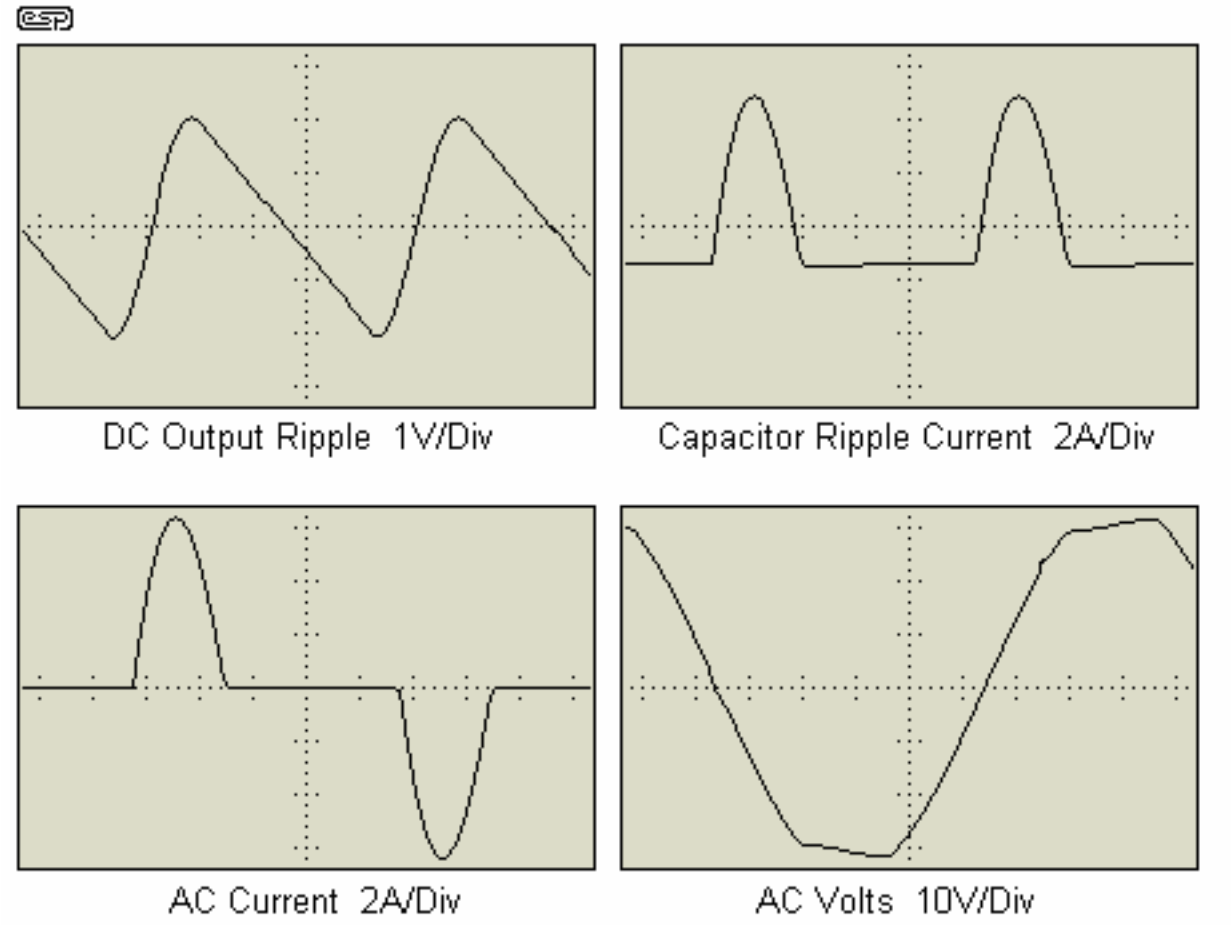

Figure 3 - Voltage and Current Waveforms

This reveals very different information from the voltage and current measurements taken before. Both are essential in understanding the rectification process. The peak AC input is only 31V, where we would normally expect 25 * 1.414 = 35V or (allowing for the voltage drop within the transformer) 33.4V. We have some missing voltage (31 - 1.8 is 29.2, not the 28.8V measured) if we simply use normal multimeters. Examination with the oscilloscope shows that the peak DC voltage is higher than the average value shown by the meter, and is 29.2V, so everything really does fall into place.

It must be pointed out that these waveforms were taken at different times, and are not exactly in phase. The positive going part of the output ripple voltage, the peaks of the AC current, the positive peaks in capacitor ripple current and the flattening of the AC input voltage all occur at exactly the same time.

Increasing Capacitance / Transformer Size

It is well known that bigger transformers have better efficiency than small ones, so it is a common practice to use a transformer that is over-rated for the application. This can

improve the effective regulation considerably, but also places greater stresses on the filter capacitor due to higher ripple current. This is quoted in manufacturer data for capacitors intended for use in power supplies, and must not be exceeded. Excessive ripple current will cause overheating and eventual failure of the capacitor.

Capacitor ripple current ratings can be ignored at your peril.

Large capacitors usually have a higher ripple current rating than small ones (both physical size and capacitance). It is useful to know that two 4,700uF caps will usually have a higher combined ripple current than a single 10,000uF cap, and will also show a lower ESR (equivalent series resistance). The combination will generally be cheaper as well - one of the very few instances where you really can get something for nothing. Using ten 1,000uF caps will generally give even better overall figures again, but the cost (in time and effort) of assembling them into a proper filter bank may not be felt worthwhile.

Above a specific value, as the capacitance is increased, the peak charging current will remain much the same for the same sized transformer, but the capacitor retains more of its charge between cycles. The switch-on current will be very much higher, and the surge will last longer as the capacitor charges. At capacitor values below optimum, the peak charge current will decrease somewhat, but there will be far greater output ripple.

There is no hard and fast rule for determining the optimum value for the filter cap, but in general I would suggest that the value should be at least that required to give a full load ripple voltage of less than 5V peak to peak. Based on this, my recommendation is that the absolute minimum value is 2,000uF per amp DC, so a 5A (continuous) power supply will have an absolute minimum of 10,000uF capacitance.

What is achieved by increasing the capacitance, is the ability of the capacitors to retain more of their charge between AC cycles. Since the current demands of a Class-AB amplifier vary so widely - with the majority of the time at very low average currents - the actual operating voltage will be closer to the no-load voltage.

With large capacitors, the momentary current peaks created by the program material will not be of sufficient duration to discharge the caps to the full load voltage levels, so there is more voltage available on a more or less consistent basis. This equates to more power for transient signals, and lower ripple voltages the rest of the time.

With a 4,700uF capacitor and a peak current of 5A (equivalent to the peak current of a 100W amp into 8 Ohms), the capacitor will lose voltage at the rate of 1V / ms between

"charges". As the capacitance is increased, this discharge rate naturally falls proportional to the capacitance. Doubling the capacitance halves the discharge rate and the ripple voltage for a given current, but increases the capacitor ripple current and the peak AC current - although the average value remains much the same. There are some small variations, but these are eventually accounted for if we analyse the waveforms critically - again, this is a relatively pointless exercise, and will not be undertaken.

What we will do, is see what happens in each individual case when ...

- The capacitance is increased
- The transformer is made bigger

Table 2 shows the currents and voltages with the same transformer used in Figure 2, but with a 10,000uF filter cap. There are insignificant increases in currents, and no worthwhile increase in the average DC output voltage. Output ripple is half that of the previous example. As can be seen, more capacitance will affect the DC ripple voltage but little else, and one may wonder if it is worth the effort (the answer is generally "yes", but it depends on the application).

Parameter	RMS	Peak
AC Voltage	23.6 V	31 V
AC Current	2.71 A	6.27 A
DC Voltage	28.8 V	-
DC Current	1.44 A	-
Ripple Current	2.29 A	4.8 A
Ripple Voltage	306 mV	1 V (P-P)

Table 2 - 120 VA Transformer / 10,000uF

Table 3 is the same data, with the original 4,700uF capacitor, but now with a transformer having 0.5 of the original total winding resistance (0.375 ohms) - this is equivalent to a transformer of about 4 times the 120VA rating used before (or about 500 VA).

Parameter	RMS	Peak
AC Voltage	24.2 V	32 V
AC Current	3.15 A	8.32 A
DC Voltage	30.3 V	-
DC Current	1.52 A	-

Ripple Current	2.76 A	6.8 A **
Ripple Voltage	731 mV	2.2 V (P-P)

Table 3 - 500 VA Transformer / 4,700uF

The increases in both average and peak currents are quite substantial, and the output voltage is higher by a small (but not especially useful) amount. The DC current is higher, only because the voltage is greater, and this is the sole reason for the increase in ripple voltage. The big test is to use the 10,000uF filter cap with this very much larger transformer, and see what increases occur.

Parameter	**RMS**	**Peak**
AC Voltage	24.2 V	32 V
AC Current	3.15 A	8.52 A
DC Voltage	30.4 V	-
DC Current	1.52 A	-
Ripple Current	2.79 A	7.0 A **
Ripple Voltage	345 mV	1.16 V (P-P)

Table 4 - 500VA Transformer / 10,000uF

In case anyone is wondering why I used a load resistance of 20 Ohms, this was to simulate one half of a 55W Class-AB amplifier operating at the onset of clipping into an 8 Ohm load, with a steady sinewave input. Any dynamic analysis is very difficult, and the results are not particularly meaningful unless the exact signal source is known, along with the specifics of the power amplifier that is connected to the supply.

> Actually, the current of 1.44A is slightly on the high side, since the RMS current will only be about 1.375A, which is 1/2 the speaker current (the other half of the speaker current is provided by the negative power supply).

In these calculations, I also made no allowance for the fact that nearly all transformers are rated for an output voltage at full current - this is invariably the voltage into a resistive load, and not a rectifier / filter combination. This means that the voltage will always be a little higher than specified at no load, and now you know why the DC is less than expected at full load.

Rectifier Types

So far we have looked at the full wave bridge rectifier, and this is but one of several different configurations. The most common rectifiers are ...

- Full Wave Bridge
- Full Wave
- Dual Full Wave (Full Wave Centre Tap)

There are others, but they are not commonly used in low voltage amplifiers. The dual full wave (using a bridge rectifier and a centre tapped transformer) is probably the most common of all, and some further analysis of this rectifier shall be covered next. I have chosen to ignore half wave rectifiers (in all their forms) and voltage doublers, since these are normally only used for low power applications where their operation is not critical. This is especially true of preamp supplies, which will almost always be followed by a regulator.

The full wave voltage doubler is still common in valve amplifier circuits and for preamp supplies.

Of the major types, the generally accepted voltage and current ratios are as follows ...

Rectifier Type	Filter Type *	RMS AC Input
Full Wave	Capacitor Input	DC x 1.2 **
Full Wave CT	Capacitor Input	DC x 1.2 **
Bridge	Capacitor Input	DC x 1.8

Table 5 - DC Output Vs. AC Input Current

* Choke input filters have not been included, since although they provide superior filtering and lower noise, they are very expensive to produce because of the sheer size of the inductance.
** This figure is for each winding of the transformer.

As can be seen from the circuits analysed so far, the figure for bridge rectifiers (AC current 1.8 times the DC current) is close enough to what was measured. It must be remembered that this is not an exact science, since there are so many variables to deal with.

Full Wave Rectifier

Unlike the bridge rectifier which uses 100% of the transformer winding at all times, the

full wave rectifier uses only 1/2 of the winding on each half cycle of the AC waveform. This leads to some additional losses, since the winding must be double the number of turns of that for a bridge rectifier. This usually means that the winding resistance is more than double that for a bridge rectifier.

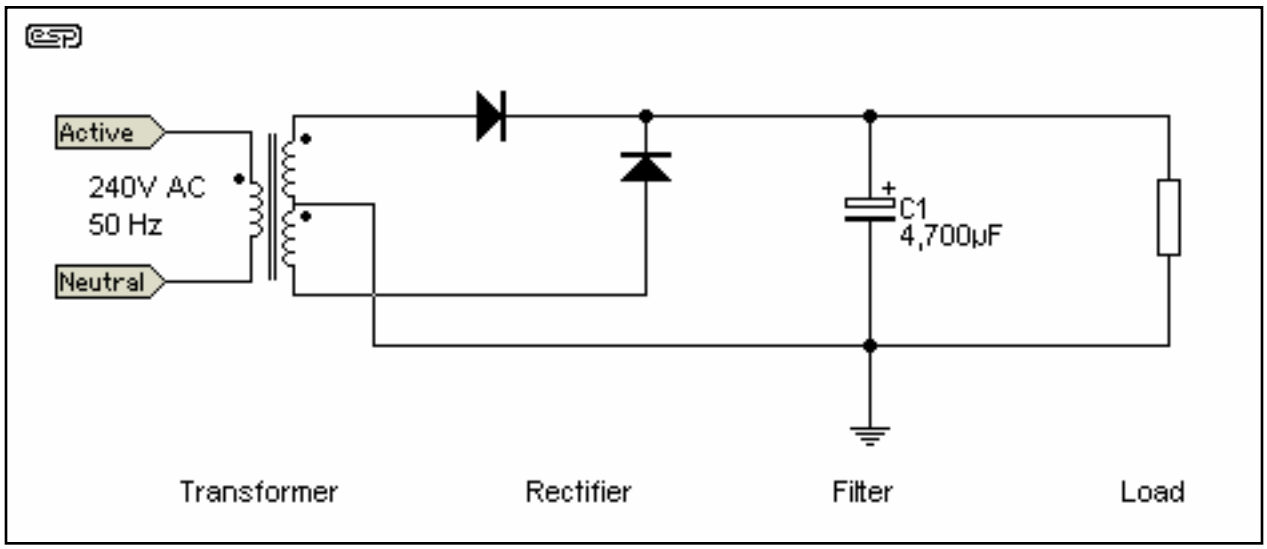

Figure 4 - Full Wave Rectifier

I have reverted to a transformer for this section, rather than the simulated version used before. This makes the drawings clearer, and the same depth of analysis will not be performed again this time. The capacitor ripple current is unaffected in principle, except that it will be slightly lower for a given VA rating since it is directly related to transformer winding resistance.

For the example in Figure 4, the AC current in each winding is 1.82A for a 1.47A DC load. This is quite close to the ratio of 1.2:1 shown in Table 5, and the difference is readily explained by measurement inaccuracy.

The biggest difference between a bridge rectifier and a full wave for a single output voltage is the transformer VA rating. Using the data from Table 5, and staying with a 25V (or 25-0-25 for the full wave) transformer and a nominal load of 1.5A ...

Bridge: Voltage = 25V, Current = 1.5 * 1.8 or 2.7A, so 25 * 2.7 = 67VA

Full wave: Voltage = 50V, Current = 1.5 * 1.2 or 1.8A, so 50 * 1.8 = 90VA

The relative inefficiency of the full wave is quite apparent, but this remains the most popular for power amps but in a modified form - the full wave centre-tapped (dual) power supply.

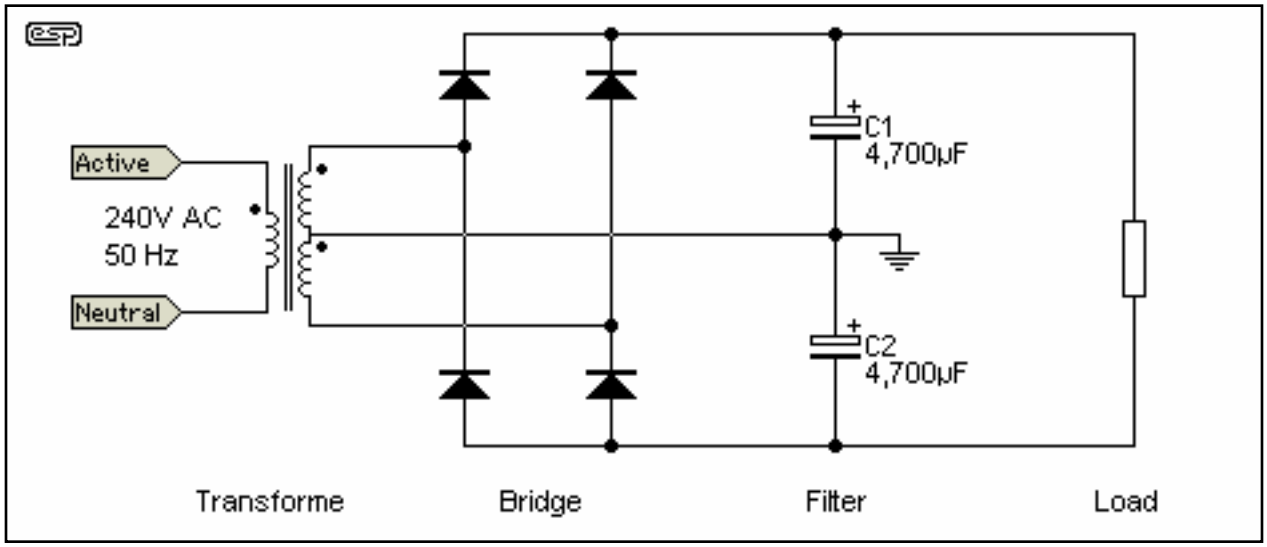

Figure 5 - Full Wave Centre Tapped Rectifier

This version now uses the entire winding all the time - each winding is used for both positive and negative supplies. Full winding utilisation means that the AC current is now the same as for a bridge rectifier, at 1.8 times the DC current, but only for a common mode load (i.e. between the supplies, rather than from one supply or the other to ground - this is identical to equal current from each supply to ground). Where the load is from only one supply or the other, the 1.2 rule applies, but power amplifiers will draw from both supplies (more or less) equally. The frequency of the signal waveform is mostly above the power supply input frequency, so the supply will effectively be loaded as common mode. All dual power supply designs must assume this load, or the result will be most unsatisfactory.

Temperature

In all power supply designs where the power is significant, the transformer temperature rise must be accounted for. Apart from the transformer radiating its heat to nearby components, any temperature rise will increase the copper losses, leading to reduced performance and even more heat. Use of a larger than required transformer will help considerably, but at the expense of capacitor ripple current.

Naturally, an increase in ripple current will cause the capacitors to become hotter, and as always, an increase in temperature causes increased losses and shortened component life expectancy.

For similar reasons, it is unwise to mount the filter capacitors anywhere near a significant heat source, such as large wirewound resistors, heatsinks or other heat generating components. Valve amplifiers are the natural enemy of electrolytic caps, due

to the often elevated temperatures within the chassis. Some manufacturers have resorted to mounting the filter caps in a separate metal enclosure on the outside of the chassis (and reasonably well away from output valves) in an attempt to keep temperatures down.

Capacitor Value

The required capacitance for a given load current and ripple voltage is determined (approximately) by the formula [1]...

$$C = (I_L / \Delta V) * k * 1,000 \text{ uF} \quad \text{... where}$$

I_L = Load current

ΔV = peak-peak ripple voltage
k = 6 for 120Hz or 7 for 100Hz ripple frequency

Since all my calculations above were done at 100Hz ripple current, this can be checked easily, so ...

I_L = 1.44, ripple = 2V p-p, therefore C = 5,040uF

It can safely be concluded that this formula is more than acceptable for our needs, the error being about 7%, which is far better than the tolerance of electrolytics anyway. The net result is that the required capacitance is about 3,500uF per amp, for a 2V peak to peak ripple (50Hz supply). The required capacitance will be less for 60Hz countries, at 3,000uF per amp - again for a 2V p-p ripple voltage.

I have seen it advocated that 100,000uF is the minimum that should be used with a powerful amp (say 200W / channel or so), but I find this difficult to justify. The law of diminishing returns comes into play quite quickly, and with both capacitance and transformer VA rating, this law becomes significant once you have doubled each of these values. With Class-AB amps, a ripple voltage of 2V P-P at full power will do nothing more than reduce the power by a few watts at the onset of clipping. Even reducing the capacitance further to (say) 1,500uF per amp will only reduce the continuous power output by a small amount. Normal music signals with their dynamic range will allow an amp with a relatively small capacitance to still provide the same maximum power for short transients.

As an example, a 100W/ 8 Ohm power amp will have a maximum output current of about 3.5A RMS into a resistive load. Since we know that a loudspeaker is not resistive, this figure should be doubled, to 7A. This is not an absolute rule - you can multiply by three if that makes you any happier. The supply current for each supply (+ve and -ve) will therefore have a peak value of about 10A (7 * 1.414), and the average will be 1/2 of the speaker current, or 3.5A. Based on the 3,500uF / amp figure above (assuming a 50Hz supply), 12,250uF per side is enough to ensure that ripple voltage never exceeds 2V P-P, but since this is a non-standard value, we would use 10,000uF.

In reality, it is probably going to be quite OK with 4,700uF, and the loss of power is negligible in real terms. As stated above, continuous power will be reduced, but normal music signals will not have transients of sufficient duration to discharge the filter caps appreciably. Note that this does not apply to amplifiers that are used for sub-woofers, nor for Class-A amps. These will place a greater load on the supply, and on a more consistent basis.

If we were to increase the capacitance to infinity (big cap!), the ripple voltage will be 0V, and we will get an extra volt (peak) from the amp before the onset of clipping with a continuous signal. This represents about 4W increase, which is completely insignificant - especially when we remember that the mains voltage could (will - at some stage) fall by up to 10%, which represents a power drop of around 20W - the 100W amp will only be capable of 80W with 10% low mains. Considering that an amplifier should not be operated at or near clipping anyway, the difference is inconsequential.

Use of a small (e.g. 1uF) polyester or polycarbonate capacitor across the DC output is a common practice. Electrolytics all exhibit a small inductance, and this causes their impedance to rise at higher frequencies. This is dependent on the physical size (specifically the length) of the cap - bigger caps usually have greater inductance. Again, the use of a paralleled bank of small (1,000uF) electros will be better in this respect than a single large can type, and will also be easier to mount and cheaper. I have never found the necessity to add a bypass cap to maintain amp stability, but it cannot hurt (some amplifiers *will* oscillate if the supply impedance is allowed to exceed some specific (low) impedance at high frequencies). Essentially it is a good idea, and in the greater scheme of things, is inexpensive. Should you choose not to include a film bypass, it is unlikely that anything 'bad' will happen - the impedance of the large electrolytic will remain much lower than that of the film cap at frequencies up to 1MHz or so.

Capacitor Ripple Current

The manufacturers' ripple current rating is the maximum continuous ripple if the quoted life expectancy of the capacitor is to be achieved (usually 2000 hours, but 12000 to 26000 hours for some manufacturers). The ripple current rating is for the capacitor operating in an ambient of 85°C (or higher for high temperature types)and the maximum ripple current can be increased by up to 2.5 times as the operating temperature is reduced (2.5 times at 30°C), though going above about 1.5 times is risky because the ESR increases as the capacitor ages and causes more heat for the same ripple current. [3]. Personally, I prefer not to exceed the quoted ripple current rating.

Capacitors in power supplies feeding Class-A amps should be operated well within their ripple current rating. In a Class-AB amp, the maximum ripple is at maximum output which only occurs occasionally (if at all!). Occasional excursions up to or even above the maximum ripple current will not significantly affect the life of the capacitor. In a Class-A, however, the ripple is at a maximum whenever the amp is switched on. If the ripple current is at the maximum for the capacitor, the life expectancy would be 2000 hours (for the normal types). This equates to a life of less than 2 years if the amp is used for 3 hours a day.

A formula for calculating ripple current would be very useful, but unfortunately (despite claims made in some articles I have read), it is almost entirely dependent on the series resistance provided by the incoming mains and the power transformer. Any formulae that do exist are only true for "sub-optimal" values of capacitance (in other words, the cap is too small to be useful). The summary (below) has some guidelines that may be useful, but be aware that these are guidelines only - the final outcome has so many variables that it is impossible to give an accurate prediction of capacitor ripple current.

Remember that large capacitor values will have a smaller surface area per unit capacitance than smaller ones, so the use of multiple small caps instead of a single large component can be beneficial. There is more surface area, the ESR will be lower, ripple current rating higher, and the combination will most often be cheaper as well. This is an "all win" situation - rarely achieved in any form of engineering. An example is worth showing - the following details are from an Australian electronics retailer's catalogue:

Value (uF)	Voltage	Size (mm) Dia x H	Surface Area (mm²)	Ripple Current (mA)	Price (AU $)
1,000	63	16 x 32	1659	1,400	1.95
2,200	50	16 x 35	1810	1,900	2.85
4,000	75	30 x 80	7634	4,600	14.50

8,000	80	35 x 76	8467	3,460	18.95
10,000	100	51 x 85	13779	8,100	32.95

Table 6 - Capacitor Comparison

For the sake of the exercise, we will assume that we need 8,000uF at a minimum of 50V, and with a ripple current rating of 7A - this is more than adequate for a 100W amp, and meets all the design criteria.

- A single 8,000uF 80V cap could be used, with a price of $18.95, ripple current of 3.46A and a surface area of 8467 mm² Overall, a simple solution but ripple current rating is 1/2 what I want, so it is excluded.
- Two 4,000uF 75V caps will cost $29, but have a ripple current of 9.2A and a surface area of 15,268 mm². Considerably more expensive, but very good performance.
- Four 2,200uF 50V caps cost $11.40, ripple current is 7.6A, and surface area is 7,240 mm². The most economical, but there is a minor performance deficiency by comparison with the previous and next options (but you do get some extra capacitance). This would be my choice for most systems, as it meets or exceeds all requirements.
- Eight 1,000uF 63V caps will cost $15.60. The ripple current is 11.2A, and surface area is 13,272 mm². For performance vs. price, there really is no contest. More effort is required to mount them, though.
- Naturally, you could also use the 10,000uF cap, but why would you do that?

I shall leave it to you to do your own comparisons, but most of the time you will get similar results. This is a very good way to reduce the size requirements as well - it is far easier to fit a number of small caps into an enclosure than a couple of large ones, and since there is an overall improvement in specs as well as a price advantage, it is an elegant solution.

It is worth pointing out that historically, filter capacitors are the number one cause of power supply failure. This is almost always because of the effects of temperature and ripple current, and close attention to this is very much worth your while.

Rectifier Diodes

One thing I strongly recommend is the use of 35A chassis mounted bridge rectifiers. Because of the size of the diode junctions, these exhibit a lower forward voltage drop

than smaller diodes, and they are much easier to keep cool, since they will be mounted to the chassis which acts as a heatsink. As always, lower temperatures mean longer life, and as was demonstrated above, the peak currents are quite high, so the use of a bigger than normal rectifier does no harm at all.

Even given the above, I have had to replace bridge rectifiers on a number of occasions - like any other component, they can (and do) fail. The bigger transformers increase the risk of failure, due to the enormous current that flows at power-on, since the capacitors are completely discharged and act as a momentary short circuit.

Diodes used in a FWCT (Full Wave Centre Tapped) or single Full Wave supply rectifier must be rated at a minimum of double the worst case peak AC voltage. So for example, a 25V RMS transformer will have a peak AC voltage of 35V when loaded, but may be as high as 40V unloaded, and double this is 80V. 100V Peak Inverse Voltage (PIV) diodes would be the minimum acceptable for this application.

For a single bridge rectifier, PIV needs to be greater than the peak AC voltage, since there are effectively two diodes in series.

In the case of a dual supply (using a 25-0-25V transformer), the worst case peak AC voltage is 80V, so the diodes must be rated at 200V PIV. The most common 35A chassis mounted bridge rectifiers are rated at 400V, and this is sufficient for all supplies commonly used for power amplifiers of any normal (i.e. < 500W into 8 ohms). Beyond this, the voltage rating is fine, but the current rating is inadequate, and a higher current bridge should be used.

There is currently a trend towards using fast recovery diodes in power supplies, since these supposedly "sound better". This is basically a bad idea, and there is absolutely no requirement for them. The purpose of a fast recovery (or any other fast diode) is to be able to switch off quickly when the voltage across the diode is reversed. All diodes will tend to remain in a conducting state for a brief period when they are suddenly reverse biased. This is extremely important for switched supplies, since they operate at high frequency, and have a squarewave input. Standard diodes will fail in seconds with the reverse current, since it causes a huge power loss in the diode.

At 50 or 60Hz, and with a sinewave input, the slowest diodes in the universe are still faster than they need to be. Indeed, Nelson Pass suggests that even the standard diodes should be slowed down with paralleled capacitors [2]. This can be an excellent idea, as it reduces the radiated harmonics from the diode switching. Typically, 100nF capacitors (optionally with a small series resistance) are wired in parallel with each diode

in the bridge, and this is quite common with some high end equipment and test gear where minimum noise is essential.

DC Sound

For reasons that I find completely obscure, there are some who claim that there are audible differences between power supply filter caps, diodes and mains leads. The net result of all the transforming, rectifying and filtering described above, is to produce DC. OK, it is not pure DC, in that it has some superimposed AC, as ripple voltage. Very few power amplifiers are so intolerant of ripple or other signals on their supply lines that a couple of volts will be audible. If this is the case, then a regulated supply, or at least a capacitance multiplier, is essential.

Very small amounts of noise that manage to get through the supply also should have no effect on an amp, and if the amp is so afflicted, the remedy is the same as for ripple. Remember that at all audio frequencies, the reactance of the capacitor is very low, and will act as a short circuit for any stray noise signals. A 10,000uF cap has a theoretical reactance (impedance) of 1.6 milliohms at 10kHz. This will never be achieved in practice - the wire has more resistance than that. Suffice to say that the impedance is pretty low, and it is extremely hard for any appreciable signal to get past the filter capacitors. The addition of one or more 1uF film type bypass caps ensures that impedance stays low even as the inductance of the electrolytics starts to have an influence.

The above assumes that the problem is noise, but this is rarely stated as the "improvement" - it is more likely to be bass "authority" or extension, or perhaps the "veil" is lifted from the highs. It can readily be demonstrated that as long as a power supply is well engineered in the first place, the "quality" of the DC output is unaffected by any of the "remedies". Ripple voltage will remain the same, amplifier power output (at all frequencies) will be unchanged, and mostly the signal to noise ratio will be unaffected. It is very easy to monitor the supply rails with an oscilloscope and a monitor loudspeaker (capacitively coupled of course), and from this it is possible to directly assess any difference should it exist.

In a similar vein, I have yet to hear from anyone who can give a plausible explanation or send me a sound file that demonstrates the difference between any two mains leads, all else being equal.

Summary

In conclusion, there are some rules of thumb that can be applied to save calculations and test measurements. These should not be considered as gospel - they are merely my suggestions on acceptable minimum requirements for a power supply.

Diode Ratings

- For most amplifiers or 50W or greater, use a 35A 400V rectifier bridge. Smaller amps can naturally use something with lower ratings. Current should be based on 10A per 100W for an 8 ohm load, or 20A per 100W for 4 ohms.
- Voltage rating must be a minimum of 200V for 100W into 8 ohms, or 100V for 100W for 4 ohms. This is not linear, so direct extrapolation is not advised. 400V diodes are adequate for amplifiers up to 2000W/ 8 ohms.

Capacitor Value

- Capacitance
  - Class-AB: The filter cap should be a minimum of 4,700uF per 100W into 8 ohms, and 10,000uF per 100W into 4 ohms. The actual value can be extrapolated from here. It is often possible to use less than the suggested capacitance, and the values shown may be halved without a significant loss of performance - this is up to the individual constructor.
  - Class-A: The cap needs to be selected on the requirements of the amplifier, but a minimum of 4,700uF for each 10W into 8 ohms is recommended.

- Voltage rating is as required by the maximum DC supply, and will usually be 50, 75 or 100V

- Ripple current ranges (from the examples shown here) from 3.3 times the load current up to 4.6 times load current, depending largely on the transformer size.
  - Class-AB: Because the amplifier will rarely draw maximum current for prolonged periods, a ripple current rating equal to double the peak output current will usually be enough. Thus a 100W/ 8 ohm amp having a peak output current of 3.5A will usually be OK with a ripple current rating of 7A. (Note: guitar amplifiers are specifically excluded from this! - I suggest double the above value as a minimum.)
  - Class-A: For the worst case possibility, I suggest that the ripple current rating should be 5 times the load current for these amplifiers. A 20W/ 8 ohm Class-A amp will draw a continuous 2.5A (typical), so ripple current rating for the capacitors needs to be 12.5A.

Transformer

- The voltage is determined by the power that you need from the amplifier. Calculate power from the formula ...

  $P = Va^2 / R$ Where P is power in Watts, Va is RMS speaker voltage, and R is speaker nominal impedance

- The supply voltage (allowing only for basic losses) is calculated as follows

  $V_{RMS} = Va * 1.1$ Where V_{RMS} is the transformer secondary voltage (for each supply rail)

- **VA Rating - Class-AB**

  The absolute minimum VA rating suggested is equal to the amplifier power. A 50W amp therefore needs a 50VA transformer, or 100VA for stereo 50W amps. Larger transformers (up to double the amp power rating) will provide a "stiffer" power supply, and this may be beneficial. For continuous operation at full power (never actually needed in audio), the transformer should have a VA rating of up to 4 times the amplifier power.

  It is suggested by some transformer manufacturers (and no doubt gleefully adhered to by many amplifier makers) that the VA rating needs only to be 0.7 of the maximum amplifier power. While this will work well enough in most cases, you will not have a "stiff" power supply - I would suggest "soggy" as an appropriate term - the voltage will waffle about like a limp biscuit.

- **VA Rating - Class-A**

  The minimum VA rating suggested is 4 to 5 times the amplifier power. A 20W Class-A amp therefore needs an 80-100VA transformer, or 160-200VA for stereo 20W Class-A amps. Larger transformers will again provide a "stiffer" power supply, and this will be beneficial. Nelson Pass suggests the ratio should be 7.5 times the amp power [2].

Fusing and Protection

Since the power supply is connected to the mains, it is necessary to protect the building wiring and the equipment from any failure that may occur. To this end, fuses are the most common form of protection, and if properly sized will generally prevent catastrophic

damage should a component fail.

Toroidal transformers have a very high "inrush" current at power-on, and slow-blow fuses are highly recommended to prevent nuisance blowing. In the case of any toroid over 500VA, a slow-start circuit is very useful to ensure that the initial currents are limited to a safe value. An example of such a circuit is presented on the Project Pages, and represents excellent insurance against surge damage to rectifiers and capacitors.

Calculating the correct value for a mains fuse is not easy, since there are many variables, but a few basic rules may help.
First, determine the maximum operating current of the system, based on continuous maximum power. The calculations done previously will help ...

The mains current is determined by the turns ratio of the transformer, calculated by

> Tr = Vpri / Vsec Where Tr is turns ratio, Vpri is primary (mains) voltage, and Vsec is secondary voltage

A 240V to 25-0-25V (i.e. a 50V secondary! - the whole secondary winding must be used in the calculations) transformer has a turns ratio of 4.8:1, the same transformer with a 120V secondary has a turns ratio of 2.4:1 - this can be calculated for any transformer. The primary current is calculated by ...

> Ipri = Isec / Tr Where Ipri is primary current, Isec is secondary current

A supply designed for our hypothetical 100W/ 8 ohm amplifier will have a secondary current of about 6.3A at full power, so primary current (for 240V) is about 1.3A. A 2 Amp fuse would seem OK for this, but if a 500VA transformer was used (for example), this is barely enough to handle the maximum transformer primary current. A 3A slow-blow fuse should be used, and this should survive the inrush current (120V countries will need a 6A slow-blow fuse).

Thermal protection (often by way of a once-only thermal fuse) is often included in transformers. If the "one-time" thermal fuse has been used, should the transformer overheat it must be discarded, since the fuse is buried inside the windings and cannot be replaced. All the more reason to ensure that the transformer is properly protected at the outset.

Note that primary fuse or circuit breaker protection does not protect the amplifier against overload or shorted speaker leads. If this happens, or should the amplifier fail, the primary fuse offers no protection against catastrophic failure and possibly fire. For this reason, secondary DC fuses should always be used - no exceptions.

Multi-tapped primaries (e.g. 120, 220, 240V) create additional problems with fusing, and often a compromise value will be used. The transformer protection is then not as good as it could be, but will generally still provide protection against shorted diodes or filter caps.

Additionally, it may be an advantage to fit Metal Oxide Varistors (MOVs) to the mains - between the active and neutral leads. These will absorb any spikes on the mains, and help to prevent clicks and pops coming through the amplifier.

It is the readers' responsibility absolutely to assess the suitability of a design or any part thereof for the intended purpose, and to take all necessary precautions to ensure the safety of himself/ herself and others.

The reader is warned that the secondary voltages present in nearly all power supplies for amplifiers are potentially lethal, and to observe all applicable laws, statutory requirements and other restrictions or requirements that may exist where you live.

WARNING: All mains wiring should be performed by suitably qualified persons, and it may be an offence to perform such wiring unless so qualified. Severe penalties may apply.

All power supplies must be fused or protected by an approved circuit breaker, and all mains wiring must be suitably insulated and protected against accidental contact to the specifications that apply in your country.

Introduction

Whether you use Bipolar Junction Transistors (BJTs) or Metal Oxide Semiconductor Field Effect Transistors (MOSFETs), there are many circuits that suggest (or require) matched transistor pairs. Some retailers sell matched devices, but they are rather expensive, and not commonly available.

Matching power transistors is theoretically easy, but in reality there are quite a few parameters that should be matched to get true matched pairs. The situation is made a little harder when you have PNP and NPN (or N-Channel and P-Channel) devices, since the simpler comparison (or bridge) techniques don't work due to the opposite polarities.

This article is not intended to cover all the possibilities, since the equipment needed is out of the range of the average hobbyist. Bear in mind that some of the tests are potentially destructive if the DUT (device under test) does not have an adequate heatsink, so the provision of a fairly substantial heatsink is essential. Ideally, a quick clamping method will be utilised so the devices

don't have to be screwed down each time - this can get seriously time consuming.

Manufacturers get around the heatsink problem by pulse testing (so the device does not get a chance to get hot), but this requires expensive equipment to do, so a simpler test is needed. Simpler actually makes it more complicated for high current tests, since you will have to mount the transistor before you start. For these tests, using mica washers is out of the question (too time consuming), so the heatsink will be at the potential of the collector (BJT) or drain (MOSFET).

You will also need a fairly substantial power supply if you want to test at high current. You must also be aware of the safe operating area of the device, since exceeding this will destroy BJTs very quickly. MOSFETs are a little more forgiving, but will still fail if pushed too far.

WARNING - The rated source to gate voltage of MOSFETs must never be exceeded

---

Test Equipment

Ideally, you will have two multimeters, but one can be used if you don't have two. The meters will most commonly be digital, and a current range up to at least 2A may be useful (but not essential).

The power supply should ideally be regulated, but again, if you don't have one, then unregulated will still work, although mains voltage variations will affect the accuracy of measurements. In reality, small variations will not cause great errors, and the final result will still have some variations - finding two identical devices is not normally expected or obtained.

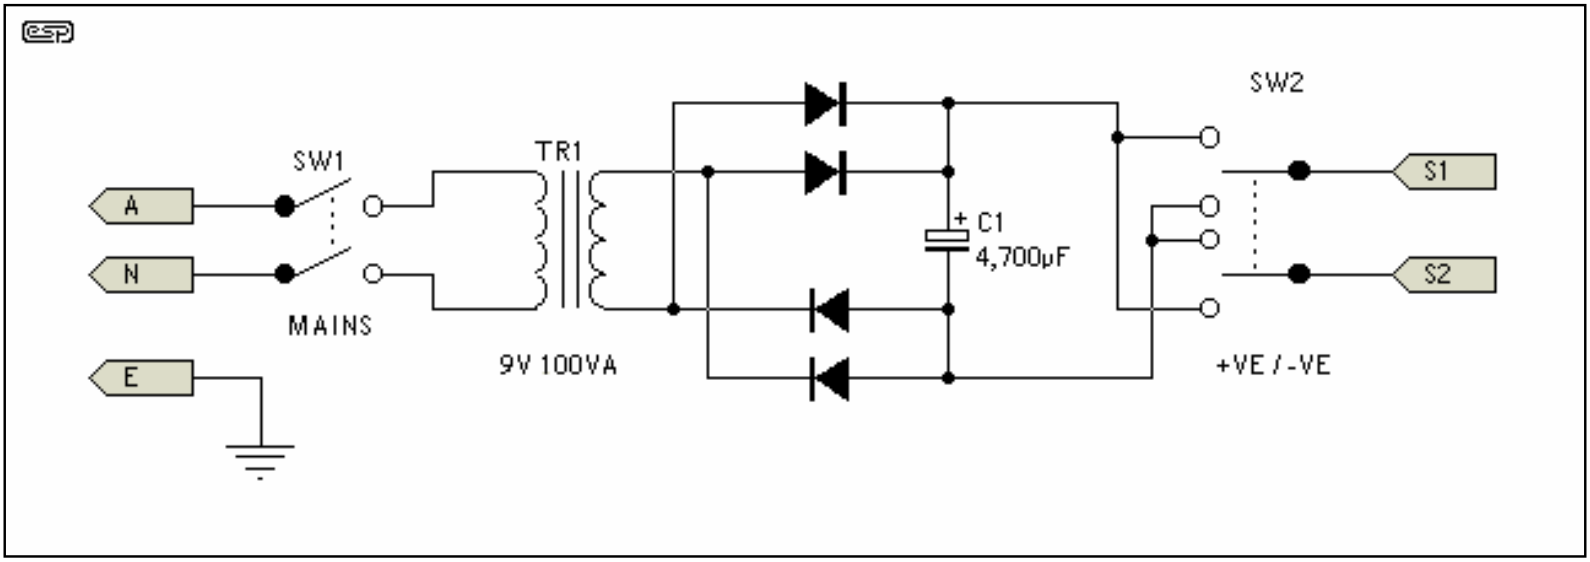

Figure 1 - Power Supply (Unregulated)

You will also need some high power resistors. The actual power rating depends on the supply voltage and the test current. For the suggested 12V supply, a maximum test current of 2A is

reasonable, so the resistors should be set up as shown - four 1 Ohm 5W resistors (as shown below) will be more than acceptable for the high current tests. The others should be as shown in Figure 2.

The bridge rectifier needs to be a high current type, and given that 35A bridges are quite cheap, this is a good choice. I suggest that the power transformer should be fairly substantial, or excessive voltage sag will be experienced during testing. A 100VA trannie will be more than sufficient.

The filter cap is not even required, and leaving it out will be very useful if you have an oscilloscope, since the waveform can be observed for matching as well as the current. Having said that, my preference is to install the capacitor anyway, and using an oscilloscope is likely to be more trouble than it's worth.

The heatsink should be designed so that transistors can be mounted and unmounted easily and quickly, or the task will become a chore very quickly. A strong spring clamp will normally be sufficient to keep the transistor clamped to the heatsink and nice and cool during the test, which should still be done reasonably quickly so that device heating does not skew the results. In all cases, the test duration should be kept the same for each device, and a fan is useful one the heatsink to ensure that heating over time does not cause errors (these can become significant with even a small increase of heatsink temperature). The fan can be powered from the supply shown.

Basic Test Process

The test itself is fairly simple. The first qualifier is for gain, and the emitter-base voltage for BJTs at a known current, or the source-gate voltage for MOSFETs, again for a known current. This first test should be done with the current set for the quiescent current (per device). Figure 1 shows the set-up, and it is deliberately fairly simple. This will work for BJTs and MOSFETs, without any changes. Remember that when testing MOSFETs, the gate is static sensitive, so appropriate precautions must be taken so the DUT is not damaged. Never exceed the rated source-gate voltage - ***ever!***

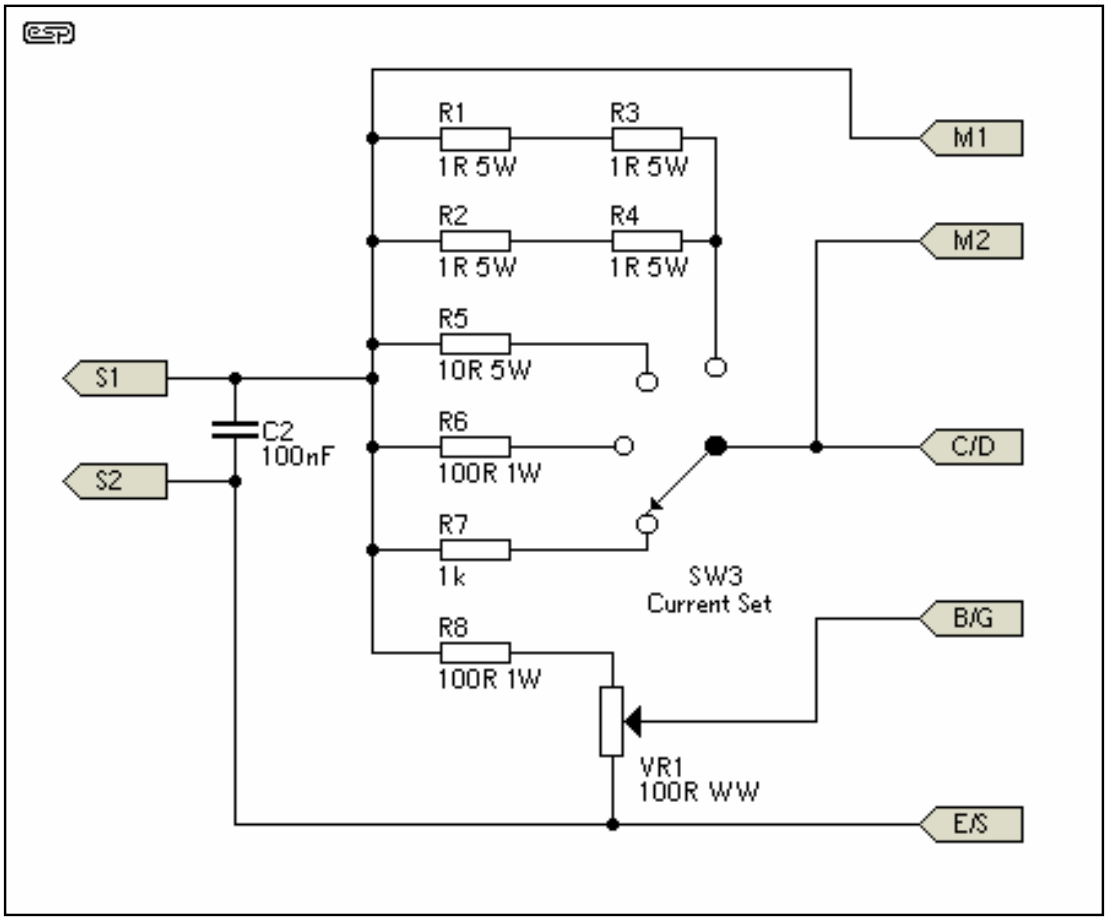

Figure 2 - Quiescent Current Gain / Voltage Test

VR1 needs to be a wirewound pot for testing BJTs, but can be a higher value carbon pot for MOSFETs. I suggest the wirewound pot as a matter of course, since it increases the usefulness of the test jig. The pot will get quite warm in operation (it dissipates nearly 1W), so make sure you switch off the power between tests. Test leads should be fitted with colour coded alligator clips for emitter/source, base/gate and collector/drain (BJTs and MOSFETs respectively).

Select a transistor at random from those on hand, and connect it into the test jig. Make sure that the pot is set to minimum, and that the correct polarity is selected first! Set the switch to the 10 Ohm range, and adjust the pot until the voltage across the M1 and M2 terminals is equal to 10 x Iq (in Amperes). If you want to use a quiescent current of 100mA, the voltage across the resistor will be 10 x 0.1 = 1V. Remember to divide the total quiescent current by the number of parallel output devices first.

Now you can measure the emitter-base or source-gate voltage. Note the readings, and mark the transistor just tested (so you can correlate the device with its measured characteristics). Repeat the test with the other devices you have, reversing the polarity as required - ***but do not adjust the pot*** - leave it exactly where it was for the first transistor. Bear in mind that the current in subsequent transistors could vary by several hundred percent, so it may be necessary to readjust the pot and re-run the test from the beginning :-(

For each device, note the emitter-base (or source-gate) voltage, voltage across the resistors (or

the current through them), and the reference number you marked on each device. When you have finished, you will have an array of voltages and currents (calculated from the resistor voltage if you don't use a current meter), and you can choose those devices that are the closest match. Generally, only the current is really significant except for devices in parallel, where the turn-on voltage becomes important. The source-gate voltage will not change if you are testing MOSFETs, so that only needs to be measured once.

By using a higher resistance, smaller devices can be tested in the same way. For driver transistors, the 100 ohm range would be satisfactory, and for small signal transistors, use the 1k ohm range. Be very careful that you keep the current and voltage within the device ratings! The rotary switch on the supply is designed for just this purpose.

The test will match devices so that they are approximately equal at the all-important crossover region - if desired, you can test at an even lower current, to ensure that there is the least possible error between devices, however the tests become very time consuming, and obtaining devices that are fully matched over the full operating range is somewhat unlikely.

High Current Test

Once you have a selection of transistors that have approximately equal low current characteristics, you can do a high current test if you want to - this uses the 1 ohm range on the rotary switch. I don't recommend that you exceed 2A, unless you are sure of what you are doing.

The test is set up in exactly the same way as before, except the current is increased to the desired test value. For each device tested, make sure that the test duration is maintained for the same time - say 10 seconds. You will need to wait for the heatsink to cool to the same temperature (or near enough to it) between tests. A fan will help here, and is highly recommended.

Again, you will note the exact current of each device with the pot in the same position as for the first transistor tested. At the end, you will have a set of figures that show the closest matching devices out of those available. I strongly suggest that you don't expect miracles - if you can get transistors that measure within 10% of each other for both the high and low current tests this is a good result. You may do better, but don't count on it, and don't get all depressed if you have to accept a wider tolerance.

For the brave (and those who have taken the time to create a really solid heatsink test set), you can run further tests at higher currents, but you will need to be extremely careful. Remember that 2A at 12V is 24W continuous dissipation, and this will heat the transistor under test very quickly - higher currents will create even more heat.

With the 1 ohm resistor, transistor dissipation is reduced only slightly, and even 24W is a lot to get rid of in any test environment. In extreme cases you will have to use thermal compound for

the DUT to prevent overheating, since it will not normally be possible to take a reading quickly enough unless you have access to a digital storage oscilloscope. If you have access to one, then pulse tests are recommended for all high current testing. The way to go about this is beyond the scope of this little article though :-)

An alternative approach is to take your measurements at high and low currents,, and then calculate (or plot) the transfer characteristics of each device. Although time consuming, this should give good results. Ideally, you will take measurements at a minimum of three points. Measure collector/drain voltage (and for MOSFETs, the source to gate voltage) at ...

- the expected design quiescent current
- close to the peak expected current, and
- a point midway between the two

Once you have these figures, you can then select those that represent the closest possible match. You will be very fortunate indeed if you get exact matching, but it should be possible to get several acceptably matched pairs from a batch of reasonable size (you will probably need a minimum of 10 devices, if possible from the same manufacturing batch.

Conclusion

The tests described are not the most accurate known, but will be well within the abilities of hobbyists. The results can be expected to be very good when used for matching, and the selected pairs will be much closer than random selection will ever give you.

The test set is fairly cheap to make, and can be used for all sorts of transistor testing - not only for matching, but to test that transistors are functional. Since it will work with bipolars and MOSFETs, it has enhanced usefulness over most conventional transistor testers for the majority of basic testing needs. The little extras added just make it that much more useful.

Elliott Sound Products **Project 56**

Variable Amplifier Impedance

Rod Elliott (ESP)

Introduction

Is this a project or an article? Since you may have arrived here from either index, you might be a little confused. This is fine, as it has elements of both, but lacks the in-depth analysis of other articles, and also lacks the application of a final design that is common to my projects. This is for the experimenter. No further work will be done to refine formulae or produce "magic" spreadsheets to allow you to determine the impedance that is best for a speaker / enclosure combination or anything else. Readers' contributions are of course welcome, and I would be interested to hear about any massive improvements that were made to systems using these techniques. (Or minor improvements, for that matter.)

The idea of being able to vary the output impedance of a power amplifier has been around for a long time. I have used these techniques for over 30 years in various designs, and much as I would like to be able to claim otherwise, I was by no means the first.

The technique has been used to drive spring reverb units, and various other transducers where current drive is preferable to voltage drive. The latter is what we all strive for with power amplifiers - a perfect (ideal) voltage amplifier has zero ohms output impedance, and the amplitude does not change as the load varies. Loudspeakers are very non-linear loads, and the impedance will change at different frequencies for all sorts of reasons.

So voltage drive maintains a constant voltage across the load, while a current drive

circuit will produce exactly the same current into the load - in both cases regardless of impedance. In reality neither approach is ideal ...

- Voltage drive will produce greater power into the load as the impedance falls, since the load voltage remains constant, and a lower impedance means more current and thus more power.
- Current drive has exactly the opposite effect, so when the load impedance rises, a greater voltage is needed to maintain the same current. So with the same current but a greater voltage there is again more power, but now it is with higher impedances rather than lower.

Most loudspeaker systems are optimised for voltage drive, however in many cases "optimised" is overly optimistic, since they are just assembled and the builder hopes for the best. A tweak here, an attenuator there, and a zobel network somewhere else rounds off the process and yet another "world's best" loudspeaker system is born.

Not so much a real project as a field day for experimenters, this article describes the methods you can use to tailor an amplifier to a specific driver. Much is empirical (i.e. design by experiment, trial and error), and although formulae are possible, the load presented by a typical loudspeaker is very complex and leaves big holes in the final result if the maths are allowed to take over. Having said that, good results can be obtained by either method (theoretical or practical), so here goes ...

Description

Figure 1 shows two amplifiers (shown as opamps), with (a) being conventional voltage drive, and (b) is current drive. The output impedances are in the order of zero ohms and infinite ohms in each case (this IS a theoretical discussion at the moment!). The gain will appear to be exactly the same for each into an 8 ohm resistive load, but will change based on load for the current amp. We shall see that this is not really the case - some power is lost in the series feedback resistor. The voltage amp has the same gain regardless of load.

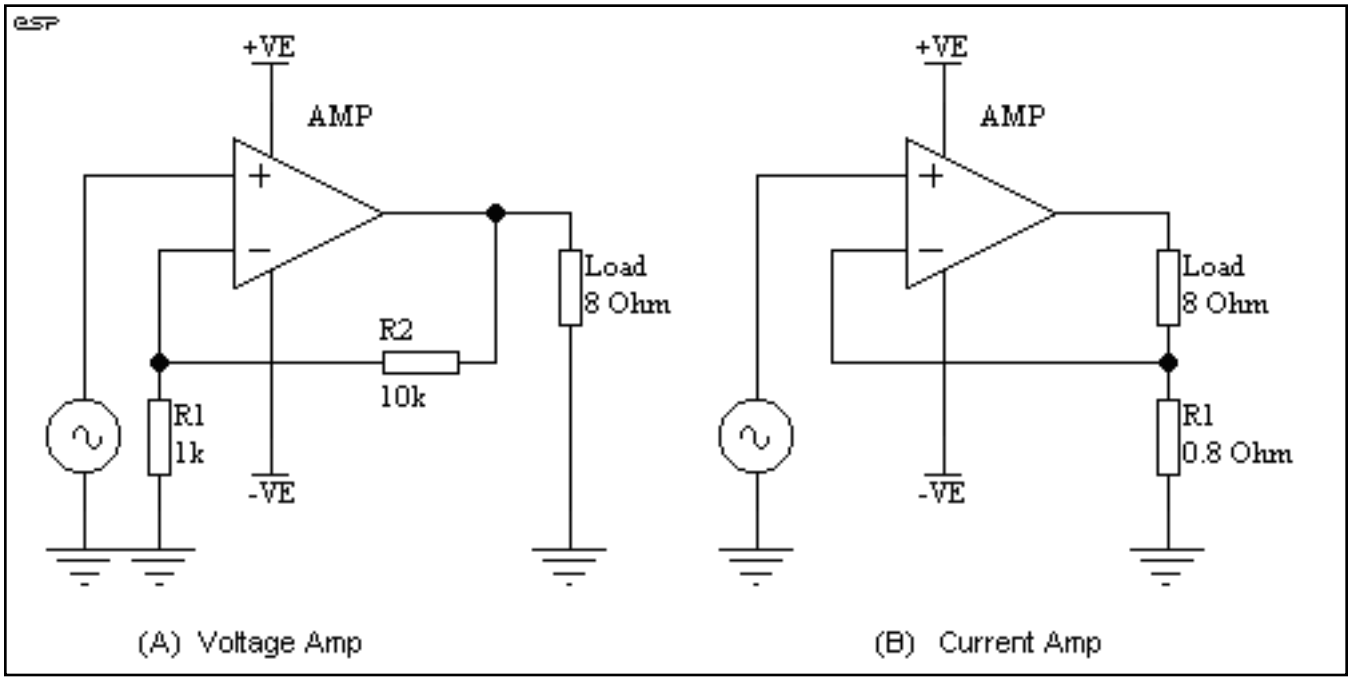

Figure 1 - Voltage and Current Amplifiers

The feedback is applied differently to achieve the desired result, as can be seen, although the difference is not at all subtle at first glance, as you look more closely you will see that it really is a simple rearrangement of feedback resistances. With the 8 ohm load, both amps have a gain of 11, but the series feedback in (B) actually means that the gain to the load is 10. With 1V AC signal applied, the voltage amp will develop 15.125W (11V at 8 ohms) into the load. The current amp will develop 12.5W (10V at 8 ohms) into the load, with 0.125W dissipated as heat in R1. This will remain constant for all load impedances.

Where things get interesting is when the load impedance changes. Should the load increase to 16 ohms (such as at resonance), the voltage amp will produce the same voltage, so power is halved. The current amp will provide the same current, so power into the load is increased fourfold to 50W, with the same 0.125W lost in the series feedback resistor. This of course assumes that the power supply voltage is high enough to allow the amp to do this without clipping.

Likewise, with a dip in impedance to 4 ohms, the voltage amp will provide double the power (30.25W - again assuming the the supply can now provide the necessary current), but the current amp will only produce 6.25W under the same conditions.

Which of these approaches is correct? For resistive loads it does not matter - both will perform identically except for the slightly lower gain of the current amp (this is easily compensated for). With loudspeaker loads, neither is ideal. Power to the load will vary widely depending on the impedance, which in turn depends upon frequency. The voltage

amp will create a dip in response at each frequency where the impedance rises (and a rise wherever there is a lower impedance), and the current amp will do exactly the opposite.

Mixed Mode Feedback

By applying a mixture of both forms of feedback, it is possible to define the output impedance at any value between the two extremes. To emulate a valve amp for example, an output impedance of about 4 to 6 ohms is needed, assuming an 8 ohm load (this is the assumed nominal load impedance for all examples cited).

Figure 2 shows the arrangement used, and with the values shown the output impedance is a bit under 4 ohms. We could simply use a 4 ohm resistor in the amp's output, but this will waste much of the amplifier power, which will be dissipated in the resistor instead of the load. The same power output is available from a current amp as a voltage amp (give or take a fraction of a dB to account for the series feedback resistor).

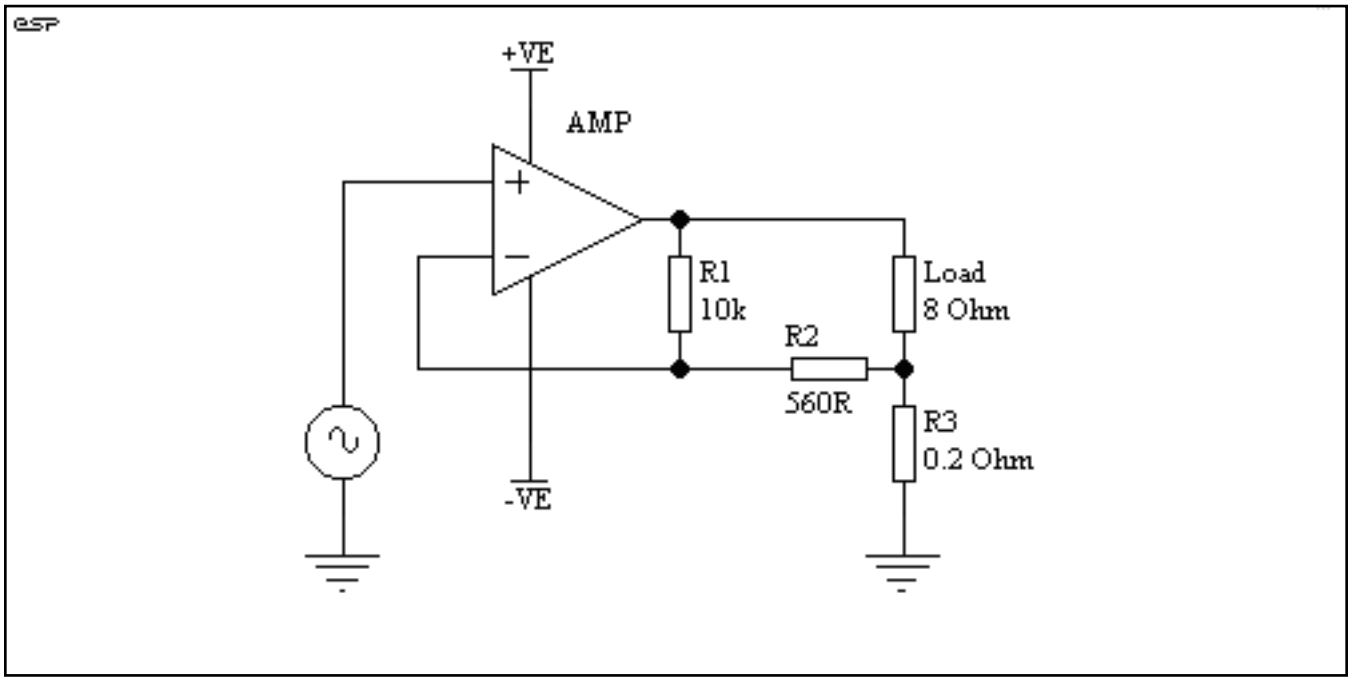

Figure 2 - A Four Ohm Output Impedance Amplifier

As can be seen, there is minimal additional complexity to achieve this result, and in my experience the final exact impedance is not overly critical, given the "real world" variations of a typical loudspeaker.

The no-load voltage is 18.8V with an input of 1V, and this drops to 12.8 at 8 ohms, and 9.7V with a 4 ohm load. These voltages are measured across the load, ignoring the

voltage drop of the series feedback resistor.

From this, we can calculate the exact output impedance from

$I_L = V_L / R_L$	(where I_L=load current, V_L=load Voltage and R_L=load resistance)
$Zo = (Vu - V_L) / I_L$	(where Zo=output impedance, Vu=unloaded voltage, V_L=loaded voltage)

$I_L = 12.8 / 8 = 1.6$

$Zo = (18.8 - 12.8) / 1.6 =$
$6 / 1.6 = 3.75$ ohms

So we have created an amp with an output impedance of 3.75 ohms, with very little loss (just over 0.5W is lost in the 0.2 ohms series feedback resistor with 20W output into 8 ohms). To see if this is useful, we will now have a look at what happens when the load impedance doubles or halves.

With a 16 ohm load, the power into the load falls to 14.6W, or about 1.37 dB. Contrast this with the conventional low impedance amp whose power will fall by 3dB (i.e. half).

When the impedance is reduced to 4 ohms, the output power is now 23.5W (an increase of 0.7dB), while a conventional amp would be producing 40W - an increase of 3dB.

Somewhere, there is a magical impedance that will give almost the same power into any load from double to half the nominal, give or take a dB or so. I am not about to test all possibilities, but having experimented with the concept for many years I am quite convinced that there are practical benefits to the use of modified current drive, where the impedance is defined. The exact impedance will depend to a very large degree on just what you are trying to achieve.

Further Applications

It has been suggested that loudspeaker intermodulation distortion is dramatically reduced by using a high impedance source (but by whom I cannot recall - I do know that one site I looked at was Russian, and a reader sent me a translation many months ago). I have experimented with this idea to some extent, but have been unable to prove that

this is the case - at least with the drivers I tried it with.

This does not mean that the claim is false, but I am unable to think of any valid reason that could account for such driver behaviour. It is interesting anyway, and some of you might like to carry out a few experiments of your own. I would be most interested to hear about your results should you decide to test this theory - preferably more thoroughly than I did.

By adjusting the impedance of an amplifier, the total Q (Qts) of a loudspeaker can also be altered, so driver behaviour in a given sized box can be changed. This can be used to adapt an otherwise unsuitable loudspeaker to a speaker enclosure, but does have limitations in terms of the overall variation that can be achieved.

More variation can be achieved by virtue of the fact that it is now possible to either retain or increase the power delivered to a loudspeaker at resonance, so that the ultimate -3dB frequency may be lowered from that theoretically claimed for a loudspeaker / enclosure combination. Care is needed, since too much additional power will make the speaker boomy, and usually additional internal damping is needed to compensate for the minimal damping factor provided by the amplifier. With the amplifier output impedance set at 4 ohms, damping factor into an 8 ohm load is 2 - a far cry from the figures of several hundred typically quoted. These (of course) fail to take into consideration the resistance of the speaker leads, and loudspeakers themselves are usually compromised by the crossover network, so the damping factor is not always as useful as it might seem.

The results of using modified impedance can be very satisfying, allowing a useful extension of the bottom end. My own speakers are driven from a 2 ohm amplifier impedance, and there is no boominess or other unpleasantness, but a worthwhile improvement in bass response is quite noticeable.

Negative Impedance

Again, this has been about for many years, but I have only found one driver type that seems to obtain any improvement from its use - horn loaded compression drivers. All cone speakers (including horn loaded) sound worse with negative impedance, but you might have some weird driver that can benefit from a negative impedance amp.

As the name suggests, when a negative impedance amp is loaded, the output voltage rises. The greater the load, the more output is applied. This is very risky, and negative impedance amplifiers can easily oscillate when connected to a reactive load such as a

loudspeaker. Indeed, negative impedance oscillators have been with us for many years in RF (and other) work, and there are quite a few electronic components that exhibit negative impedance. So, not new, but interesting.

Figure 3 shows how the circuit is rearranged to accomplish this most bizarre of ideas. By simply substituting the "real" earth connection for the junction of load and series feedback resistor, the voltage developed across the resistor now increases the gain by adding to the input signal voltage.

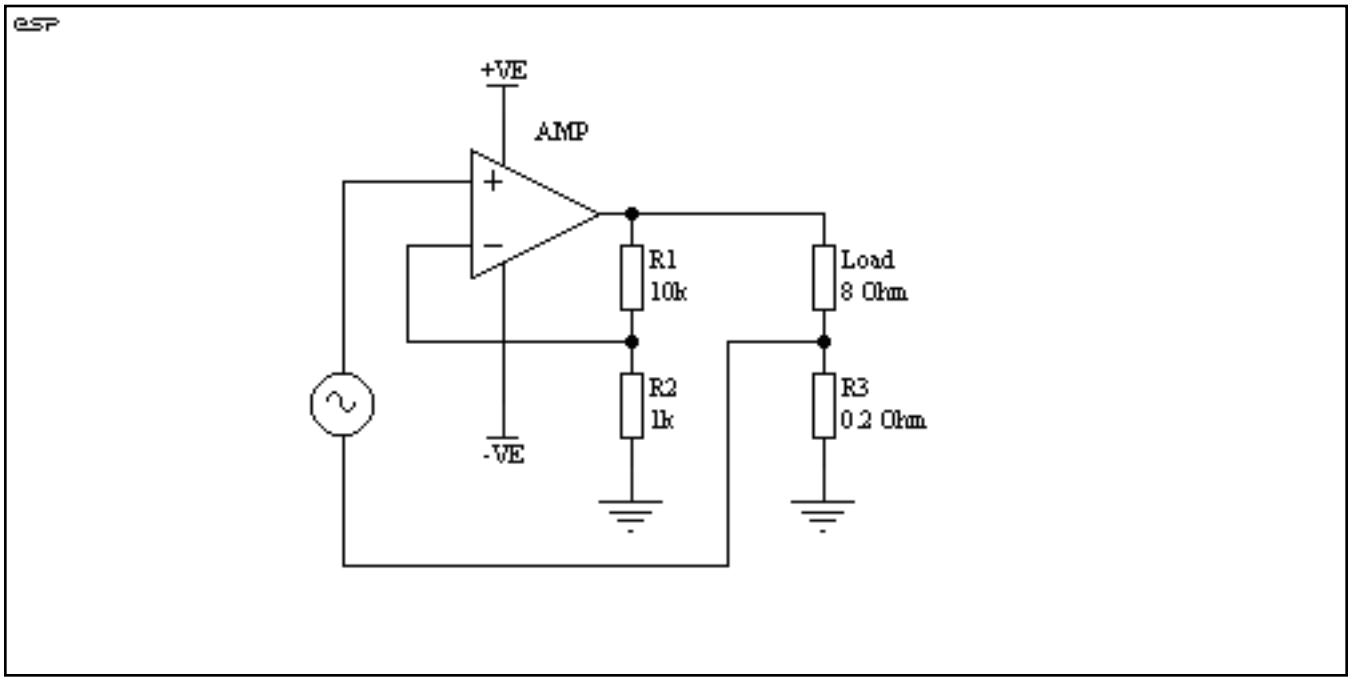

Figure 3 - A Negative Impedance Amplifier

This circuit with the values as shown will provide an open circuit load with 11V (as with a conventional amplifier as shown above), but when the load is applied the voltage increases as the load resistance is reduced. With the values shown, the load voltage will increase from 11V to 14.7V with an 8 ohm load, rising to 22V with a 4 ohm load. A quick calculation using the formulae above will show that the output impedance is about -2 ohms.

The negative impedance amp is by its very nature unstable - the output voltage will continue to rise as the load is reduced, until at some point positive feedback exceeds negative feedback and the circuit will oscillate. Another undesirable side-effect is that distortion is increased, because negative feedback (which reduces distortion) is being counteracted by positive feedback. Again, this is a non-linear function, and the results are unpredictable at best. Reactive loudspeaker loads can cause a negative impedance amp to oscillate, either at the frequency between the loudspeaker's resonance and box resonance (where impedance falls), or at some other frequency determined by

crossover components. Such oscillation can damage speakers (and ears!), so care is needed to ensure that this cannot happen. Low values of negative impedance (not less than -4 ohms) are strongly recommended.

I have found that only relatively small amounts of negative impedance are useful in practice. For example, one could use negative impedance to remove the resistance of the speaker cable and crossover components, although the results will not be as good as expected, and probably far worse. Even with a negative impedance of about 1 ohm, most speakers will show signs of "displeasure", and amplifier distortion will be increased - usually by an amount that is disproportional to the feedback factor.

Conclusions

This "project" is not really a project at all (which is why it has also been included in the articles index), but more of a starting point for experimenters. The circuits shown will all work with "real" amplifiers, but great care and considerable testing are needed to ensure that the results you actually obtain are providing a real benefit.

It is too easy to make a change such as shown here, and fully believe that the result is an improvement, where in reality (as eventually discovered after extensive listening and comparison) the opposite is true. While negative impedance may be found useful for horn compression drivers, it is unlikely (in my experience) to provide any benefit at all to cone loudspeakers.

Positive impedance can produce an improvement in bass response, but the cost can be high - boomy, over-accentuated bass at resonance, usually accompanied by a loss of bass "speed" and definition. There will be more freedom for the speaker cone to waffle about after the signal has gone ("overhang"), and it is rare that a speaker driven by a higher than normal impedance will perform well without additional damping in the enclosure.

There is no doubt that at output impedances in the order of 4 to 6 ohms your amp will sound more like a valve amp (but without the distortion), but it is up to you to decide if this is what you really want to do. The technique works well for guitar amps, as it allows the speaker to add its own colouration to the sound, which adds to the overall combination of distortion and other effects to produce pleasing results. For Hi-Fi the case is less clear, and experimentation is the only way you will ever find out for sure.

Introduction

The so called "baffle step" is an increase in output from a loudspeaker as the size of the baffle becomes significant in terms of the wavelength of sound for a range of frequencies. At low frequencies, where the baffle (the panel the loudspeaker is mounted on) is small compared to the wavelength, the speaker is assumed to be operating with a spherical radiation pattern. While this may be the case should the speaker be situated up a tree in the middle of a field, it hardly qualifies as true when the same loudspeaker is installed in your listening room. There may of course be something about you that I don't know (for example that your speakers really ***are*** up in trees), but for the majority this will not be the case.

As frequency increases, the size of the baffle becomes significant, and the spherical radiation pattern no longer applies. This is also partly to do with the loudspeaker drivers

themselves - as frequency increases, typical cone drivers become more and more directional anyway - this occurs as the dimensions of the cone become significant with respect to wavelength.

Baffle Step Response

It has been shown by Olson et. al. that the optimum enclosure for a loudspeaker driver is a sphere - that is to say that there is no "baffle" as such, but that the driver is installed in a spherical enclosure. While this is all very well in theory, spheres are hard to build, and even harder to include in a typical lounge room unobtrusively.

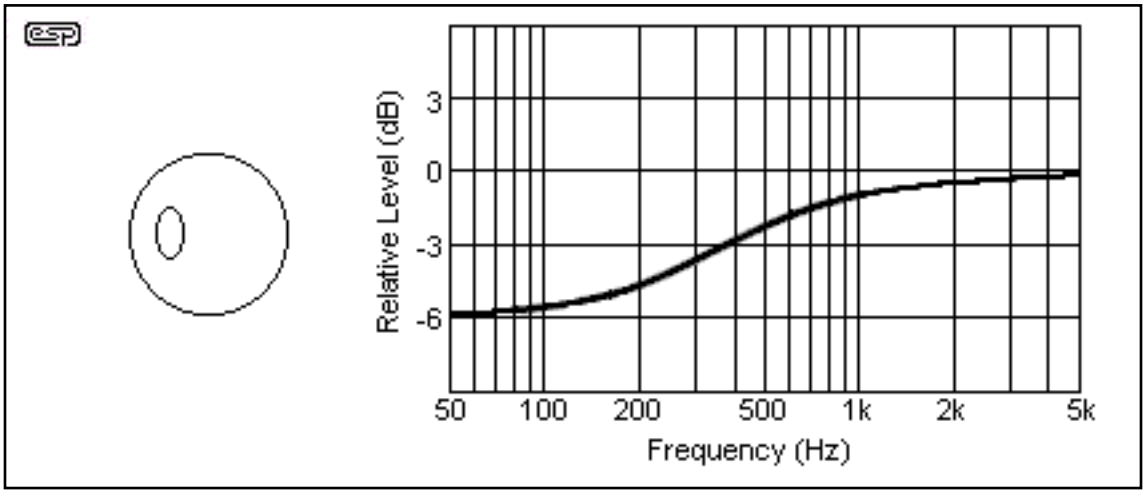

Figure 1 - Response Behaviour - 300 mm Sphere (After Olson)

The increase in output can be seen as the dimensions of the sphere approach the wavelength of the reproduced frequency. Once the wavelength is smaller than the diameter of the sphere, the response flattens out again, having risen by 6dB from the low frequency level. The radiating efficiency of the driver starts to increase earlier than one might imagine - there is a 1dB increase in SPL at the frequency where the baffle is about 0.2 of a wavelength, and the baffle step effect has no influence when the baffle width is greater than 3 wavelengths. At this point, the driver is effectively radiating into a hemisphere.

The absolute worst enclosure is a circular tube (cylinder), with the driver mounted in the exact centre of an end-cap. The response ripples caused by this are extreme, but with most systems this is not an issue, since this would be a very unusual shape for an enclosure. The response in a cylinder shows fluctuations in level that are quite unacceptable, and it is not a shape I would recommend to anyone. A cube is little better, and again the effect is made very much worse if the driver is mounted in the centre. Bacause these shapes are (or should be) avoided altogether, I have not

included any response graphs.

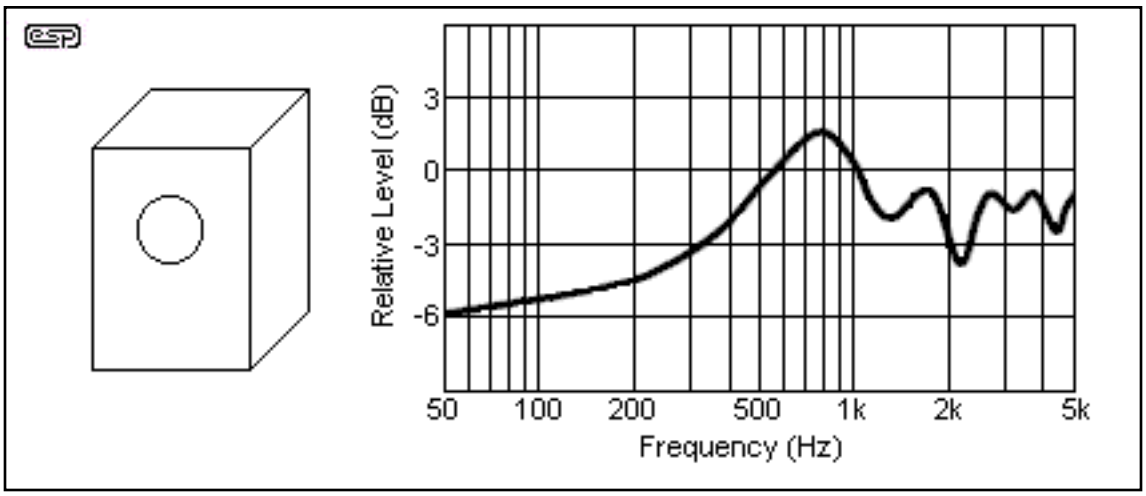

Figure 2 - Response Behaviour - 300mm Wide Rectangular Box (After Olson)

The overall behaviour is greatly improved with any mounting method if you ensure that the centre of the driver is a different distance from each edge of the box. These distances should be "non-harmonic", which is to say that they should be different, but in such a way that no one distance is an even multiple of any other.

When the distances from the driver centre to three sides are equal, the response will be much like that shown in Figure 2. This is better than a cube or cylinder, but much greater improvements can be made, just by changing the position of the driver. In addition, rounded edges will cause less refraction than square or raised edges, further improving the overall response, and particularly at the higher frequencies.

Baffle Step Equalisation

The baffle step is easily compensated for where the speakers are mounted in trees or are in other (more sensible) outdoor environments, but becomes much more difficult as a normal listening room is introduced. Adjacent walls, cabinets and other furnishings will all have an effect, and the outcome is unpredictable at best.

It has been determined that the baffle step may only be a couple of decibels in some circumstances, and sometimes less. In a normal room, it is unlikely that the step will be greater than 3dB, unless the speakers are a considerable distance from the walls.

To this end, I have determined a simple passive network that allows you to adjust the level with a pot, until the response is optimum. The frequency is fixed, and is easily determined based on the width of the baffle. The equaliser circuit should be placed

between the preamp and power amp - it is not suitable for use in the speaker lines. Although circuits exist for use in the speaker lines, I would not recommend them in any situation, since power losses are very high, and they cannot be adjusted easily to suit your listening environment.

Based on an excellent formula developed by John Murphy (True Audio), we can calculate the frequency easily for the box ...

$f_3 = 115 / W_B$ (where W_B is the baffle width in meters)

$f_3 = 380 / W_B$ (where W_B is the baffle width in feet)

Needless to say, I will use metres, and as shown in the graphs above, will use a baffle 300 mm wide. The frequency is therefore ...

$f_3 = 115 / 0.3 = 383$ Hz

Variable Equaliser

A circuit is needed that will provide a typical 3dB decrease in level at the calculated frequency, and the (very simple) schematic is shown in Figure 3.

The value of C1 is determined by the following (1/2 of the pot value is added to the resistor value, since both are in series, and a typical situation will have a pot setting of around halfway - there will always be some error, but it will normally be quite small in practice) ...

$C1 = 1 / (2 * \pi * (R1 + (VR1 / 2) * f)$

$C1 = 1 / 2 * \pi * 15k * 383 = 27nF$

Since the formula will regularly give values that are not obtainable, we may use the closest available value with little error. Certainly the error will be very much smaller than that created by the room acoustics and other influences. The sample circuit is shown in Figure 3, and as shown is valid for a box with a 300mm wide baffle. The only change that you will need is to the value of C1 according to the above formula.

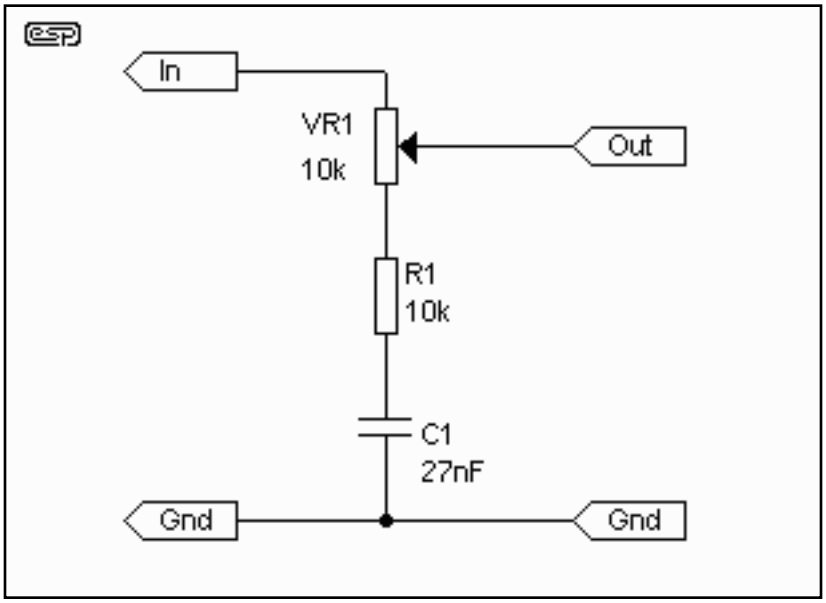

Figure 3 - The Baffle Step Correction Circuit

It is essential that the compensation circuit be driven from a low impedance source, and the load impedance should be reasonably high. There will be little error with loading above 20k, but basically the higher the impedance, the better. Opamp buffers at the input and output may be used if you cannot ensure that the source impedance is 100 ohms or less, and that the load impedance of the following stage is greater than 20k. My recommendation would be to use a buffer stage at the output with an input impedance of about 100k.

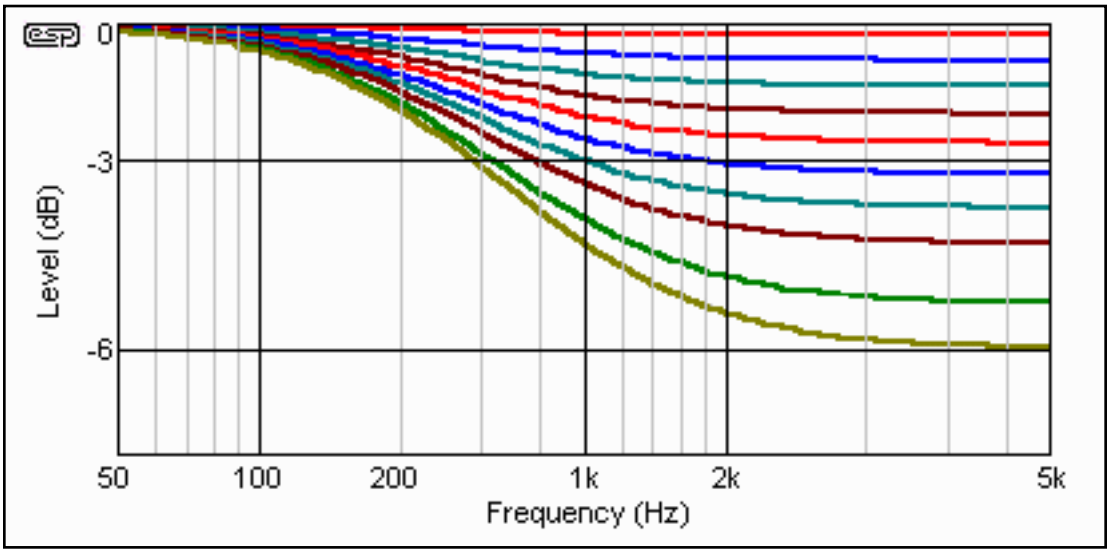

Figure 4 - Typical Frequency Response at 10% Increments

As shown in Figure 4, the pot may be moved from a flat response right through to full 6dB compensation. The graph shows 10% increments of the pot. When the pot wiper is at the top of its travel (based on the schematic), the circuit is inactive, and maximum compensation occurs at at the opposite end of the pot's travel. Nearly all normal

listening room environments will use a setting somewhere in between.

1 Introduction

Since Thiele published his seminal paper on the design of reflex enclosures [1], his original table of 28 'alignments' has been greatly extended, and these are widely available in both speaker design cook books and on the net.

The impression that seems to be given about these alignments is that they are chiseled in stone, and that if one has a particular driver then one is stuck with the f3 and box volume dictated by the alignment. This however is not true. The fact that the driver's suspension compliance is very insensitive to system parameters, i.e. ...

α, h, f3

means that very many alignments exist that are close to but not quite the 'classical' ones usually published and, as White states, 'virtually any driver can be fitted into an alignment', [2, p.892]. Thiele states that from certain points of view the suspension compliance is *'unimportant'* (his italics), [1, p.188].

The miracle of fitting just about any driver to just about any alignment is performed by a procedure called 'compliance scaling', and was, as far as the author is aware first published by Keele, in a 1974 AES paper, [3].

In addition to compliance scaling two other techniques are outlined, electronically increasing Qt and modifying auxiliary filter damping factor.

Programs available as downloads such as WinISD do a good job of system modeling, the difficulty is that once one strays from the standard alignments that these usually have as defaults, one is in the dark as to what to change and by how much, in order to achieve the desired response.

What follows is a simple method that yields some figures to enter into such programs to give a desired result, and allows you to design a box with a particular driver to achieve a target f3, and or a target box volume, also included is a method of increasing Qt.

But first a word about compliance in relation to the Thiele - Small parameters.

---

2 T-S Parameters and Compliance

The T-S parameters have become the standard way of specifying the performance parameters of low frequency moving coil drivers. This is because they clump the fundamental physical properties together in such a way as to ease the problem of calculation and specification.

they are related to the physical properties by the following relationships ...

Vas = *po*C² CmsSd²
Qt = √(Mms / Cms) (1 / Rmt)
Fs = 1 / (2π √(Mms Cms)

Where **Cms** = suspension compliance (m/N), **Mms** = moving mass (kg), **Sd** = diaphragm area (m²), ***po*** = density of air (1.2kg / m³), and **c** = speed of sound (343m/s).

As can be seen compliance plays an important role in all of the above, and also in the system parameters, **α, h, f3**

As stated by Keele, [4 p.254], typical batches of drivers have a 10-20% variation in T-S parameters, and this is largely due to differences in suspension compliance, but luckily for the speaker designer this has little effect upon the frequency response in a given box because of the insensitivity of this to alignment.

The actual scaling procedure entails applying a set of transforms to a 'seed' alignment to give use a new set of system parameters, and this uses a 'normalised compliance' constant, **Cn** defined as ...

Cms / Cms'

Where **Cms** is the driver compliance, and **Cms'** is the driver compliance that would be needed for the driver to be 'correct' for the alignment. **Cn** then gives us the transform set ...

h = h' √Cn
Qt = Qt' / √Cn
α = α'Cn
f3 / fs = f3' / fs' √Cn
fa = fa' √Cn

Applying these transforms to a standard B4 alignment gives the following results, (Data copied from, [2, p.892]), for the Cn values of 0.25, 1.0, 4.0 ...

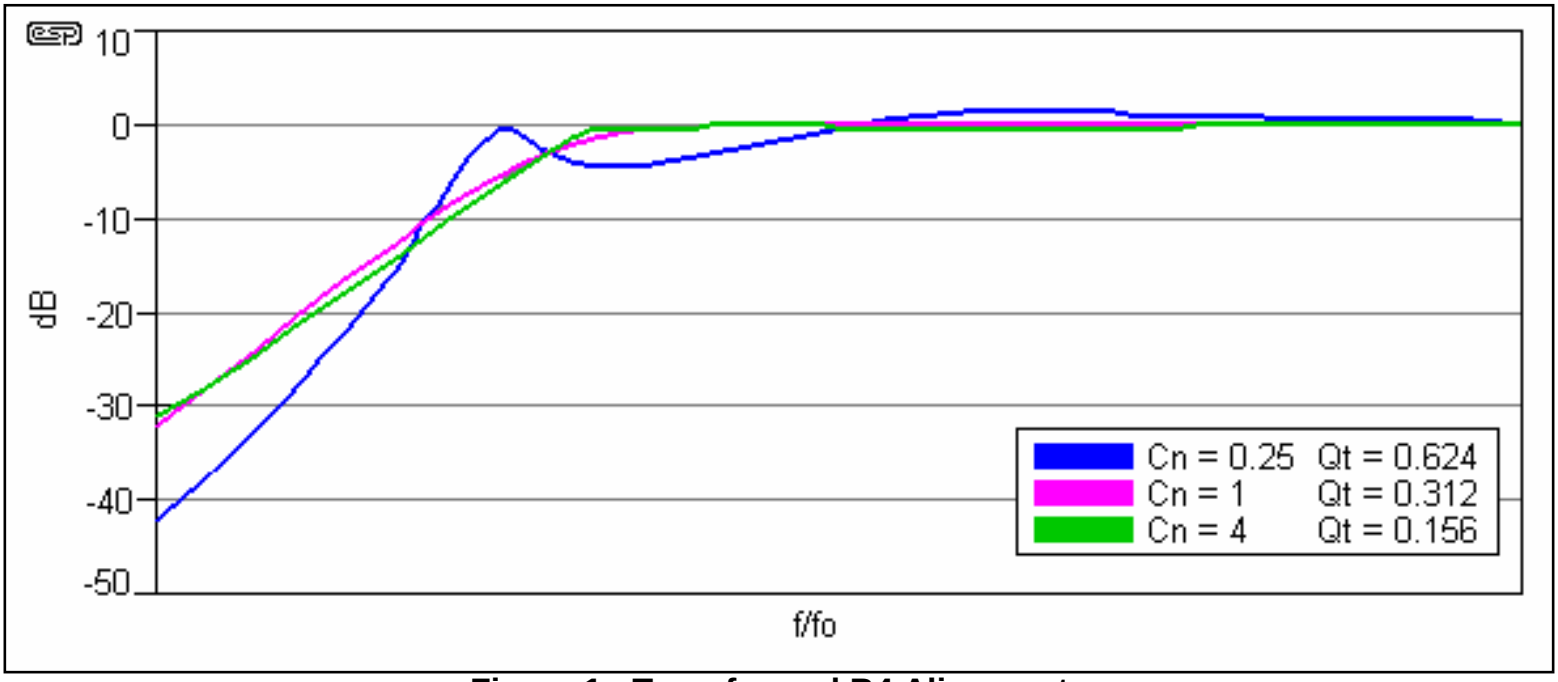

Figure 1 - Transformed B4 Alignments

In the above graph the blue plot is for a Cn = 0.25, this corresponds to a Qt of 0.624, the magenta line is for Cn = 1, Qt = 0.312, the exact B4 alignment, and the green is for a Cn of 4, Qt being 0.156 It can be seen that the greatest deviation is for low Cn values. Figure 2 is for a filter assisted B6 alignment ...

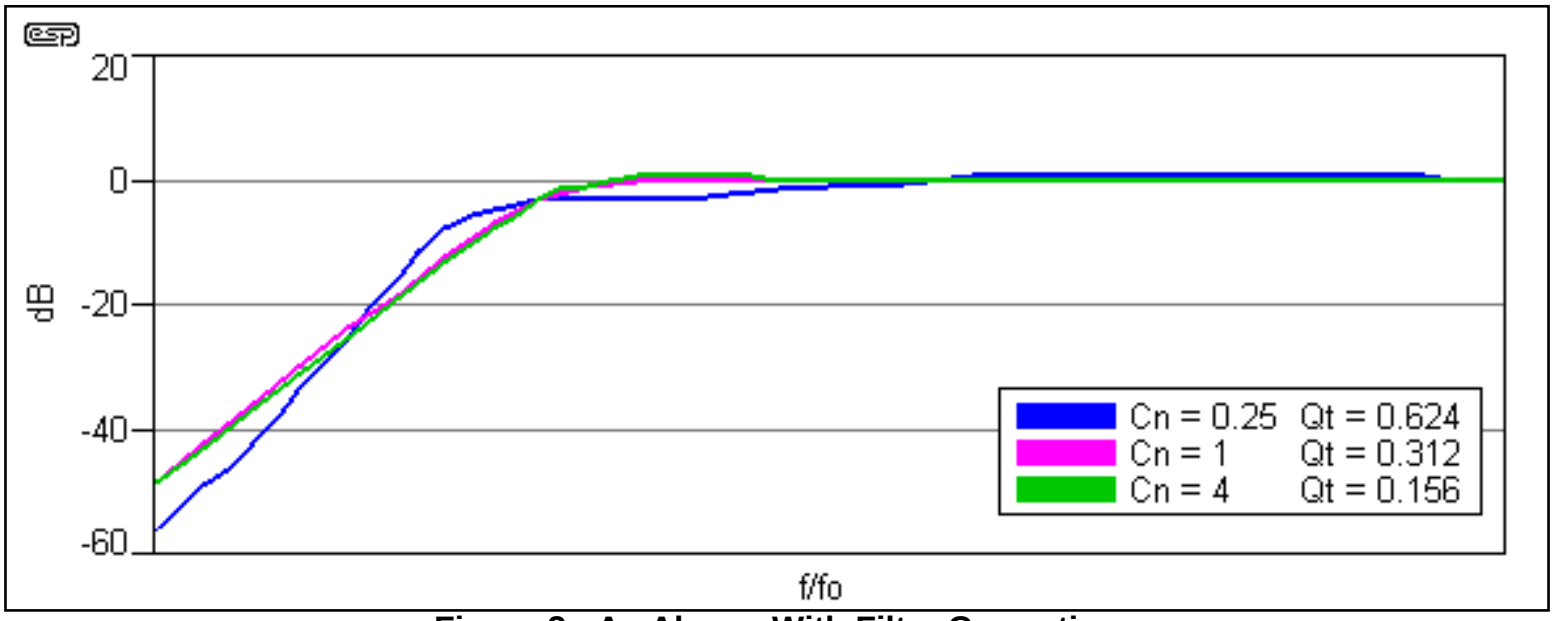

Figure 2 - As Above, With Filter Correction

The Cn values are the same for this plot, and the low Cn plot is somewhat smoother than for the non filter assisted case. Overall the Qt can vary over a wide range without any significant change in overall frequency response and at the low frequencies involved this slight aberration is completely swamped by room effects.

3 Using The Transforms

We usually have a specific f3 or box volume in mind when we design a speaker. The techniques that follow allow you to obtain a specific f3 or box volume. Also discussed is the method of alignment adjustment by means of increasing power amplifier source impedance by means of current feedback around the power amplifier, (see Rods article). To make it easier the tables that follow contain two constants, one enables a particular f3 to be obtained, another a particular box size. From the transforms we can write f3 as ...

f3 = (fs / f3' Qt') / (Qt fs')

This separates into two constants, one characteristic of the enclosure, the other of the driver, these are ...

kbf = (f3' qt') / fs' and **kdf = fs / Qt**

Likewise the expression for Vb ...

Vb = (Vas Qt² Vb') / (Vas Qt'²)
kbv = Vb' / (Vas x Qt'²) and **kdv = Vas x Qt²**

Table #1 has the values of kbv and kbf for the Qb5 alignments (alignment table in 'Satellites and Subs' article).

Qt	kbv	kbf	Qt	kbv	kbf	Qt	kbv	kbf

Table 1 - Qb5 Alignments

4 Using the Qb5 Table

In recent years the tower type loudspeaker system has become popular, these have the major advantage of a high SAF (Spouse Acceptance Factor). The larger of these generally has two 200mm drivers in either a two, two and a half or three way configuration. Two 200mm drivers have sufficient cone area and excursion to provide useful bass down to 30Hz, especially if used in a filter assisted alignment. A typical high quality 200mm driver is the Peerless Model CSX 217H, from the data in WinISD, This has ...

kdf = 27.4 / 0.281 = fs / Qt = 97.51

This needs ...

kbf = 30 / 97.51 = 0.308

From the QB 5 Class I alignment table the suitable alignment is No. 1 with a **kbf** = 0.303, so ...

√**Cn = 0.324 / 0.281 = 1.153**, therefore **Cn = 1.329**
a = 1.989 x 1.329 = 2.64
h = 0.995 x 1.153 = 1.322
fa = 0.944 x 1.153 = 1.255

multiplying or dividing the a, h and fa data in the QB5 table by **Cn** or √**Cn** as appropriate, gives the transformed values ...

Vb = (2 x 81.58) / 2.64 = 61.8 litres
Fb = 27.4 x 1.322 = 36.2 Hz

Fa = 27.4 x 1.255 = 34.4 Hz

Putting these figures into WinISD gives the result ...

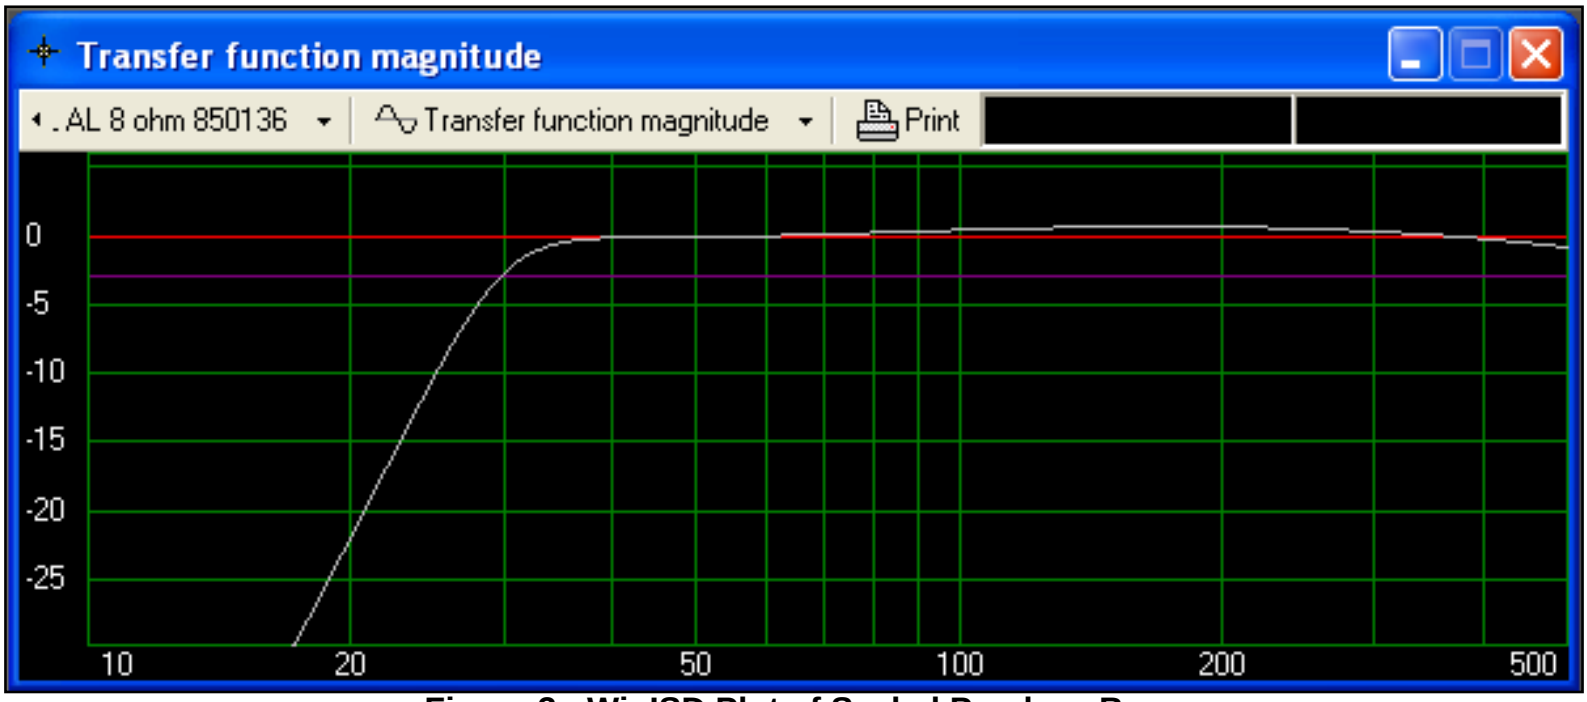

Figure 3 - WinISD Plot of Scaled Peerless Box

By using the compliance scaling and filter assistance this is a much better result than would normally be expected. The filter is a second order high-pass, having a -3dB frequency of 29.8Hz and a Q of 2.141

Should anyone simply select the same driver and run WinISD, the optimum result is actually far from optimal, having a -3dB frequency of almost 47Hz. While the box is smaller, it will be sadly lacking in the bottom end.

---

5 Calculating kp

Small's power handling parameter 'kp', is a very useful tool in determining the excursion limited power handling of a particular system. I have yet to find any reference to it on the Net except for my QB5 alignment article, I suspect this is because kp is difficult and tedious to calculate, and programs like WinISD provide a plot of maximum SPL. However, I still like to check by calculating kp, and the simplest way I have found is as follows ...

- Enter the data for the exact QB5 alignment for your driver
- Find pk. Excursion for this
- Enter the data for your transformed alignment

- Find pk. Excursion for this

Divide the peak excursion for your transformed alignment by the 'correct' one, and substitute in Small's expression, [5, P.439] ...

$kp1 = 0.425 / ((f3 / fs)^4\ j(xmax)^2)$

Where kp' is the correct 'seed', kp

$J(xmax)' = (0.424 / ((f3 / fs)^4 / kp)^{0.5}$
$J(xmax) = ((pkx / pkx')\ j(max))'$
$Kp' = 0.425 / ((f3' / fs')^4\ j(xmax)'^2)$

In our first example the low pk. Excursion is = 1.69mm and the high pk = 0.873mm, an average of 1.28mm. The 'correct' alignment has low pk = 0.532 and high pk = 0.977, averaging 0.755

The correct alignment has a kp of 9.349, giving j(max.)' of 0.131, j(max) is then = 0.222 giving Kp = 5.98

Giving a conservatively rated output of around 105db Peak for a pair before the linear excursion limit is reached, the SLS 213 driver will give more output before excursion limiting, but at the expense of a box twice as large. It should also be noted that since the class I alignments have an average of 6db of boost at around the f3, they need around four times the power that the nominal efficiency would indicate, this is the price we pay for a small box.

---

6 Increasing Qt

We can increase Qt by increasing Qe, and this can be done by increasing the driving amplifiers output impedance by means of current feedback,[6], (Rods article).

If we write Qe as [7] ...

$Qe = Rvc / Lces\ ws$

We can increase Qe by adding a source resistance to Rvc

$Qe' = (Rvc + Ro) / Lces\ ws$

If the Qe we need is = Qe', then The required Qe' is given by ...

Qe' = 1 / (1 / Qt' - 1 / Qm)

Where Qt'= the required Qt., The required source resistance is then ...

Kl = Rvc/Qe

Ro = Qe'Kl - Rvc

[ ] The following diagram shows the essentials of modifying the amplifier's output impedance, giving a circuit that is relatively easily scaled for any loaded gain and a defined output impedance. The calculations for this are fairly straightforward, but only if you can accept an apparently random loaded gain. If you want to specify the loaded gain, the calculations become extremely tedious. While a far better mathematician than the editor may be able to derive a suitable equation, I was unable to do so, and as a result have written a small Visual Basic application to perform the maths needed to arrive at a satisfactory set of component values. This is still under development to get it right - the full details will be published in a second part to the current page.

Although I did try this with a spreadsheet (and that's where the formulae I eventually used came from), it is a reiterative process. Those wishing to experiment are encouraged to do so. All the necessary formulae and the finalised calculator will be available with Part 2 of this article.

Essentially, the calculations involve solving for an unbalanced Wheatstone bridge network, with specific desired end results. Of course you can always cheat and use a series resistor of the appropriate value, but this will have to dissipate considerable power with any amplifier capable of reasonable output power.

In essence, the determination of the correct values is not easy. Because we generally need to specify the output impedance, as well as the normal loaded gain (so the amp is in line with others in the system), we end up with too many unknown variables - the circuit may look simple, but calculations for it are not.

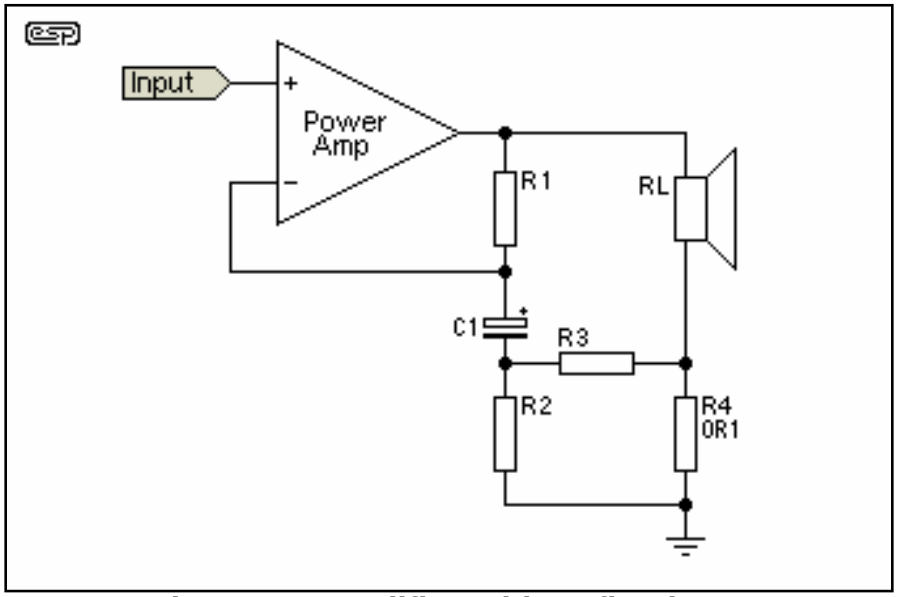

Figure 4 - Amplifier With Defined Z_{out}

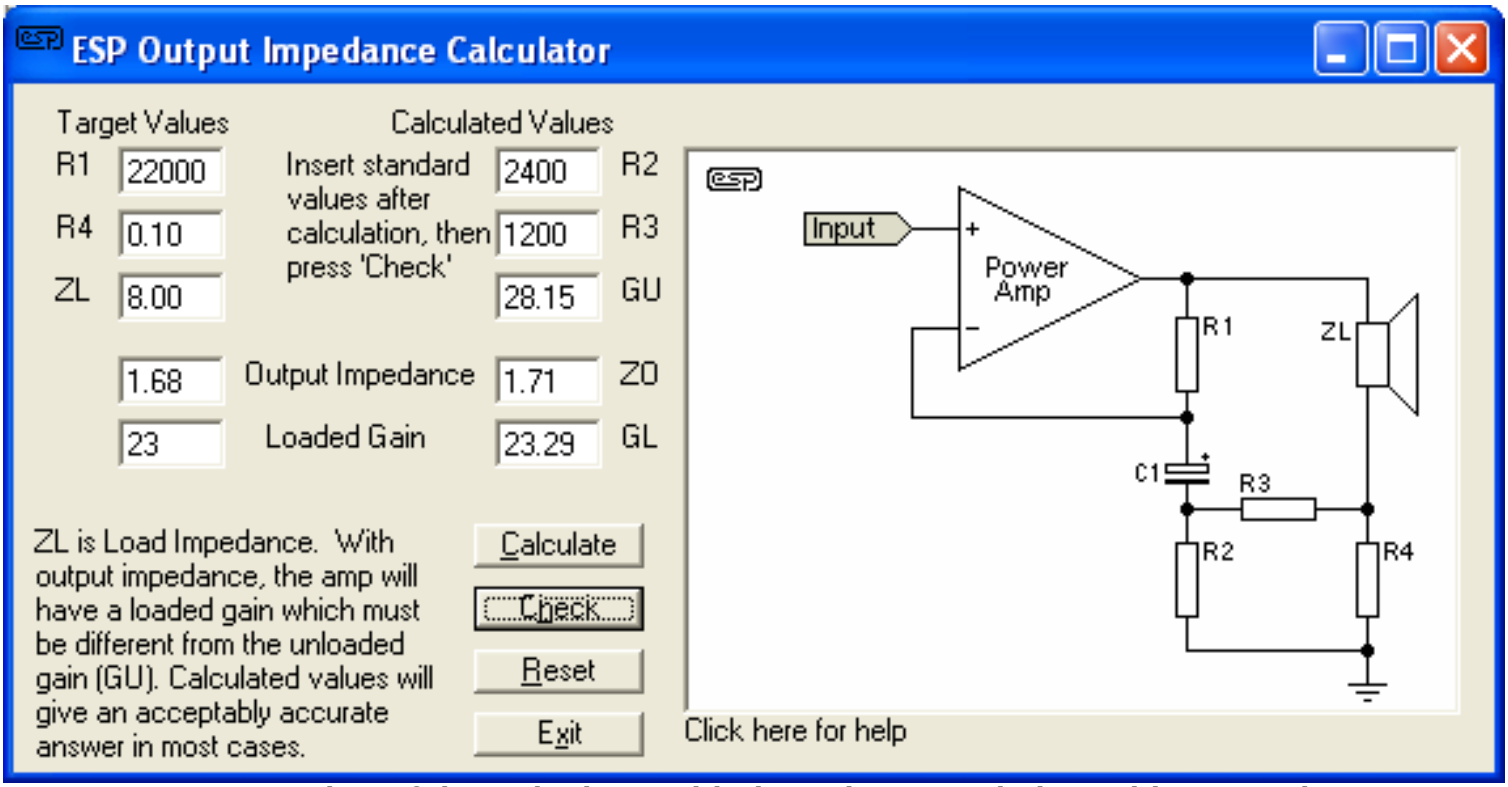
The circuit above is almost identical to that shown in the article / project Variable Amplifier Impedance. By varying R2, R3 and R4, it is possible to achieve a wide range of impedances that will be usable in this application. The circuit can be made variable, however this is not normally useful except for ongoing design and experimentation.



Screen Shot of the Calculator with the Values Needed For this Example

The above screen shot shows the values determined for the example presented here using the first draft of the calculator program. Standard values were used for R2 and R3, and the results checked as shown. The difference between the desired 1.68 ohms and the

calculated 1.71 ohms is minimal and will not have a significant effect on the result.

Note that the loudspeaker driver's nominal impedance is used to determine the loaded gain, and this is useful because nearly all ESP amps are designed with a gain of 23 (approx. 27dB). The calculator program is available as a download (see below). Sorry, but because it is written in Visual Basic, it is only suitable for Windoze machines (or Macs running Wine emulation or similar - perhaps - this has not been tested).

As shown above, the values apply for the following example. R1 is 22k as used in most ESP amplifier designs, and the feedback resistor (R4) is 0.1 ohm. Using 2.4k (2 x 1.2k in series) for R2 and 1.2k for R3, the output impedance is 1.71 Ohms, and the loaded gain is 23.29 - almost exactly the same as other amps as may be used in the system. [/]

This scheme is especially useful for increasing the Qt of low Qt high efficiency drivers, such as the JBL K140. This driver is still much available on the internet as a re-cone, and is especially designed for bass guitar applications. If we put it into a filter assisted alignment the result is an increase power handling. Increasing Qt has the advantage that the drivers high efficiency is preserved whilst achieving a low enough f3 in a small box. We want f3 = 40Hz for the usual bass guitar tuning.

Looking at the QB5 class I alignments the required f3 / fs of 1.333 is achieved by the alignment No. 7, this needs a Qt of 0.271, and a box of 92 litres ...

Qe' = 1 / (1 / 0.271 - 1 / 5) = 0.287
Ro = 1.68

The above values are perfect, with only the smallest discrepancy which is of no consequence in the final design. WinISD gives the following ..

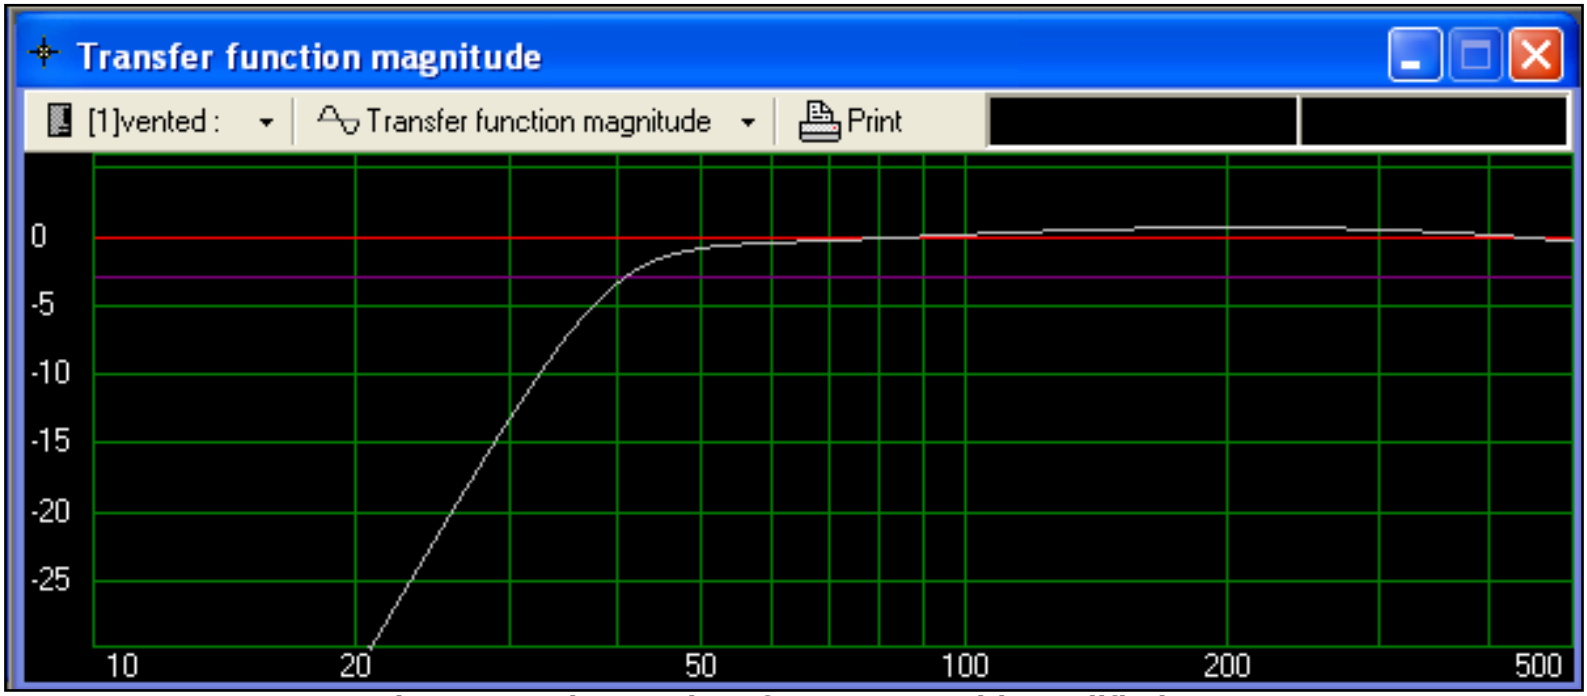


Figure 5 - WinISD Plot of JBL K140 With Modified Qt

This is achieved by using the amplifier set for an output impedance of 1.7 Ohms, and with a second order 40Hz high-pass filter having a Q of 1.658. It is worth noting that using any one or two of the techniques described will not work - the final result is derived only by the combination of compliance scaling, elevated source impedance and filter assistance applied as a complete system solution.

---

7 Auxiliary Filter Damping

Thiele points out that all other things being equal, doubling Qt results in a +6db peak at the resonant frequency, [1], i.e.

20 Log(Qt / Qt')

From this we can fit a driver to a particular filter assisted alignment by modifying the fa damping by the amount

dbfa' = dbfa - (20 Log(Qt / Qt'))

---

8 A small Satellite Surround Speaker

With the advent of five and now seven speaker surround systems, there is an increasing need for small speaker systems with good power handling, and the all important SAF

index improves with less intrusive enclosures. A typical high quality 150mm. Bass/mid. Driver is the Vifa P17WJ. In this case we fit it to a box that will give an f3 of around 80Hz, making it suitable for use as a satellite, and use a QB5 class II alignment, this optimizes excursion limited power handling.

If we use the QBQ class II alignment No. 14, we have

Vb = 12.6 litres, fb = 68.6 Hz, Fa = 78.1 Hz, 1/Qfa = 1.9

Giving the WinISD plot ...

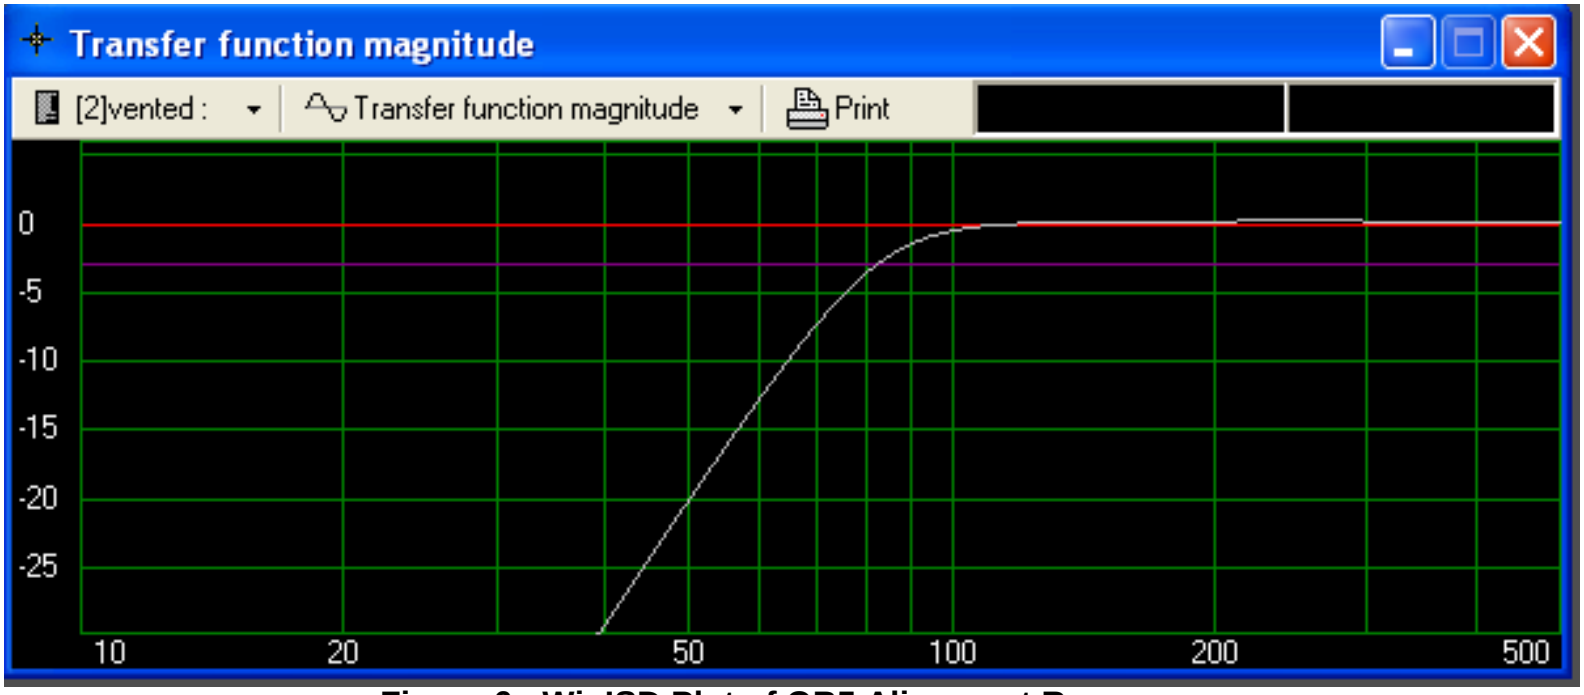

Figure 6 - WinISD Plot of QB5 Alignment Response

---

9 The B5 Alignments

In some cases we only want to use a simple passive first order filter, in others we only want to use two passive first order sections, in which case we have a fixed auxiliary filter damping factor of two. This is characteristic of the auxiliary filters in the QB5 class III alignments. In the case of being able to use only a single first order section, the B5 alignments [8], are useful, these are reproduced in table #2.

Table 2 - B5 Alignments

A driver that is popular for computer speakers is the Tangband, W3-926S. Using a B5 alignment with an F3 = 100Hz. Gives a box of 4.7 litres, tuned to 105Hz. This achieves its

rated x_{peak} with *one Watt* of input. If you put this driver into a sealed box the maximum output at 100Hz is 77.9dB, with the B5 box this is raised to 89.9db. Using a QB5 class III box gives a rather large 7.5litres.

It also should be noted that putting a capacitor between 150 and 220 uF. in series with the driver only changes the frequency response by around 2db. As shown in the Matlab plot of Figure 7 the frequency response with 220uF is not as smooth as with an isolated filter, but is within acceptable limits.

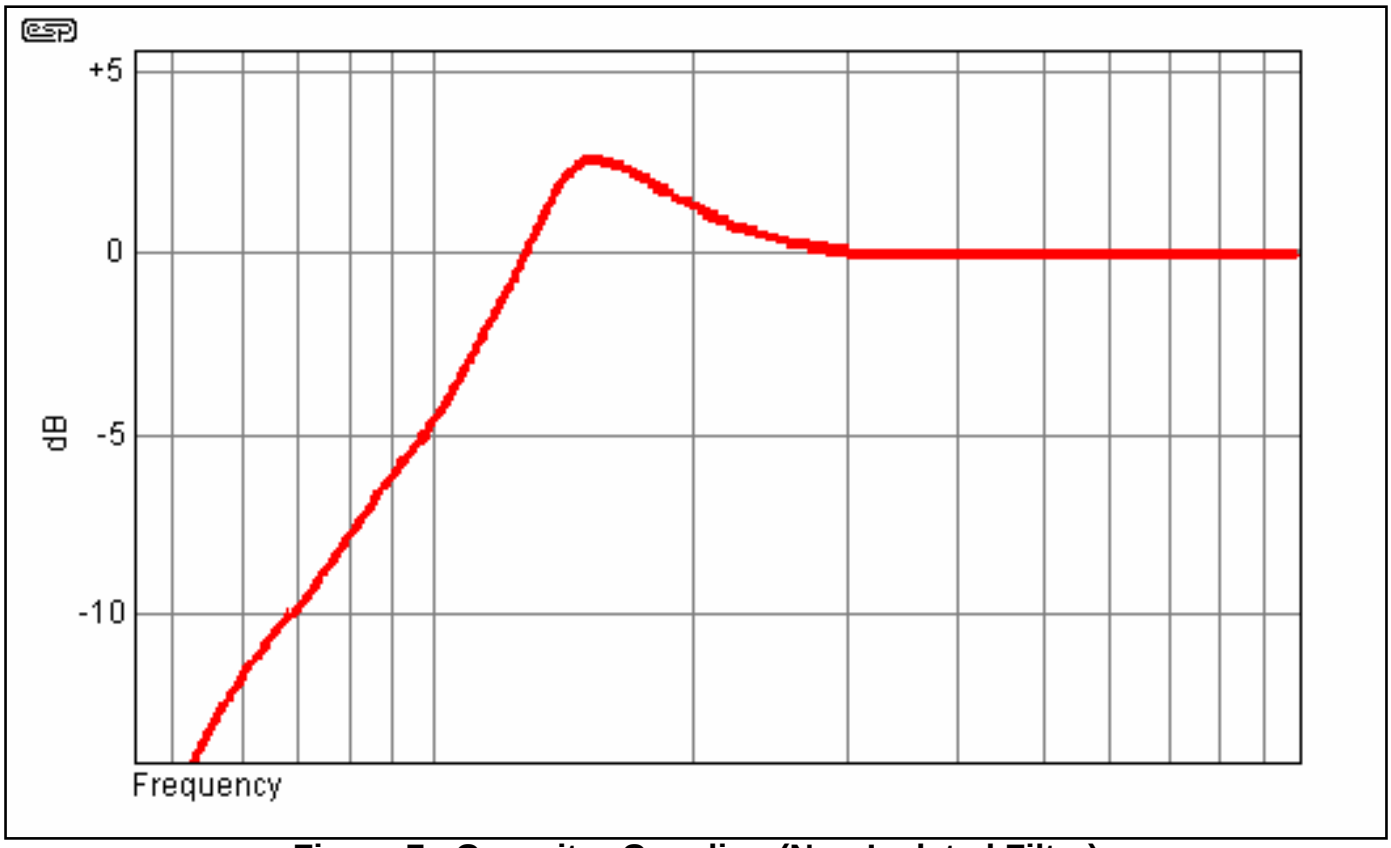

Figure 7 - Capacitor Coupling (Non-Isolated Filter)

In some instances it is convenient to provide one isolated and one non isolated filter, i.e. by means of an input coupling capacitor on the amplifier, and a capacitor in series with the driver. Using a first order isolated filter of twice the non isolated filters f3 gives a plot of Figure 8.

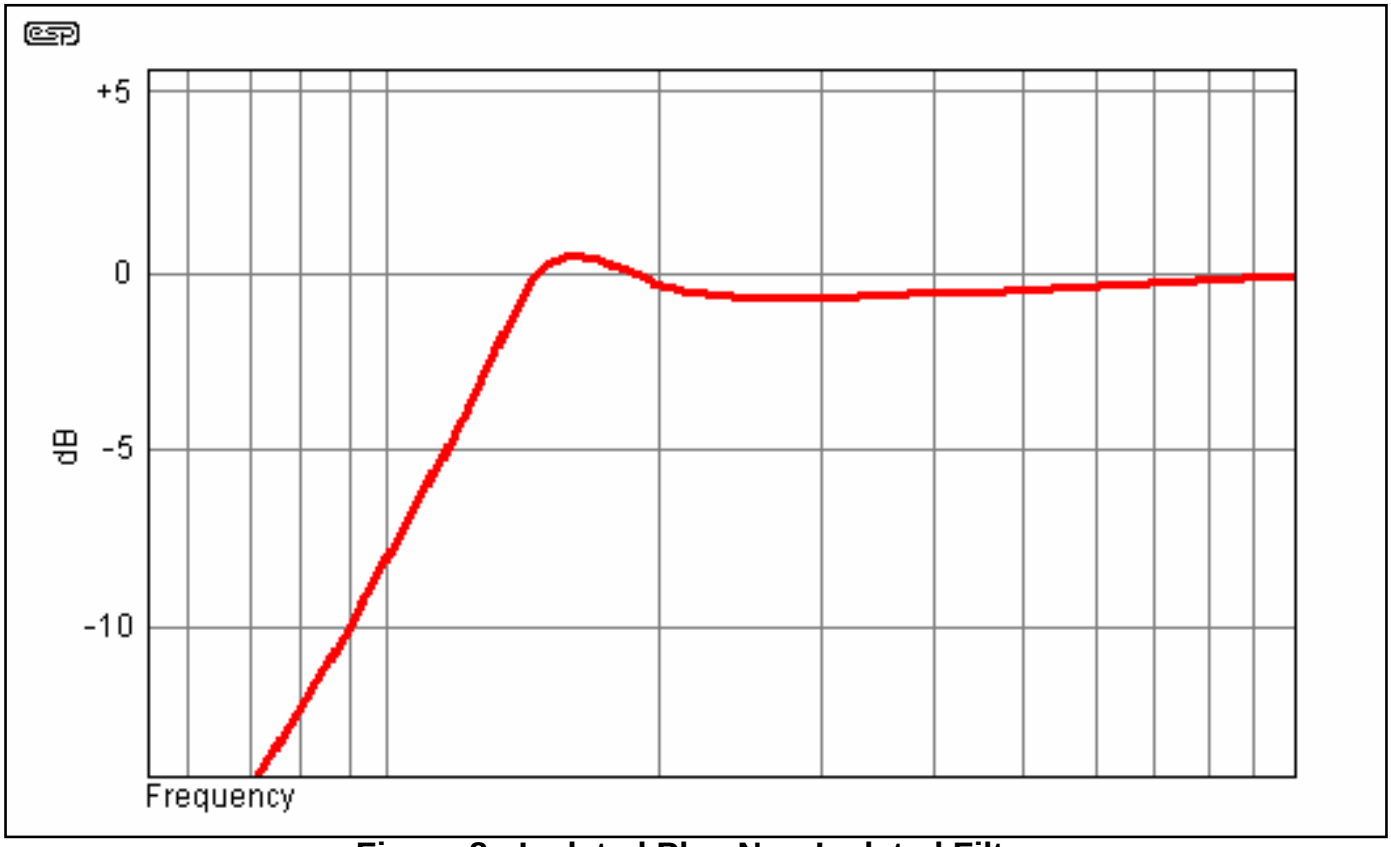

Figure 8 - Isolated Plus Non-Isolated Filter

As illustrated in this article it is possible to fit just about any driver to just about any alignment using the three techniques outlined, or indeed a combination of them.

All efforts have been made to make the calculations of the simple plug in the numbers variety, I apologise where this is not possible. Anybody is at liberty to turn this article into a spread sheet, or some other easy to use form, do not ask me for this however - programming computers is a thing that I dislike, and avoid at all costs.
