The final thing to be considered is that low power supply voltage invariably means single-supply design, and single-supply design is tougher than split-supply design. Remember to get the two sets of data points, put them in simultaneous equations, solve for the slope and intercept, select the circuit configuration, and calculate the component values. DACs are a little different because you have to account for the polarity of the current, but their design generally follows the same procedure. A good reference for single supply design is the Texas Instruments application report *Single Supply Op Amp Design Techniques* (TI literature number SLOA030).

Appendix A

Single-Supply Circuit Collection

Ron Mancini and Richard Palmer

A.1 Introduction

Portable and single-supply electronic equipment is becoming more popular each day. The demand for single-supply op amp circuits increases with the demand for portable electronic equipment because most portable systems have one battery. Split- or dual-supply op amp circuit design is straightforward because op amp inputs and outputs are referenced to the normally grounded center tap of the supplies. In the majority of split-supply applications, signal sources driving the op amp inputs are referenced to ground, thus with one input of the op amp referenced to ground, as shown in Figure A–1, there is no need to consider input common-mode voltage problems.

$$V_{OUT} = -V_{IN}\frac{R_F}{R_G} \qquad \text{A–1A}$$

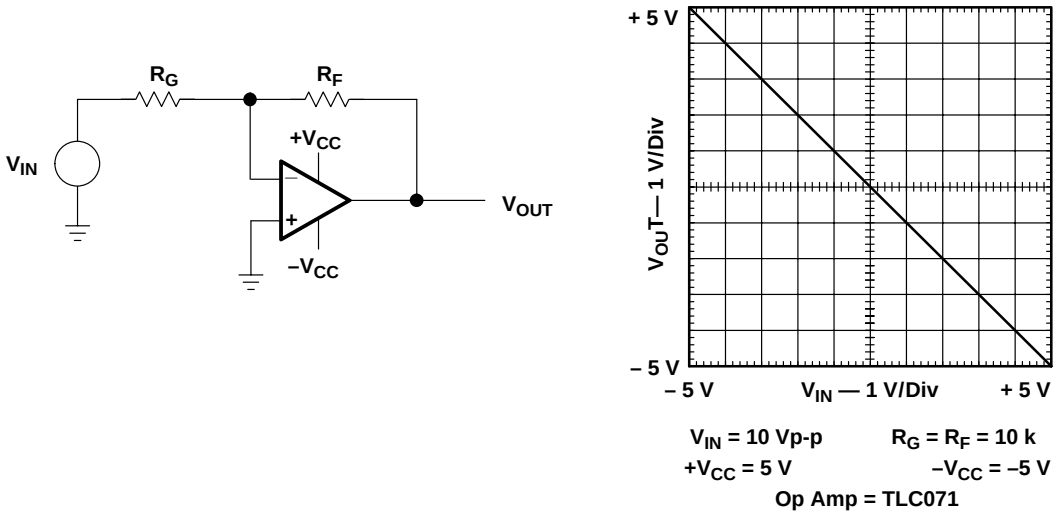

Figure A–1. Split-Supply Op Amp Circuit

When the signal source is not referenced to ground (see Figure A–2 and Equation A–1B), the voltage difference between ground and the reference voltage shows up amplified in the output voltage. Sometimes this situation is OK, but other times the difference voltage must be stripped out of the output voltage.

$$V_{OUT} = -\left(V_{IN} + V_{REF}\right)\frac{R_F}{R_G} \qquad \text{A–1B}$$

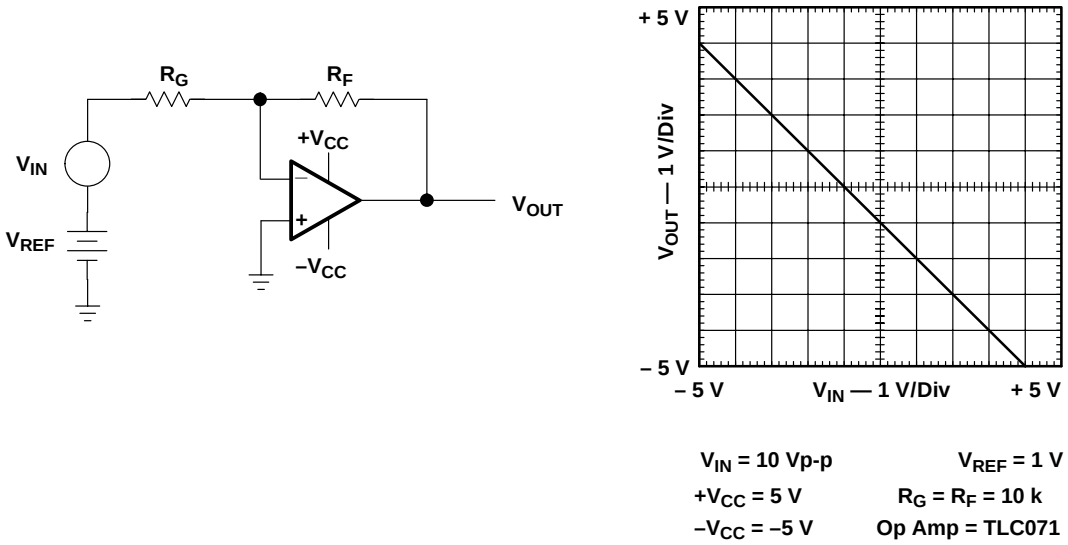

Figure A–2. Split-Supply Op Amp Circuit With Reference Voltage Input

An input bias voltage is used to eliminate the difference voltage when it must not appear in the output voltage (see Figure A–3 and Equation A–1C). The voltage, V_{REF}, is in both input circuits, hence it is named a common-mode voltage. Voltage-feedback op amps, like those used in this document, reject common-mode voltages because their input circuit is constructed with a differential amplifier (chosen because it has natural common-mode voltage rejection capabilities).

$$V_{OUT} = -\left(V_{IN} + V_{REF}\right)\frac{R_F}{R_G} + V_{REF}\left(\frac{R_F}{R_F + R_G}\right)\left(\frac{R_F + R_G}{R_G}\right) = -V_{IN}\frac{R_F}{R_G} \qquad \text{A–1C}$$

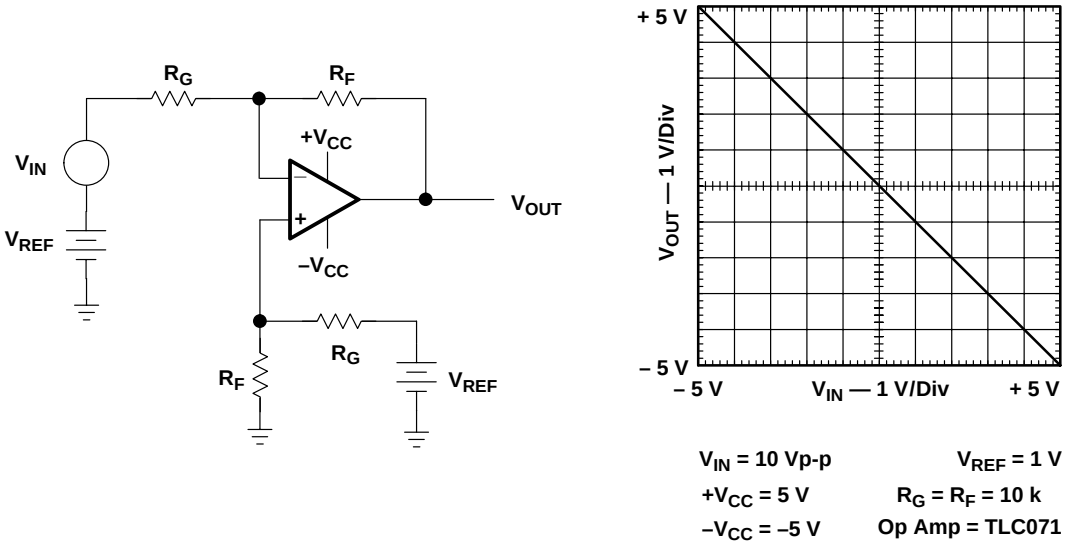

Figure A–3. Split-Supply Op Amp Circuit With Common-Mode Voltage

When signal sources are referenced to ground, single-supply op amp circuits always have a large input common-mode voltage. Figure A–4 shows a single-supply op amp circuit that has its input voltage referenced to ground. The input voltage is not referenced to the midpoint of the supplies like it would be in a split-supply application, rather it is referenced to the lower power supply rail. This circuit malfunctions when the input voltage is positive because the output voltage would have to go negative — hard to do with a positive supply. It operates marginally with small negative input voltages because most op amps do not function well when the inputs are connected to the supply rails.

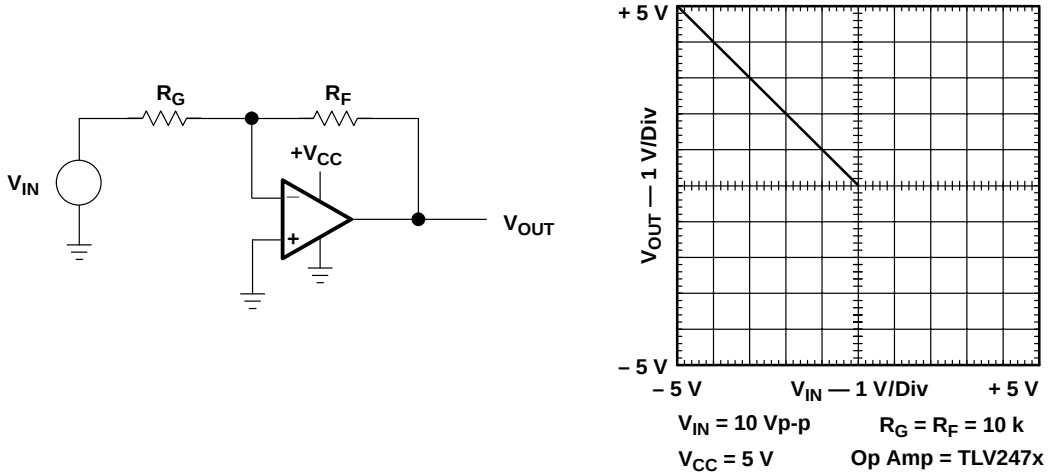

Figure A–4. Single-Supply Op Amp Circuit

The constant requirement to account for inputs connected to ground or other reference voltages makes it difficult to design single-supply op amp circuits. This appendix presents a collection of single-supply op amp circuits, including their description and transfer equation. Those without a good working knowledge of op amp equations should reference the *Understanding Basic Analog* series of application notes available from Texas Instruments. Application note SLAA068, *Understanding Basic Analog — Ideal Op Amps* develops the ideal op amp equations. Circuit equations in this appendix are written with the ideal op amp assumptions as specified in *Understanding Basic Analog — Ideal Op Amps.* The assumptions appear in Table A–1 for easy reference.

Table A–1. Ideal Op Amp Assumptions

PARAMETER NAME	PARAMETER SYMBOL	VALUE
Input current	I_{IN}	0
Input offset voltage	V_{OS}	0
Input impedance	Z_{IN}	∞
Output impedance	Z_{OUT}	0
Op amp gain	a	∞

Detailed information about designing single-supply op amp circuits appears in application note SLOA030, *Single-Supply Op Amp Design Techniques*. Unless otherwise specified, all op amp circuits shown here are single-supply circuits. The single supply may be wired with the negative or positive lead connected to ground, but as long as the supply polarity is correct, the wiring does not affect circuit operation.

A.2 Boundary Conditions

All op amps are constrained to output voltage swings less than or equal to their power supply. Use of a single supply limits the output voltage to the range of the supply voltage. For example, when the supply voltage V_{CC} equals +10 V, the output voltage is limited to the range $0 \le V_{OUT} \le 10$. This limitation precludes negative output voltages when the circuit has a positive supply voltage, but it does not preclude negative input voltages. As long as the voltage on the op amp input leads does not become negative, the circuit can handle negative voltages applied to the input resistors.

Beware of working with negative (positive) input voltages when the op amp is powered from a positive (negative) supply because op amp inputs are highly susceptible to reverse-voltage breakdown. Also, ensure that no *start-up* condition reverse biases the op amp inputs when the input and supply voltage are opposite polarity. It may be advisable to protect the op amp inputs with a diode (Schottky or germanium) connected anode to ground and cathode to the op amp input.

A.3 Amplifiers

Many types of amplifiers can be created using op amps. This section consists of a selection of some basic, single-supply op amp circuits that are available to the designer during the concept stage of a design. The circuit configuration and correct single-supply dc biasing techniques are presented for the following cases: inverting, noninverting, differential, T-network, buffer and ac-coupled amplifiers.

A.3.1 Inverting Op Amp with Noninverting Positive Reference

The ideal transfer equation is given in Equation A–1.

$$V_{OUT} = -V_{IN}\frac{R_F}{R_G} + V_{REF}\left(\frac{R_F + R_G}{R_G}\right) \qquad \text{A–1}$$

The transfer equation for this circuit (Figure A–5) takes the form of Y = –mX + b. The transfer function slope is negative, and the dc intercept is positive. R_F and R_G are contained in both halves of the equation, thus it is hard to obtain the desired slope and dc intercept without modifying V_{REF}. This is the minimum component count configuration for this transfer function. When the reference voltage is 0, the input voltage is constrained to negative voltages because positive input voltages would cause the output voltage to saturate at ground.

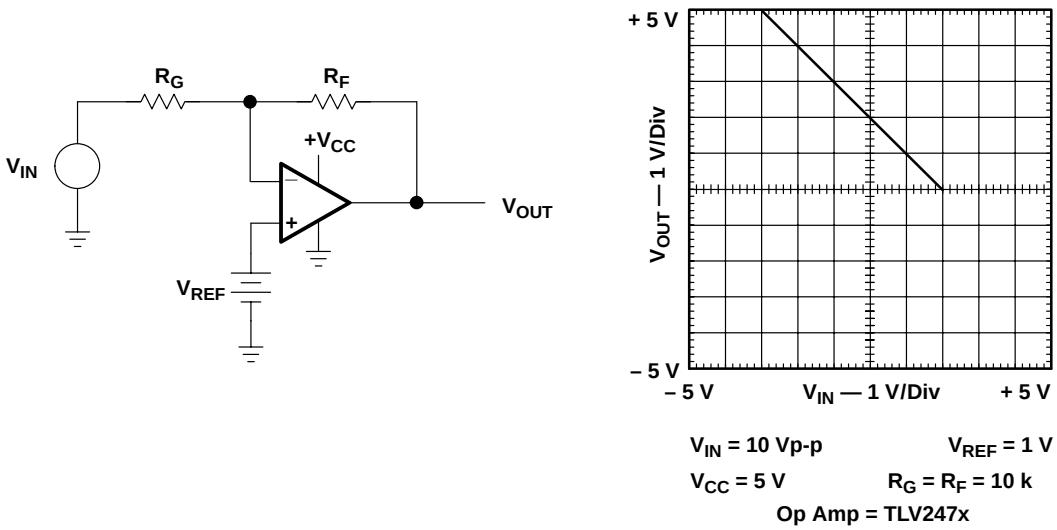

Figure A–5. Inverting Op Amp with Noninverting Positive Reference

A.3.2 Inverting Op Amp with Inverting Negative Reference

The transfer equation takes the form of Y = –mX + b and is given in Equation A–2.

$$V_{OUT} = -V_{IN}\frac{R_F}{R_{G1}} + V_{REF}\frac{R_F}{R_{G2}} \qquad \text{A–2}$$

The transfer function slope is negative, and the dc intercept is positive (Figure A–6). R_{G1} and R_{G2} are contained in the equation, thus it is easy to obtain the desired slope and dc intercept by adjusting the value of both resistors. Because of the virtual ground at the inverting input, R_{G2} is the terminating impedance for V_{REF}. When the reference voltage is 0, the input voltage is constrained to negative voltages because positive input voltages would cause the output voltage to saturate at ground.

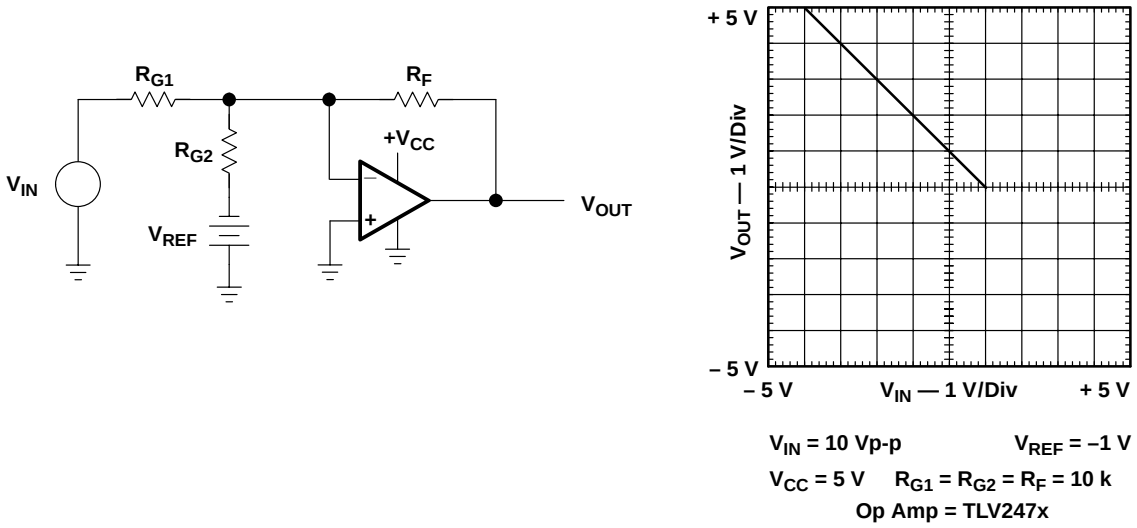

Figure A–6. Inverting Op Amp with Inverting Negative Reference

A.3.3 Inverting Op Amp with Noninverting Negative Reference

The transfer equation takes the form of Y = –mX – b and is given in Equation A–3.

$$V_{OUT} = -V_{IN}\frac{R_F}{R_G} - V_{REF}\left(\frac{R_F + R_G}{R_G}\right) \qquad \text{A–3}$$

The transfer function slope is negative, and the dc intercept is negative. R_F and R_G are contained in both halves of the equation, thus it is hard to obtain the desired slope and dc intercept without modifying V_{REF}. This is the minimum component count configuration for this transfer function. The slope and dc intercept terms in Equation A–3 are both negative, hence, unless the correct input voltage range is selected, the output voltage will saturate at ground. The negative input voltage must be limited to less than –400 mV because op amp inputs either break down or have protection circuits that forward bias when large negative voltages are applied to the inputs.

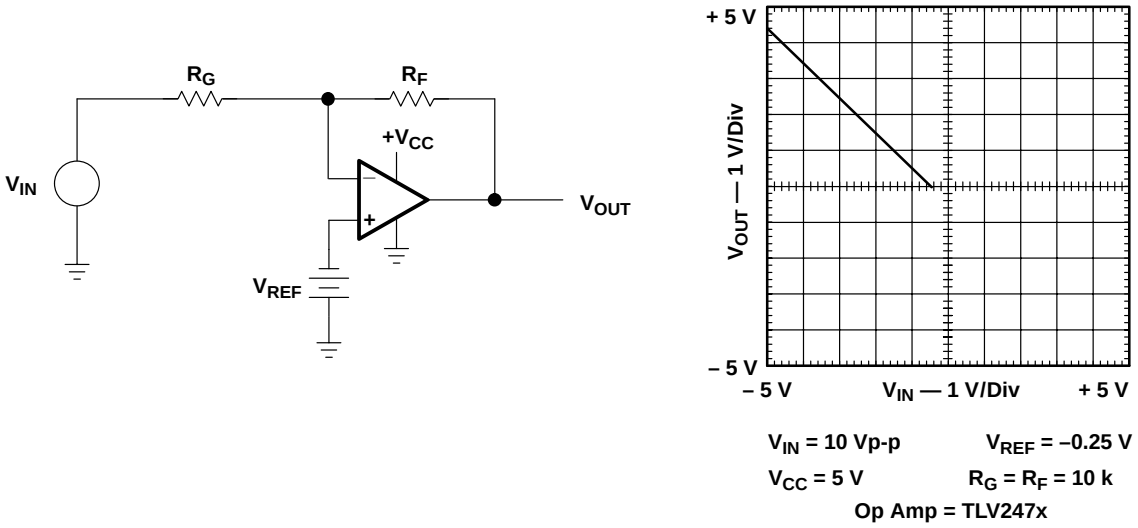

Figure A–7. Inverting Op Amp with Noninverting Negative Reference

A.3.4 Inverting Op Amp with Inverting Positive Reference

The transfer equation takes the form of Y = –mX – b and is given in Equation A–4.

$$V_{OUT} = -V_{IN}\frac{R_F}{R_{G1}} - V_{REF}\frac{R_F}{R_{G2}} \qquad \text{A–4}$$

The transfer function slope is negative, and the dc intercept is negative. R_{G1} and R_{G2} are contained in the equation, thus it is easy to obtain the desired slope and dc intercept by adjusting the value of both resistors. Because of the virtual ground at the inverting input, R_{G2} is the terminating impedance for V_{REF}. The slope and dc intercept terms in Equation A–4 are both negative, hence, unless the correct input voltage range is selected, the output voltage will saturate.

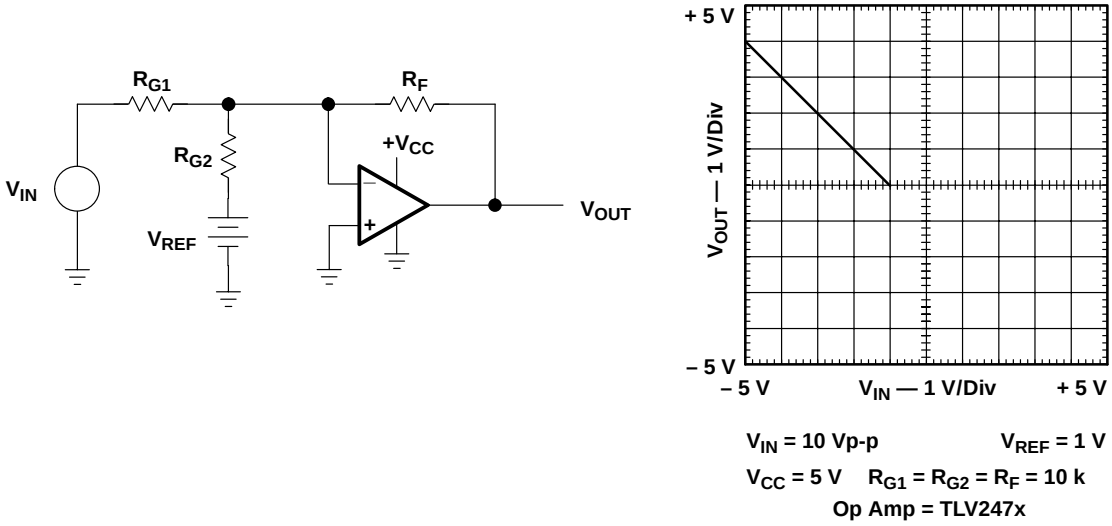

Figure A–8. Inverting Op Amp with Inverting Positive Reference

A.3.5 Noninverting Op Amp with Inverting Positive Reference

The transfer equation takes the form of Y = mX – b and is given in Equation A–5.

$$V_{OUT} = V_{IN} \frac{R_F + R_G}{R_G} - V_{REF} \frac{R_F}{R_G} \qquad \text{A–5}$$

The transfer function slope is positive, and the dc intercept is negative. This is the minimum component count configuration for this transfer function. The reference termination resistor is connected to a virtual ground, so R_G is the load across V_{REF}. R_F and R_G are contained in both halves of the equation, thus it is hard to obtain the desired slope and dc intercept without modifying V_{REF} or placing an attenuator in series with V_{IN}.

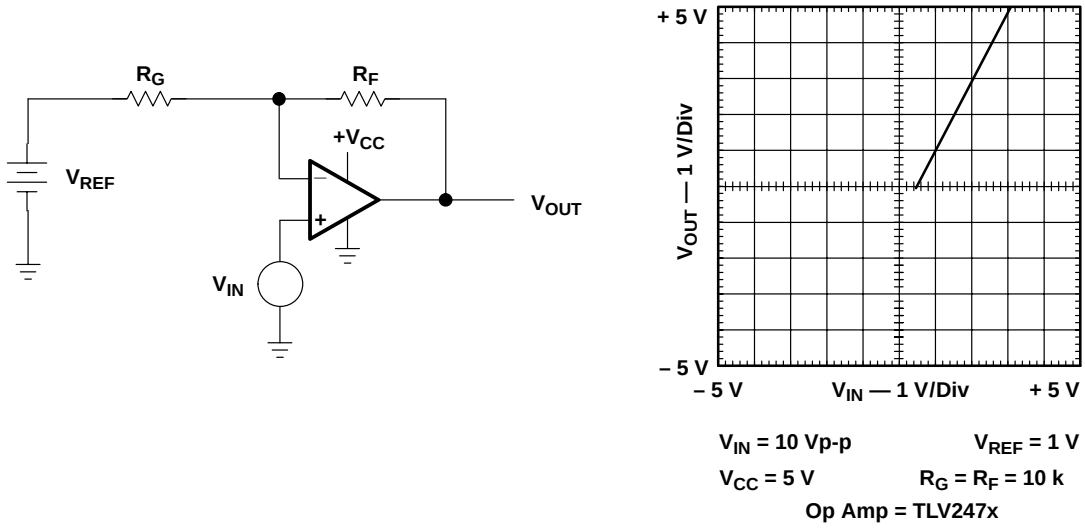

Figure A–9. Noninverting Op Amp with Inverting Positive Reference

A.3.6 Noninverting Op Amp with Noninverting Negative Reference

The transfer equation takes the form of Y = mX – b and is given in Equation A–6.

$$V_{OUT} = V_{IN}\left(\frac{R_2}{R_1 + R_2}\right)\frac{R_F + R_G}{R_G} - V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\frac{R_F + R_G}{R_G} \qquad \text{A–6}$$

The transfer function slope is positive, and the dc intercept is negative. The reference is terminated in R_1 and R_2. R_1 and R_2 can be selected independent of R_F and R_G to obtain the desired slope and dc intercept. The price for the extra degree of freedom is two resistors.

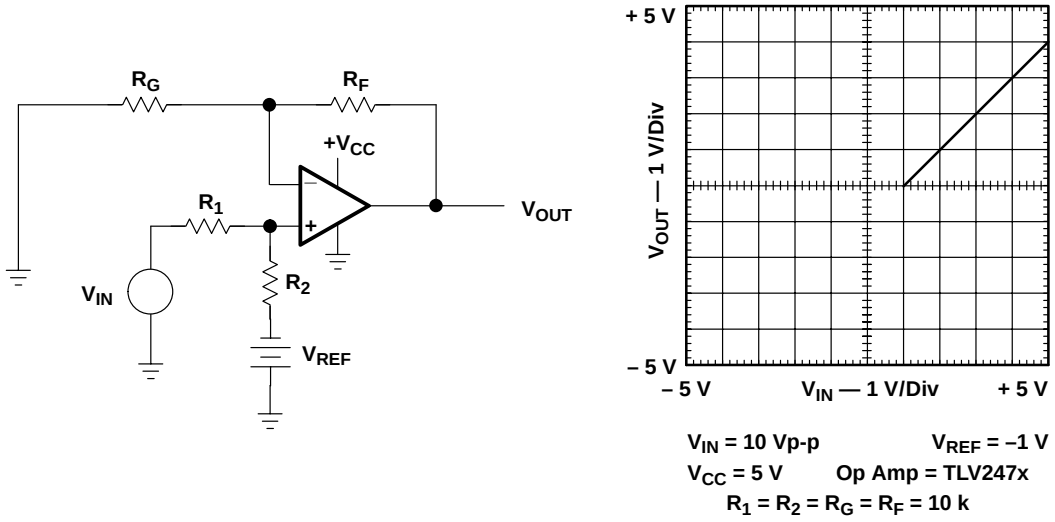

Figure A–10. Noninverting Op Amp with Noninverting Negative Reference

A.3.7 Noninverting Op Amp with Inverting Negative Reference

The transfer equation takes the form of Y = mX + b and is given in Equation A–7.

$$V_{OUT} = V_{IN} \frac{R_F + R_G}{R_G} + V_{REF} \frac{R_F}{R_G} \qquad \text{A–7}$$

The transfer function slope is positive, and the dc intercept is positive. This is the minimum component count configuration for this transfer function. The reference termination resistor is connected to a virtual ground, so R_G is the load across V_{REF}. R_F and R_G are contained in both halves of the equation. Thus it is hard to obtain the desired slope and dc intercept without modifying V_{REF} or placing an attenuator in series with V_{IN}.

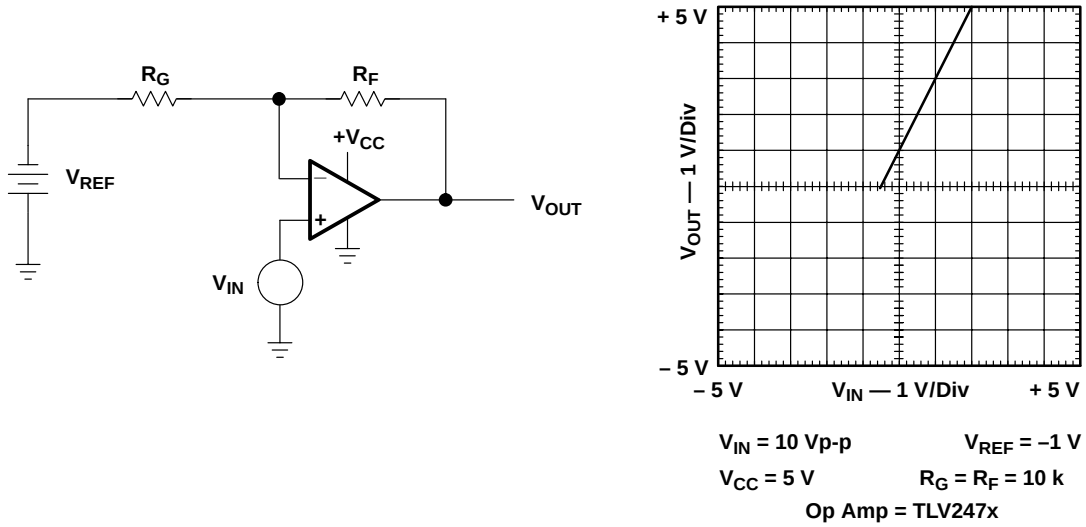

Figure A–11. Noninverting Op Amp with Inverting Positive Reference

A.3.8 Noninverting Op Amp with Noninverting Positive Reference

The transfer equation takes the form of Y = mX + b and is given in Equation A–8.

$$V_{OUT} = V_{IN}\left(\frac{R_2}{R_1 + R_2}\right)\frac{R_F + R_G}{R_G} + V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\frac{R_F + R_G}{R_G} \qquad \text{A–8}$$

The transfer function slope is positive, and the dc intercept is positive. The reference is terminated in R_1 and R_2. R_1 and R_2 can be selected independent of R_F and R_G to obtain the desired slope and dc intercept. The price for the extra degree of freedom is two resistors.

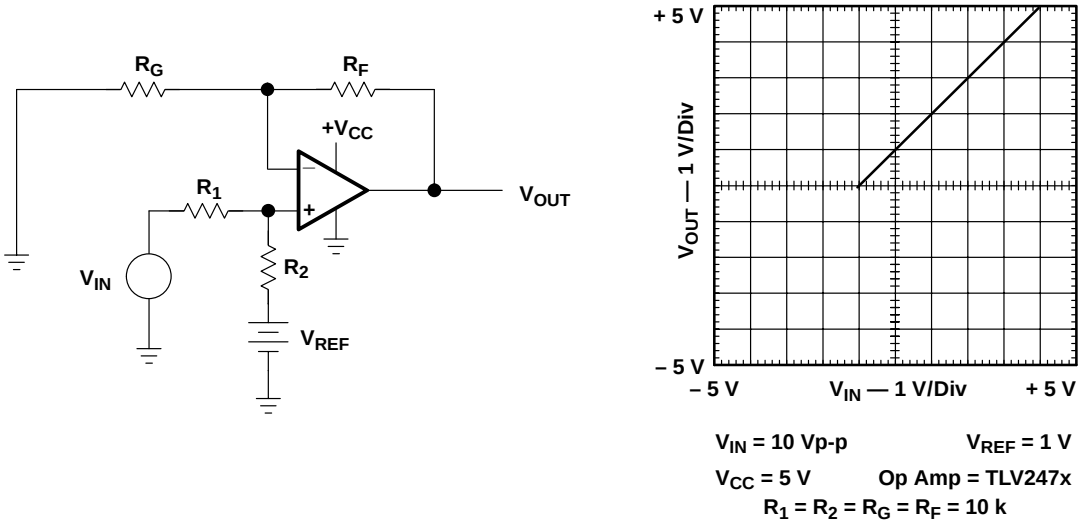

Figure A–12. Noninverting Op Amp with Noninverting Positive Reference

A.3.9 Differential Amplifier

When R_F is set equal to R_2 and R_G is set equal to R_1, Equation A–9 reduces to Equation A–10.

$$V_{OUT} = V_{IN2}\,\frac{R_F + R_G}{R_G}\left(\frac{R_2}{R_1 + R_2}\right) - V_{IN1}\,\frac{R_F}{R_G} \qquad \text{A–9}$$

$$V_{OUT} = \left(V_{IN2} - V_{IN1}\right)\frac{R_F}{R_G} \qquad \text{A–10}$$

These resistors must be matched very closely to obtain good differential performance. The mismatch error in these resistors reduces the common-mode performance, and the mismatch shows up in the output as an amplified common-mode voltage.

Consider Equation A–10. Note that only the difference signal is amplified, thus this configuration is called a differential amplifier. The differential amplifier is a popular circuit in precision applications where it is used to amplify sensor outputs while rejecting common-mode noise.

The inverting input impedance is R_G because of the virtual ground at the inverting op amp input. The noninverting input impedance is $R_F + R_G$ because the noninverting op amp input impedance approaches infinity. The two input impedances are different, and this leads to two problems with this circuit.

First, mismatched input impedances preclude any attempts to cancel input bias currents through resistor matching. Often R_2 is set equal to $R_F \,||\, R_G$ so that the bias currents develop equal common-mode voltages which the op amp rejects. This is not possible when $R_2 = R_F$ and $R_1 = R_G$ unless the source impedances are matched. Second, high output impedance sensors are often used, and when high output sensors work into mismatched input impedances, errors occur.

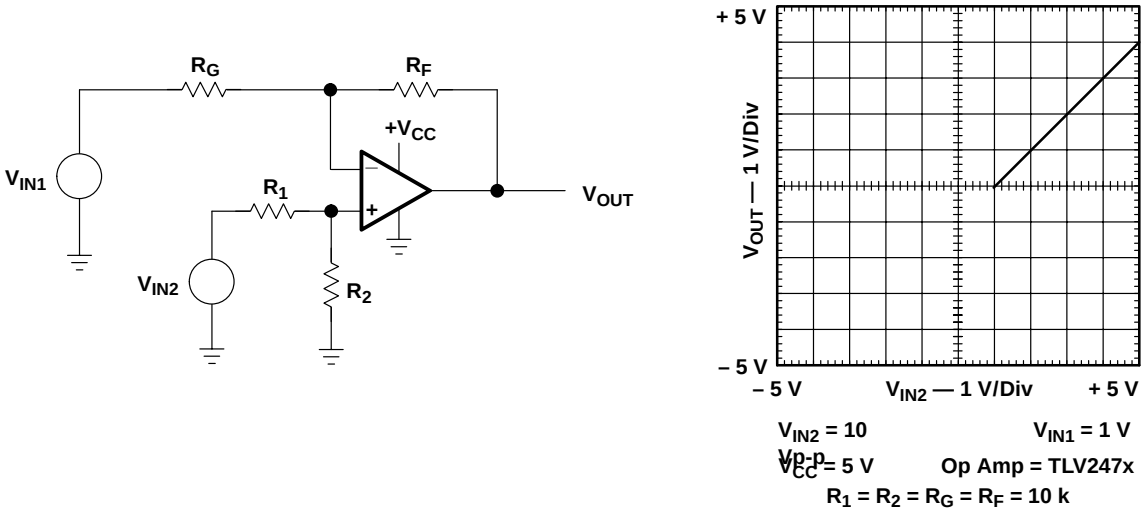

Figure A–13. Differential Amplifier

A.3.10 Differential Amplifier With Bias Correction

When R_F is set equal to R_2 and R_G is set equal to R_1, Equation A–11 reduces to Equation A–12.

$$V_{OUT} = V_{IN2}\frac{R_F + R_G}{R_G}\left(\frac{R_2}{R_1 + R_2}\right) + V_{REF}\frac{R_F + R_G}{R_G}\left(\frac{R_1}{R_1 + R_2}\right) - V_{IN1}\frac{R_F}{R_G} \quad \text{A–11}$$

$$V_{OUT} = \left(V_{IN2} - V_{IN1}\right)\frac{R_F}{R_G} + V_{REF} \quad \text{A–12}$$

When an offset voltage must be eliminated from or added to the input signal, this differential amplifier circuit is employed. The reference voltage can be positive or negative depending upon the polarity offset required, but care must be taken to protect the op amp inputs and not exceed the output range.

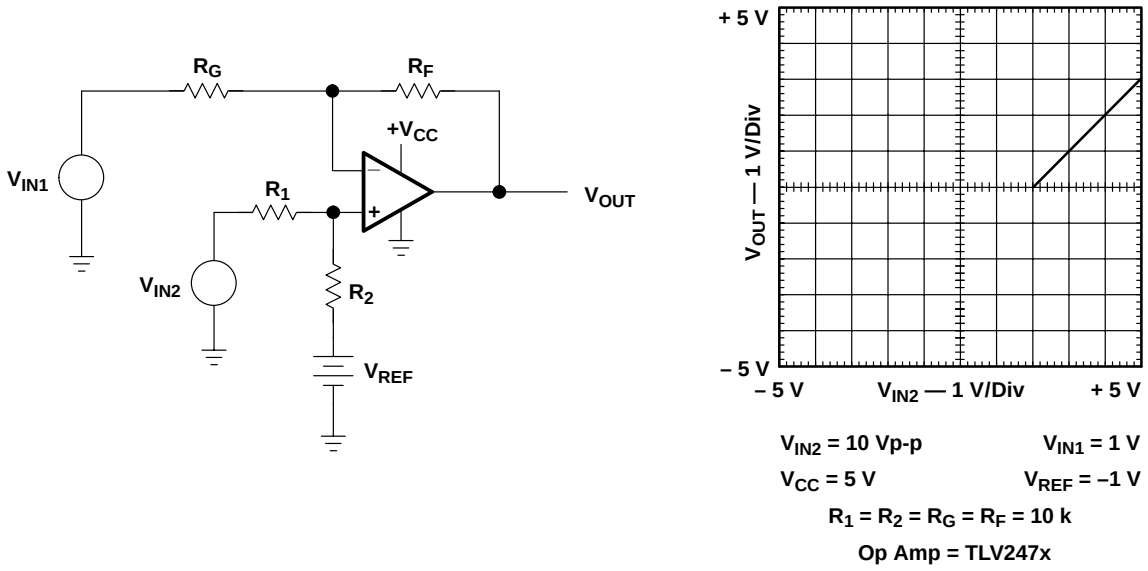

Figure A–14. Differential Amplifier with Bias Correction

A.3.11 High Input Impedance Differential Amplifier

When R_F is set equal to R_1 and R_G is set equal to R_2, Equation A–13 reduces to Equation A–14.

$$V_{OUT} = V_{IN1} \frac{R_1 + R_2}{R_1}\left(-\frac{R_F}{R_G}\right) + V_{IN2} \frac{R_F + R_G}{R_G} \qquad \text{A–13}$$

$$V_{OUT} = \left(V_{IN2} - V_{IN1}\right)\frac{R_F + R_G}{R_G} \qquad \text{A–14}$$

Each input signal is connected to an op amp noninverting input that is very high impedance. The input impedance of the circuit is very high, and it is matched, so this circuit is often used to interface to high-impedance sensors. Each op amp has a signal propagation time, and V_{IN1} experiences two propagation delays versus V_{IN2}'s one propagation delay. At high frequencies, the propagation delay becomes a significant portion of the signal period, and this configuration is not usable at that frequency.

R_F and R_2, and R_G and R_1 should be matched to achieve good common-mode rejection capability. Bias current cancellation resistors equal to $R_F \parallel R_G$ should be connected in series with the input sources for precision applications.

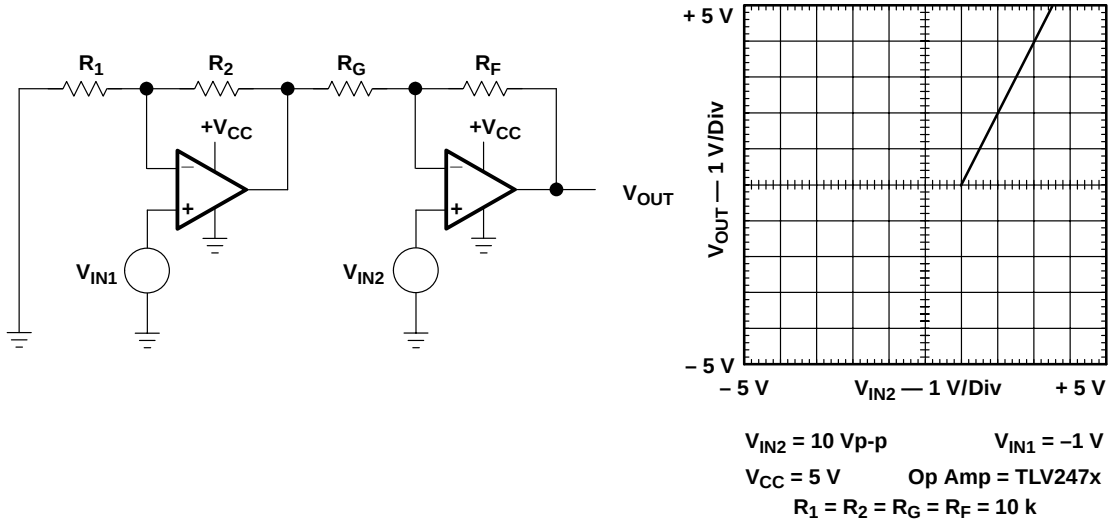

Figure A–15. High Input Impedance Differential Amplifier

A.3.12 High Common-Mode Range Differential Amplifier

When all resistors are equal, Equation A–15 reduces to Equation A–16.

$$V_{OUT} = V_{IN2}\left(-\frac{R_2}{R_1}\right)\left(-\frac{R_F}{R_{G1}}\right) + V_{REF1}\left(\frac{R_1 + R_2}{R_1}\right)\left(-\frac{R_F}{R_{G1}}\right) + V_{IN1}\left(-\frac{R_F}{R_{G2}}\right) + V_{REF2}\left(\frac{R_F + R_{G1} \parallel R_{G2}}{R_{G1} \parallel R_{G2}}\right) \quad \text{A–15}$$

$$V_{OUT} = \left(V_{IN2} - V_{IN1}\right) - 2V_{REF1} + 3V_{REF2} \quad \text{A–16}$$

R_1 and R_{G2} are equal-value resistors terminated into a virtual ground, hence, the input sources are equally terminated. This configuration has high common-mode capability because R_1 and R_{G2} limit the current that can flow into or out of the op amp. Thus, the input voltage can rise to any value that does not exceed the op amp's drive capability. The voltage references, V_{REF1} and V_{REF2}, are added for bias purposes. Without bias, the output voltage of the op amps would saturate at ground, and the bias voltages keep the output voltage of the op amp positive.

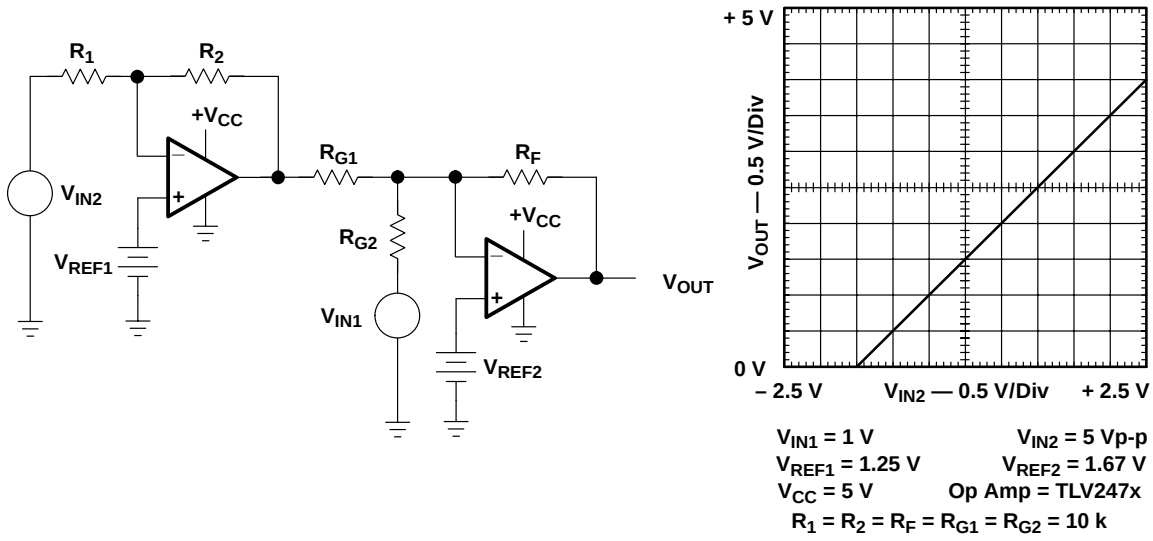

Figure A–16. High Common-Mode Range Differential Amplifier

A.3.13 High-Precision Differential Amplifier

When $R_7 = R_6$, $R_5 = R_2$, $R_1 = R_4$, and $V_{REF1}=V_{REF2,}$ Equation A–17 reduces to Equation A–18.

$$V_{OUT} = \left(V_{IN2} + V_{REF2}\right)\left(\frac{2R_4 + R_3}{R_3}\right)\left(\frac{R_7}{R_5 + R_7}\right)\left(\frac{R_6 + R_2}{R_2}\right) - \left(V_{IN1} + V_{REF1}\right)\left(\frac{2R_1 + R_3}{R_3}\right)\frac{R_6}{R_2} + V_{REF3}\left(\frac{R_5}{R_5 + R_7}\right)\left(\frac{R_6 + R_2}{R_2}\right) \quad \text{A–17}$$

$$V_{OUT} = \left(V_{IN2} - V_{IN1}\right)\left(\frac{2R_1}{R_3} + 1\right)\left(\frac{R_6}{R_2}\right) + V_{REF3} \quad \text{A–18}$$

In this circuit configuration, both sources work into the input impedance of a noninverting op amp. This impedance is very high, and if the op amps are identical, both impedances are very nearly equal. The propagation delay is still equal to two op amp propagation delays, but the propagation delay is very nearly equal, so any distortion resulting from unequal propagation delays is minimized.

The equal resistors should be matched with more precision than is expected from the circuit. Resistor matching eliminates distortion due to unequal gains, and it reduces the common-mode voltage feed through. Resistors equal to $(R_1 \parallel R_3)/2$ may be placed in series with the sources to reduce errors resulting from bias currents. This differential amplifier has the unique feature that the gain can be changed with only one resistor, and if the gain setting resistor is R3, no resistor matching is required to change gain.

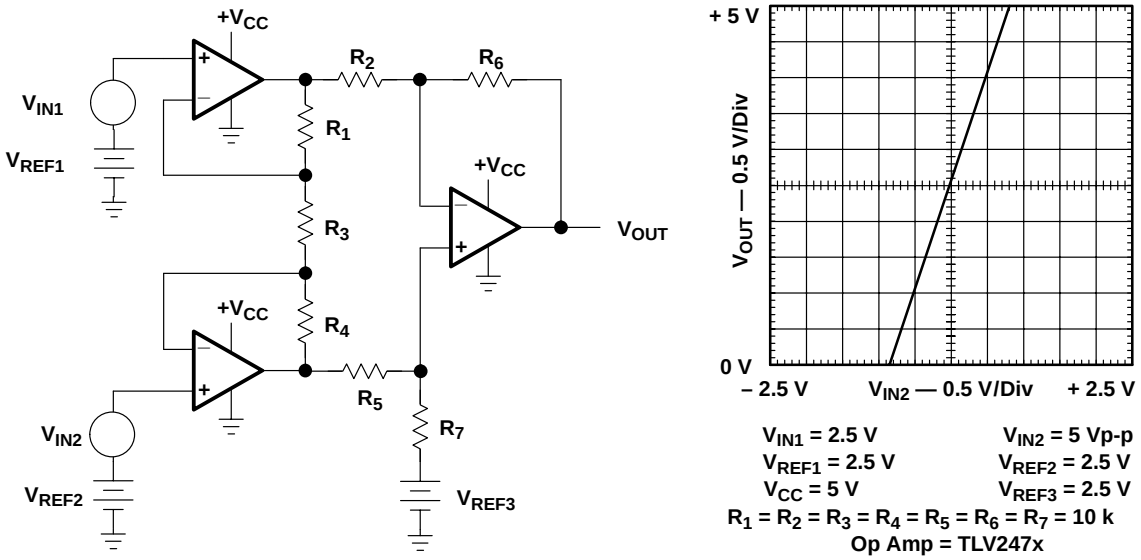

Figure A–17. High-Precision Differential Amplifier

A.3.14 Simplified High-Precision Differential Amplifier

When R_F is set equal to R_2, R_G is set equal to R_1, and $V_{REF1} = V_{REF2}$, Equation A–19 reduces to Equation A–20.

$$V_{OUT} = (V_{IN2} + V_{REF2})\left(\frac{R_F + R_G}{R_G}\right)\left(\frac{R_2}{R_1 + R_2}\right) - (V_{IN1} + V_{REF1})\left(\frac{R_F}{R_G}\right) + V_{REF3}\left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \quad \text{A–19}$$

$$V_{OUT} = (V_{IN2} - V_{IN1})\left(\frac{R_F}{R_G}\right) + V_{REF3} \quad \text{A–20}$$

Both input sources are loaded equally with very high impedances in the simplified high precision differential amplifier. This configuration eliminates three resistors, two of which are matched, but it sacrifices flexibility in gain setting capability because the gain must be set with a matched pair of resistors.

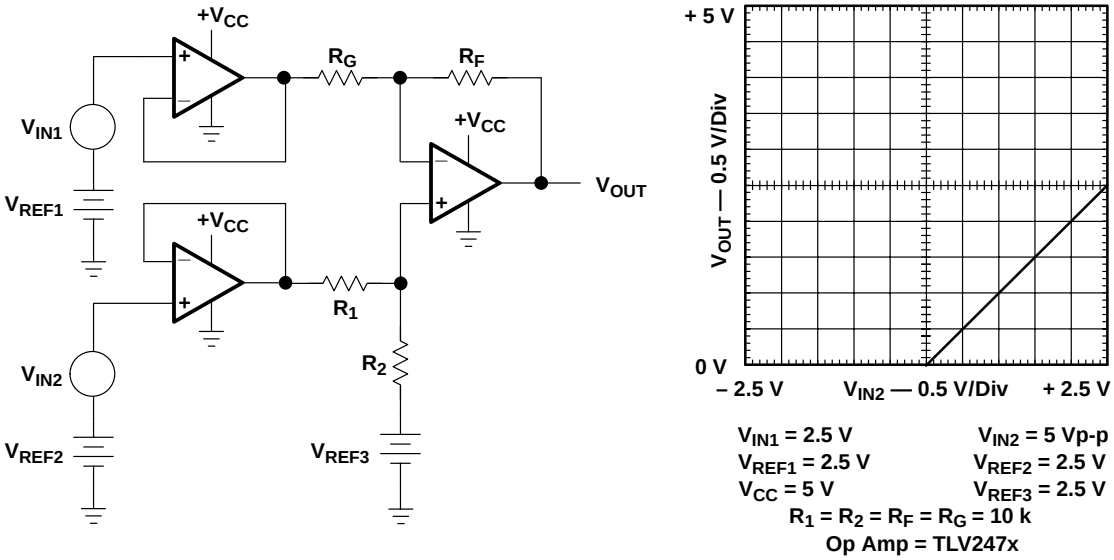

Figure A–18. Simplified High-Precision Differential Amplifier

A.3.15 Variable Gain Differential Amplifier

When R_1 is set equal to R_3 and R_2 is set equal to R_4, Equation A–21 reduces to Equation A–22.

$$V_{OUT} = V_{IN1}\left(\frac{R_2}{R_1 + R_2}\right)\left(\frac{R_3 + R_4}{R_3}\right)\left(\frac{R_G}{R_F}\right) - V_{IN2}\left(\frac{R_4}{R_3}\right)\left(\frac{R_G}{R_F}\right) \qquad \text{A–21}$$

$$V_{OUT} = \left(V_{IN2} - V_{IN1}\right)\left(\frac{R_4}{R_3}\right)\left(\frac{R_F}{R_G}\right) \qquad \text{A–22}$$

When a function is enclosed in a feedback loop, the function acts inverted on the closed loop transfer function. Thus, the gain stage R_F/R_G ends up being an attenuator. The circuit shown in Figure A–19 can be used with any of the differential amplifiers to change gain without affecting matched resistors. R_1, R_3 and R_2, R_4 must be matched to reduce the common-mode voltage.

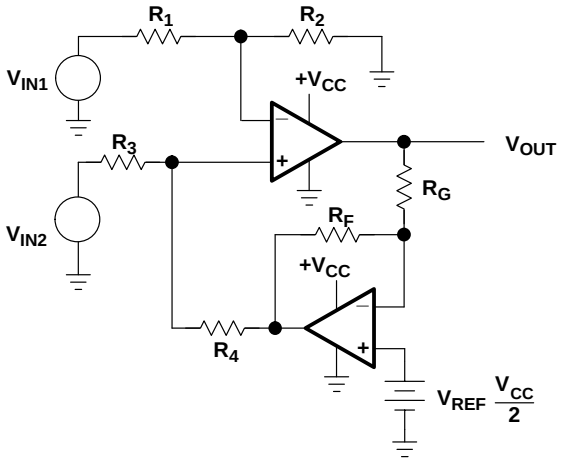

Figure A–19. Variable Gain Differential Amplifier

A.3.16 *T* Network in the Feedback Loop

Sometimes it is desirable to have a low-resistance path to ground in the feedback loop. Standard inverting op amps cannot do this when the driving circuit sets the input resistor value and the gain specification sets the feedback resistor value. Inserting a *T* network in the feedback loop yields a degree of freedom that enables both specifications to be met with a low dc resistance path to ground in the feedback loop.

$$V_{OUT} = -V_{IN}\left(\frac{R_2 + R_3 + \frac{R_2R_3}{R_4}}{R_1}\right) + V_{REF}\left(1 + \frac{R_2 + R_3 + \frac{R_2R_3}{R_4}}{R_1}\right) \quad \text{A–23}$$

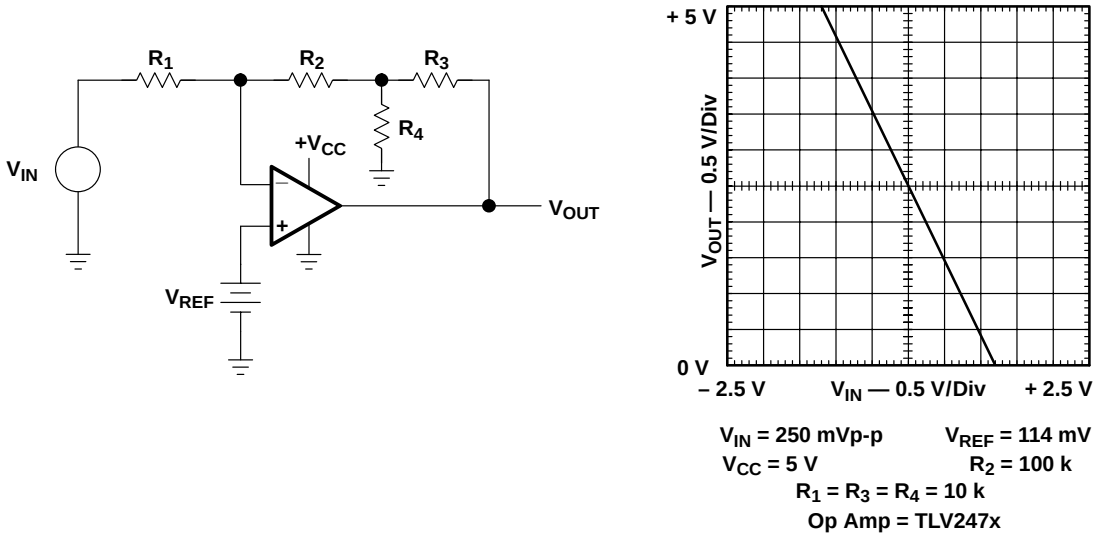

Figure A–20. T Network in the Feedback Loop

A.3.17 Buffer

The buffer input signal polarity must be unipolar because the output voltage swing is unipolar. When this limitation precludes the buffer, a differential amplifier with the negative input correctly biased is used, or a reference voltage is added to the buffer to offset the output voltage. R_F must be included when the op amp inputs are not rated for the full supply voltage. In that case, R_F limits the current into the op amp inputs, thus preventing latch up. Most new op amp inputs can withstand the full supply voltage, so they often leave R_F out as cost savings. The main attraction of the buffer is that it has very high input impedance and very low output impedance. The impedance transformation capability is why buffers are often added to the input of other circuits.

$$V_{OUT} = V_{IN} + V_{REF} \qquad \text{A–24}$$

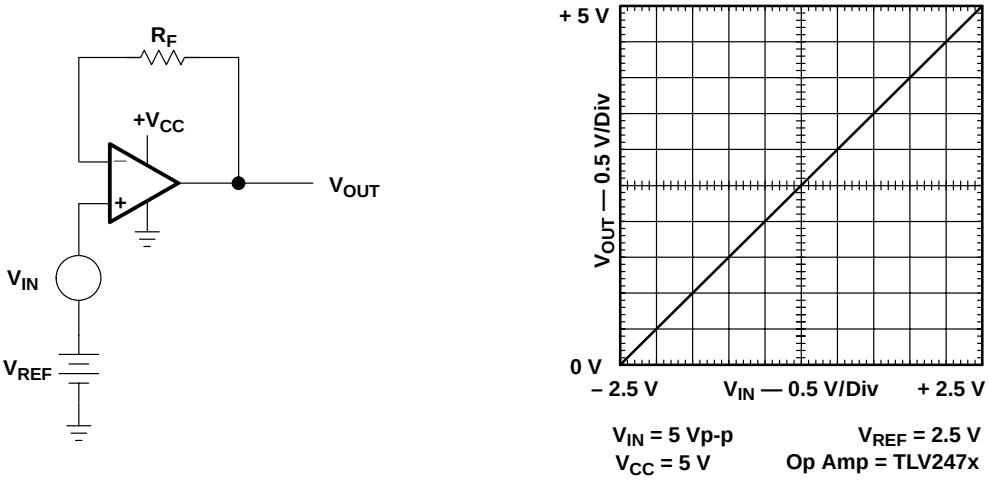

Figure A–21. Buffer

A.3.18 Inverting AC Amplifier

V_{CC} and resistors R set a dc level of $V_{CC}/2$ at the inverting input. R_G is connected to ground through a capacitor, thus the circuit functions as a buffer for dc. This causes the dc output voltage to be $V_{CC}/2$, so the quiescent output voltage is the middle of the supply voltage, and it is ready to swing to either rail as the input signal commands.

The ac gain is given in Equation A–25. R_G and C form a coupling network for the ac signal. Good coupling networks should be constant low impedance at the signal frequencies, so Equation A–26 should be satisfied to get good low-frequency performance. The lowest frequency component of the input signal, f_{MIN}, is determined by completing a Fourier series on the input signal. Then, setting $f_{MIN} = 100f$ in Equation A–26 ensures that the 3-dB breakpoint introduced by R_G and C is two decades lower than f_{MAX}.

$$V_{OUT} = -V_{IN}\frac{R_F}{R_G} + \frac{V_{CC}}{2} \qquad \text{A–25}$$

$$f = \frac{1}{200\pi R_G C} \qquad \text{A–26}$$

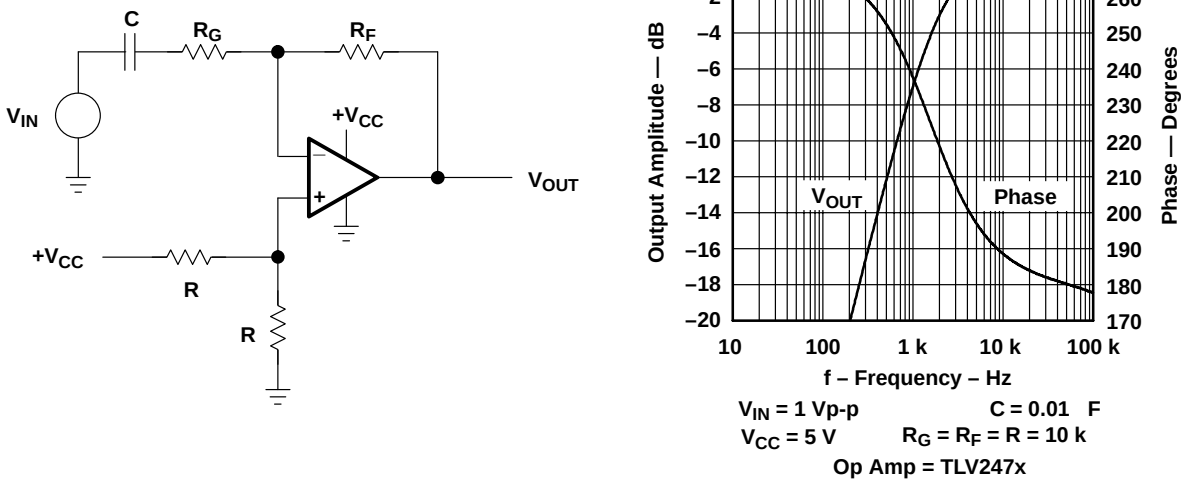

Figure A–22. Inverting AC Amplifier

A.3.19 Noninverting AC Amplifier

V_{CC} and the resistors (R) set a dc level of $V_{CC}/2$ at the inverting input. R_G is connected to ground through a capacitor, thus the circuit functions as a buffer for dc. This causes the dc output voltage to be $V_{CC}/2$, so the quiescent output voltage is the middle of the supply voltage, and it is ready to swing to either rail as the input signal commands.

The ac gain is given in Equation A–27. R_G and C create a coupling network for the ac signal. Good coupling networks should be a constant low impedance at the signal frequencies, so Equation A–28 should be satisfied to get good low frequency performance. The lowest frequency component of the input signal, f_{MIN}, is determined by completing a Fourier series on the input signal. Then, setting $f_{MIN} = 100f$ in Equation A–28 ensures that the 3-dB breakpoint introduced by R_G and C is two decades lower than f_{MAX}. The breakpoint for R_G and C_1 is set in a similar manner.

$$V_{OUT} = V_{IN}\frac{R_F + R_G}{R_G} + \frac{V_{CC}}{2}\left(\frac{R_F + R_G}{R_G}\right) \qquad \text{A–27}$$

$$f = \frac{1}{200\pi R_G C} \qquad \text{A–28}$$

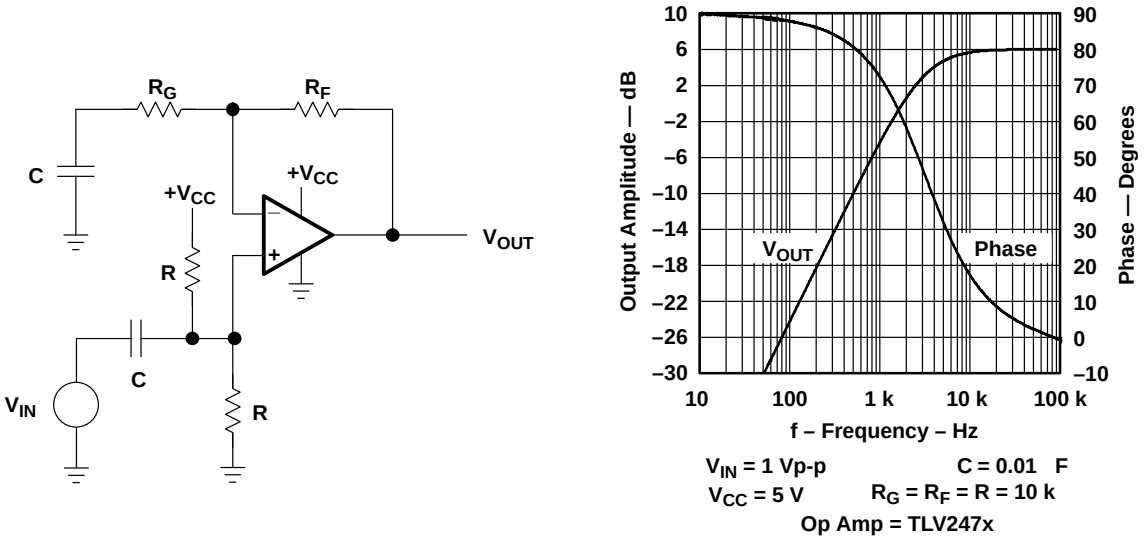

Figure A–23. Noninverting AC Amplifier

A.4 Computing Circuits

Four versions of the inverting op amp and four versions of the noninverting op amp were given in the previous section. During the concept stage of the design, one of these eight op amp circuits is selected. Specifications for the input and output voltage are the selection criteria that determines which circuit configuration is used.

There are four versions of most of the circuits given in this and following sections, but just the simplest version of any circuit is included in this appendix because of space limitations. Each circuit configuration can be modified as required to fit specific applications. Look back to the first section to determine what bias is required to fit the application, and adapt that bias to the new circuit.

A.4.1 Inverting Summer

The three input voltages are inverted and added as Equation A–29 shows. R_B should be made equal in value to the parallel combination of R_F, R_{G1}, R_{G2}, and R_{G3} to convert the input bias current to a common-mode voltage so the op amp can reject it. V_{REF} sets the output voltage somewhere between the supply limits, and this allows negative addition (subtraction) to take place.

$$V_{OUT} = -\left(V_{IN1}\frac{R_F}{R_{G1}} + V_{IN2}\frac{R_F}{R_{G2}} + V_{IN3}\frac{R_F}{R_{G3}} + \ldots\right) + V_{REF}\left(1 + \frac{R_F}{R_{G1} \parallel R_{G2} \parallel R_{G3} \ldots}\right) \quad \text{A–29}$$

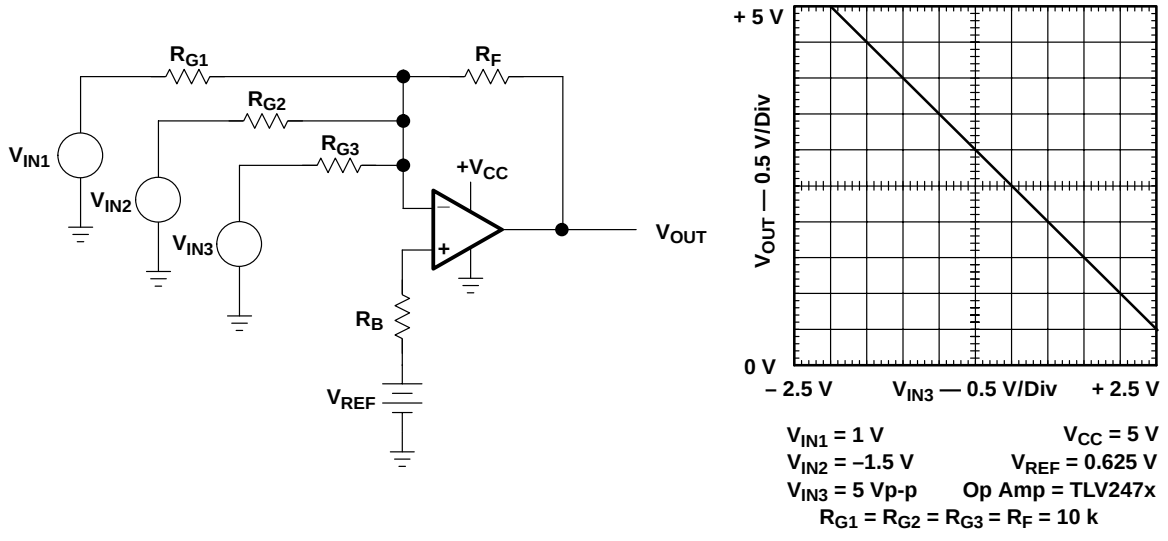

Figure A–24. Inverting Summer

A.4.2 Noninverting Summer

This circuit adds the input voltages and multiplies them by the stage gain. R_{G1}, R_{G2}, and R_{G3} in parallel should be equal to R_F in parallel with R_G to cancel the input bias current using the common-mode input voltage rejection technique. V_{REF} is added to the circuit to enable the addition of negative values.

$$V_{OUT} = + \left(\frac{V_{IN1}\left(R_{G2} \parallel R_{G3}\right)}{R_{G1} + R_{G2} \parallel R_{G3}} + \frac{V_{IN2}\left(R_{G1} \parallel R_{G3}\right)}{R_{G2} + R_{G1} \parallel R_{G3}} + \frac{V_{IN3}\left(R_{G2} \parallel R_{G1}\right)}{R_{G3} + R_{G2} \parallel R_{G1}} \right) \times \left(\frac{R_F + R_G}{R_G} \right) - V_{REF} \frac{R_F}{R_G} \qquad \text{A–30}$$

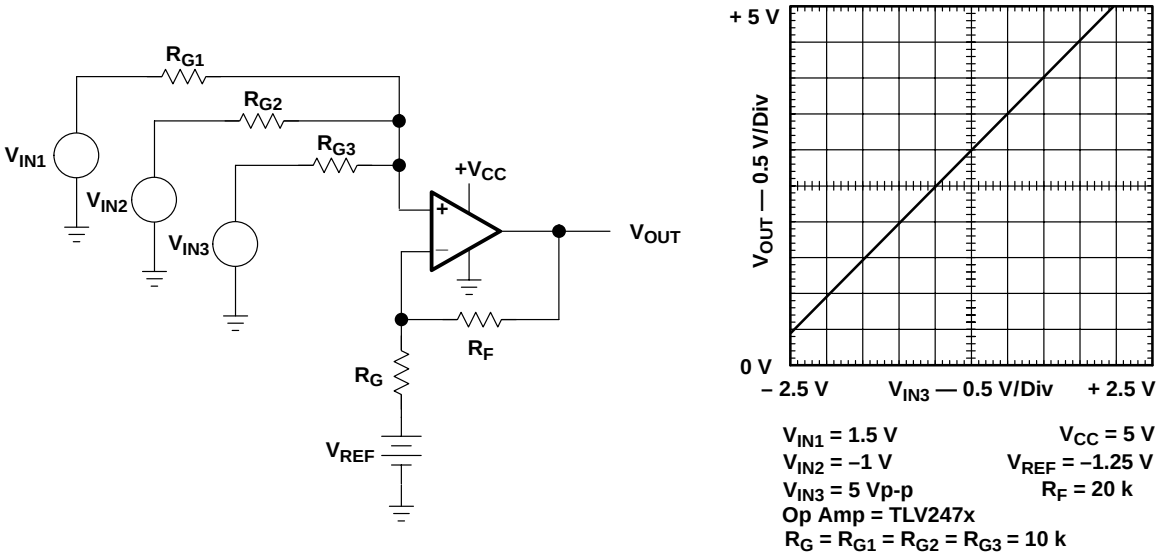

Figure A–25. Noninverting Summer

A.4.3 Noninverting Summer with Buffers

V_{REF1} and V_{REF2} are added to enable the buffers to handle positive input voltages. Their output contribution to the last stage is cancelled out by V_{REF3}. This configuration uses fewer resistors at the expense of two op amps. R_{G1}, R_{G2}, and R_F in parallel should be made equal to R_B to cancel the input bias current.

$$V_{OUT} = V_{IN1}\frac{R_F}{R_{G1}} + V_{IN2}\frac{R_F}{R_{G2}} - V_{REF1}\frac{2R_F}{R_{G1}} - V_{REF2}\frac{2R_F}{R_{G2}} + V_{REF3}\left(1 + \frac{R_F}{R_{G1} \parallel R_{G2}}\right) \quad \text{A–31}$$

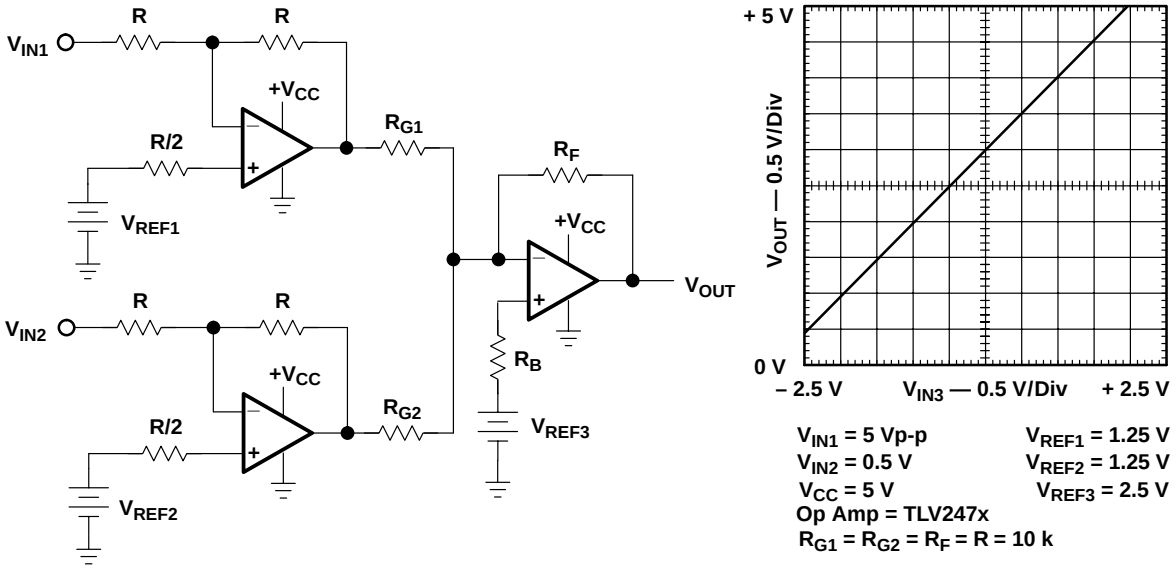

Figure A–26. Noninverting Summer with Buffers

A.4.4 Inverting Integrator

The Laplace operator, s= jω, is used in Equation A–32, and the mathematical operation 1/s constitutes an integration. Differentiation circuits are shown later, and the mathematical operation, s, constitutes a differentiation. The integration time constant is RC, thus the magnitude crosses 0 dB on a log plot when RC = 1. Also the phase is –45° when RC = 1.

$$V_{OUT} = - V_{IN} \frac{1}{RCs} \qquad \text{A–32}$$

This integrator is not very practical because there is no method of discharging the capacitor; hence, any leakage current will eventually charge the capacitor until the circuit becomes saturated. The positive input of the integrator is biased at V_{CC} / 2 to center the output voltage at V_{CC} / 2; thus allowing for positive and negative voltage swings. The bias resistors are selected as 2R so that the parallel combination equals R. This offsets the input current drawn through R.

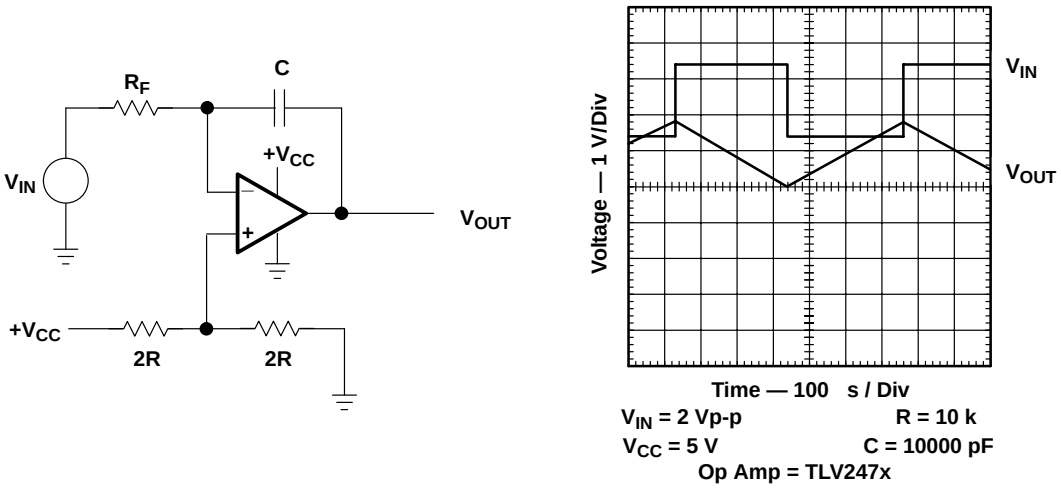

Figure A–27. Inverting Integrator

A.4.5 Inverting Integrator with Input Current Compensation

Functionally, this circuit is the same as that shown in Figure A–27, but a current compensation network has been added to offset the input current. V_{CC}, R_1, and R_2 bias the positive input at V_{CC} / 2 to center the output voltage at V_{CC} / 2; thus allowing for positive and negative voltage swings.

R_1 and R_2 are selected as relatively small values because the current flowing through R_A also flows through the parallel combination of R_1 and R_2. R_A forward biases the diode with a constant current, thus the diode acts like a small voltage regulator. The diode voltage drop is temperature sensitive, and this factor works in our favor because the input transistors are temperature sensitive. The two temperature sensitivities cancel out if the diode current is selected correctly. R_B is a large-value resistor that acts like a current source, so it is selected such that it supplies the input bias current. Selecting R_B correctly ensures that no input current flows through the integration resistor, R.

This integrator is not very practical because there is no method of discharging the capacitor. Hence, any input current will eventually charge the capacitor until the circuit becomes saturated. The bias circuit drastically reduces the input current flowing through R, thus it extends the integration time. A reset circuit is needed to make the integrator more practical.

This bias compensation scheme is set up for an op amp that has NPN input transistors. The diode must be reversed and connected to ground for op amps with PNP input circuits.

$$V_{OUT} = -V_{IN1}\frac{1}{RCs} \qquad \text{A–33}$$

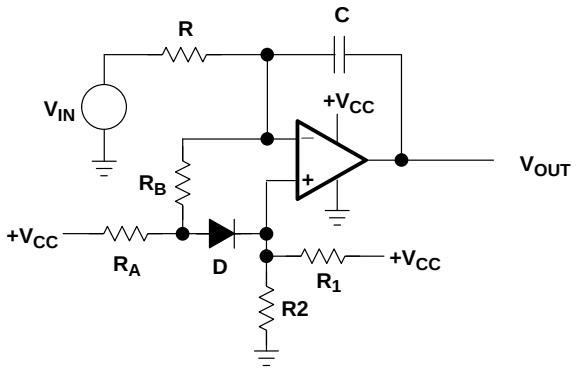

Figure A–28. Inverting Integrator with Input Current Compensation

A.4.6 Inverting Integrator with Drift Compensation

Functionally, this circuit is the same as that shown in Figure A–27, but it uses an RC circuit in the positive lead to obtain drift compensation. The voltage divider is made from a series string of resistors (R_A), and V_{CC} biases the input in the center of the power supply.

Positive input current flows through R and C in parallel, so the positive input current drops the same voltage across the parallel RC combination as the negative input current drops across its series RC combination. The common-mode rejection capability of the op amp rejects the voltages caused by the input currents. Much longer integration times can be achieved with this circuit, but when the input signal does not center around $V_{CC}/2$, the compensation is poor.

$$V_{OUT} = - V_{IN1} \frac{1}{RCs} \qquad \text{A–34}$$

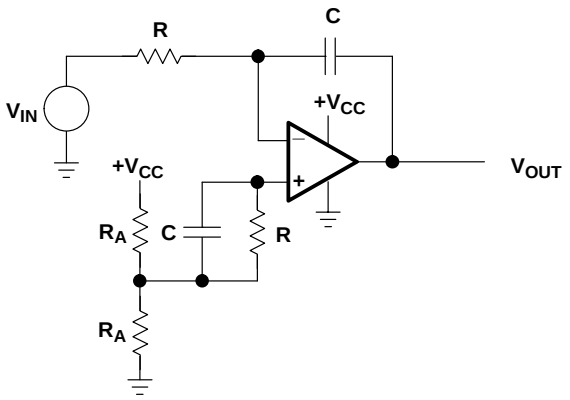

Figure A–29. Inverting Integrator with Drift Compensation

A.4.7 Inverting Integrator with Mechanical Reset

Functionally, this circuit is the same as that shown in Figure A–27, but a method has been provided to discharge (reset) the capacitor. S_1 is a mechanical switch or relay and when the contacts close, they short the integrating capacitor forcing it to discharge. Some capacitors are sensitive to fast discharge cycles, so R_S is put in the discharge path to limit the initial discharge current. When R_S is absent from the circuit, the impulse of current that occurs at the first instant of discharge causes considerable noise, so the selection of R_S is also based on noise considerations. For all practical purposes, the time constant formed by R_S and C determines the discharge rate.

One advantage of mechanical discharge methods is that they are isolated from the remainder of the circuit. Their size, weight, time delay, and uncertain actuating time offset this advantage. When the disadvantages of mechanical reset outweigh the advantages, circuit designers go to electronic reset circuits.

$$V_{OUT} = - V_{IN1} \frac{1}{RCs} \qquad \text{A–35}$$

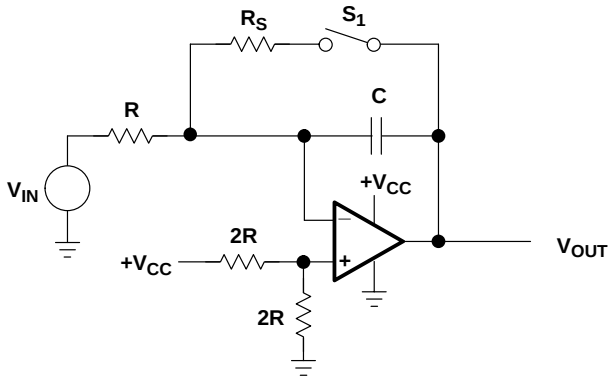

Figure A–30. Inverting Integrator with Mechanical Reset

A.4.8 Inverting Integrator with Electronic Reset

Functionally, this circuit is the same as that shown in Figure A–27, but an electronic method has been provided to discharge (reset) the capacitor. Q_1 is controlled by a gate drive signal that changes its state from on to off. When Q_1 is on, the gate-source resistance is low, less than 100 Ω. And when Q_1 is off, the gate-source resistance is high — about several hundred MΩ.

The source of the FET is at the inverting lead that is at ground, so the Q_1 gate-source bias is not affected by the input signal. Sometimes, the output signal can get large enough to cause leakage currents in Q_1, so the designer must take care to bias Q_1 correctly. Consult a transistor book for more detailed information on transistor reset circuits. A major problem with electronic reset is the charge injected through the transistor's stray capacitance. This charge can be large enough to cause integration errors.

$$V_{OUT} = -V_{IN1}\frac{1}{RCs} \qquad \text{A–36}$$

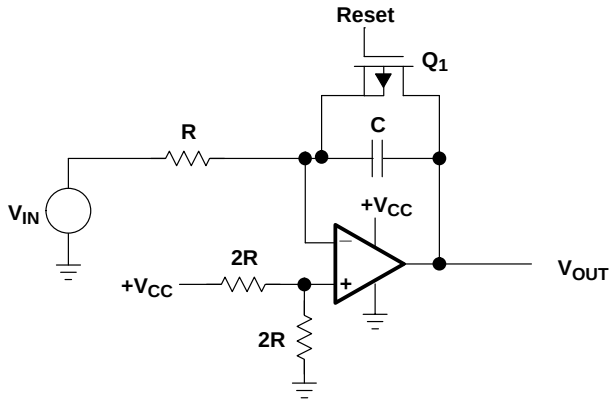

Figure A–31. Inverting Integrator with Electronic Reset

A.4.9 Inverting Integrator with Resistive Reset

This circuit differs from that shown in Figure A–27 because it yields a breakpoint rather than a pure integration. On a log plot, the integrator slope is –6 dB per octave at the 0 frequency intercept, and the 0 dB intercept occurs when f = 1/2πRC. A breakpoint plots flat on a log plot until the breakpoint where it breaks down at –6 dB per octave. It is –3 dB when f = 1/2πRC.

R_F is in parallel with the integrating capacitor, C, so it is continually discharging C. The low frequency attenuation that is the best attribute of the pure integrator is sacrificed for the reset circuit complexity

$$V_{OUT} = -V_{IN1}\left(\frac{R_F}{R_G}\right)\frac{1}{R_F C + 1} \qquad \text{A–37}$$

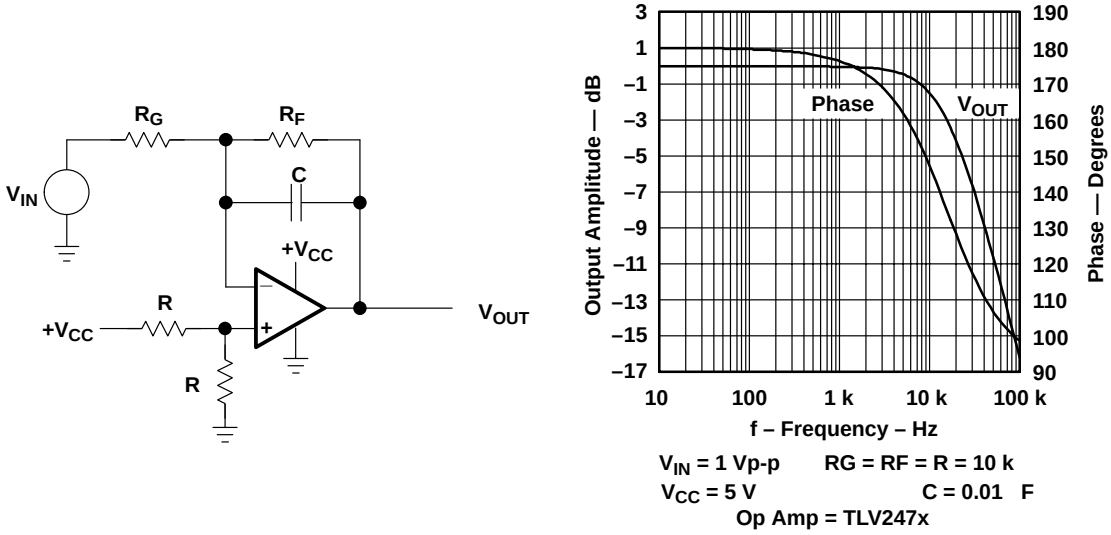

Figure A–32. Inverting Integrator with Resistive Reset

A.4.10 Noninverting Integrator with Inverting Buffer

This circuit is an inverting integrator preceded by an inverting buffer. Eliminating the signal inversion costs an op amp and four resistors, but this is the easiest way to get true noninverting integrator performance.

$$V_{OUT} = \frac{R_A}{R_A}\left(-V_{IN}\,\frac{1}{RCs}\right) = V_{IN}\,\frac{1}{RCs} \qquad \text{A–38}$$

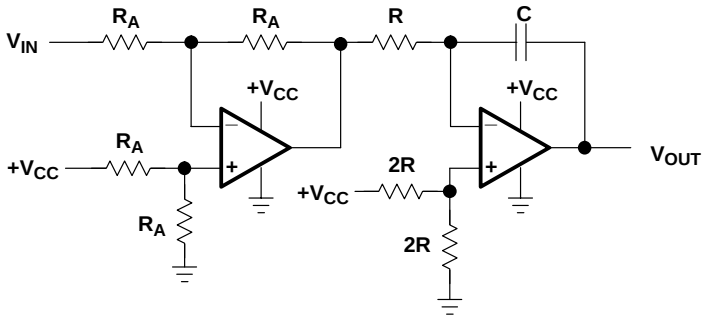

Figure A–33. Noninverting Integrator with Inverting Buffer

A.4.11 Noninverting Integrator Approximation

This circuit has fewer parts than the *Noninverting Integrator With Inverting Buffer* (Figure A–33), but it is not a true integrator because there is a zero in the transfer equation. The log plot starts rolling off at a –6 dB per octave rate at low frequencies, but when f = 1/2πRC, the zero cuts in. The zero causes the log plot to flatten out because the slope decreases to 0 db per decade.

This circuit functions as an integrator at very low frequencies, but at frequencies higher than f = 1/2πRC, it functions as a buffer.

$$V_{OUT} = \frac{RCs + 1}{RCs} \qquad \text{A–39}$$

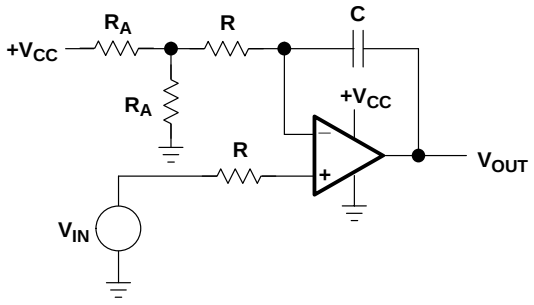

Figure A–34. Noninverting Integrator Approximation

A.4.12 Inverting Differentiator

The log plot of the differentiator is a positive slope of 6-dB per octave passing through 0 dB at f = 1/2πRC. At extremely high frequencies, the capacitive reactance goes to very low values, thus the circuit gain approaches the op amp open-loop gain. This performance emphasizes any system noise or noise generated by the op amp. The poor noise performance of this circuit limits its application to a very few specialized situations.

This configuration has a pole in the feedback loop. If the op amp has more than one pole, and most op amps have several poles, this configuration can become oscillatory. The V_{CC} and R_A circuit bias the output in the center of the power supplies. $R_A/2$ should be selected equal to $R_G||R_F$ so that input currents are canceled out.

$$V_{OUT} = - V_{IN} RCs \qquad \text{A–40}$$

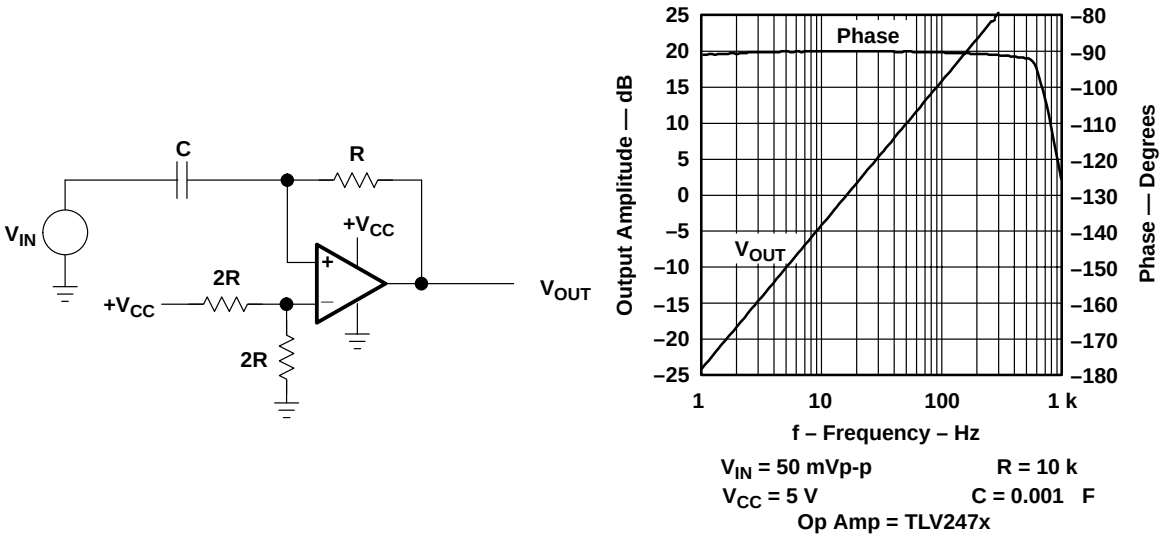

Figure A–35. Inverting Differentiator

A.4.13 Inverting Differentiator with Noise Filter

This circuit has a pure differentiator that rises at a 6-dB per octave slope from zero frequency. At $f = 1/2\pi R_F C_F$, the pole kicks in and the slope is reduced to zero. The pole has two effects. First, it stabilizes the circuit by canceling zero's phase shift. Second, it limits the circuit gain to 1 at high frequencies, so it acts like a noise filter.

R/2 should equal R_F for good input current cancellation, and V_{CC} coupled with R centers the output voltage.

$$V_{OUT} = - V_{IN} \frac{R_F C s}{R_F C_F s + 1} \qquad \text{A–41}$$

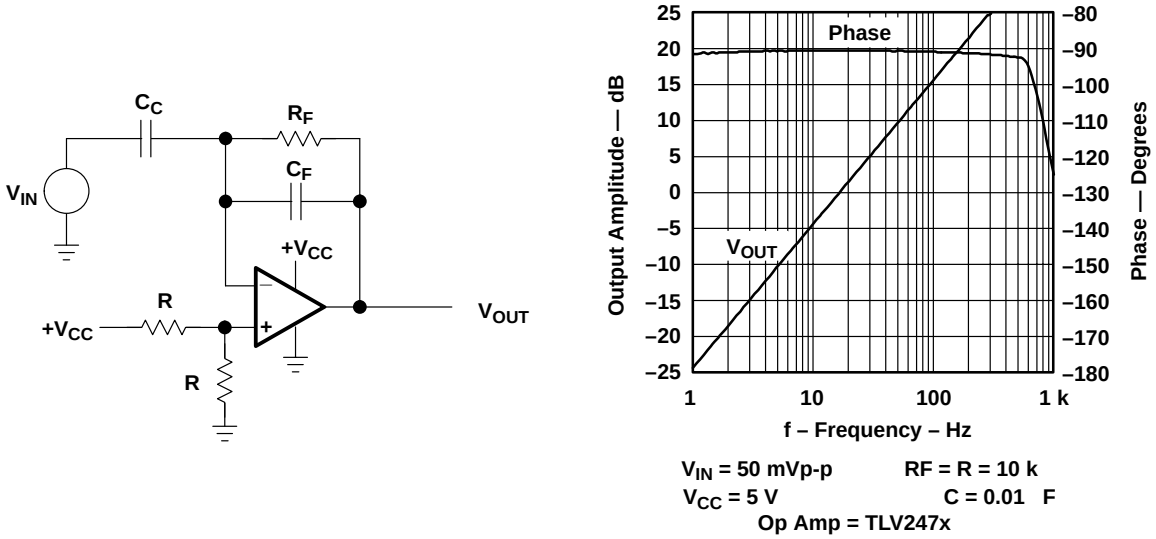

Figure A–36. Inverting Differentiator with Noise Filter

A.5 Oscillators

This section describes some general op amp sinewave oscillator circuits that fall under three main categories: Wien bridge, phase shift, and quadrature. A brief description and of each type is provided, along with one or two variations. Op amp sinewave oscillators are used to create references in applications such as audio and function/waveform generators.

A.5.1 Basic Wien Bridge Oscillator

When $\omega = 2\pi f = 1/RC$, the feedback is in phase (this is positive feedback), and the gain is 1/3, so oscillation requires an amplifier with a gain of 3. When $R_F = 2R_G$ the amplifier gain is 3 and oscillation occurs at $f = 1/2\pi RC$. Normally, the gain is larger than 3 to ensure oscillation under worst case conditions.

V_{REF} sets the output dc voltage in the center of the span.

The output sine wave is highly distorted because limiting by saturation and cutoff is controlling the output voltage excursion. The distortion decreases when the gain is decreased, but the circuit may not oscillate under worst-case low gain conditions.

$$V_{REF} = \frac{\frac{V_{CC}}{2}}{1 + \frac{R_F}{R_G}} \qquad \text{A–42}$$

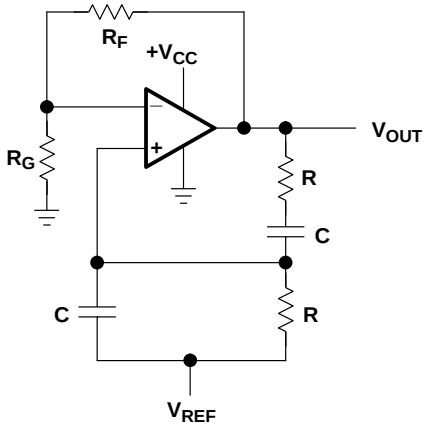

Figure A–37. Basic Wien Bridge Oscillator

A.5.2 Wien Bridge Oscillator with Nonlinear Feedback

When the circuit gain is 3, $R_L = R_F/2$.

Substituting a lamp (R_L) for the gain setting resistor reduces distortion because the non–linear lamp resistance adjusts the gain to keep the output voltage smaller than the power supply voltage. The output voltage never approaches the power supply rail, so distortion doesn't occur. R_F and R_L determine the lamp current (see Equations A–43 and A–44).

$$I_{LAMP} = \frac{V_{OUT(RMS)}}{R_F + R_L} \qquad \text{A–43}$$

$$R_F = \frac{2\left(V_{OUT(RMS)}\right)}{3\left(I_{OUT(RMS)}\right)} \qquad \text{A–44}$$

The lamp is selected by examining lamp resistance curves until a lamp with a resistance approximately equal to $R_F/2$ at $I_{OUT(RMS)}$ is found. The output voltage swing should be less than 75% of the maximum guaranteed voltage swing, and 3 R_L must be greater than the load resistance specified for the voltage swing specification. V_{REF} should be $V_{CC}/5$.

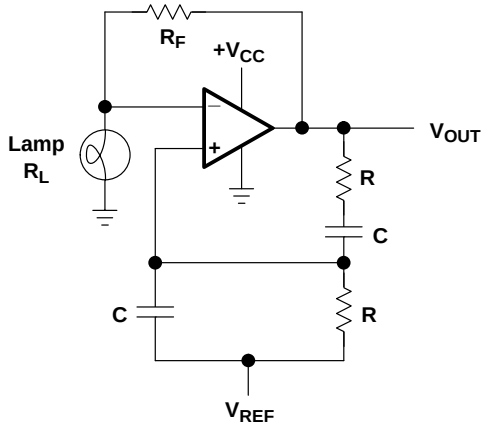

Figure A–38. Wien Bridge Oscillator with Nonlinear Feedback

A.5.3 Wien Bridge Oscillator with AGC

The op amp is configured as an ac amplifier to ease biasing problems. The gain equation for the op amp is given below. R_{G1} or R_{G2}, but not both resistors, is required depending on the selection of the Q_1.

The diode, D_1, half-wave rectifies the output voltage and applies it to the voltage divider formed by R_1 and R_2. The voltage divider biases Q_1 in its linear region, and they eventually set the output voltage. C_1 filters the rectified sine wave with a long time constant so that the output voltage stays constant. C_2 must be selected large enough to act as a short at the oscillation frequency.

As the output voltage increases, the negative voltage across the gate of Q_1 increases. The increased negative gate voltage causes Q_1 to increase its drain-to-source resistance. This results in increased op amp gain and an output voltage decrease. When the voltage divider and FET are selected properly, the output voltage swing is less than the guaranteed maximum swing, so distortion doesn't occur.

$$G = \frac{R_F}{R_{G1} + R_{G2} \parallel R_{FET}} \qquad \text{A–45}$$

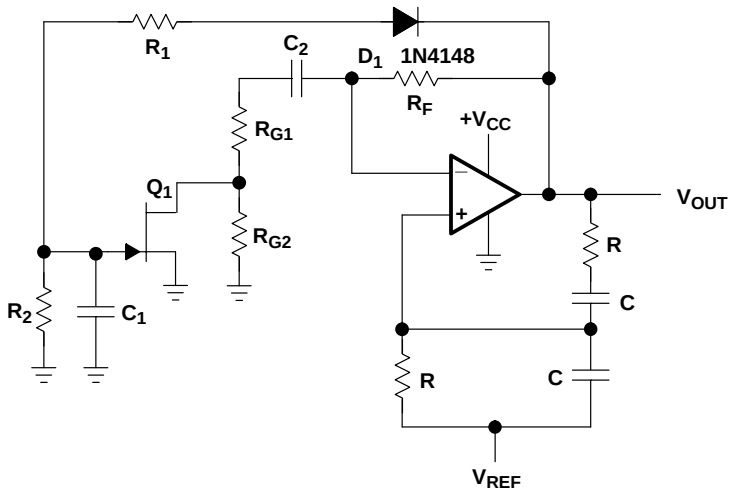

Figure A–39. Wien Bridge Oscillator with AGC

A.5.4 Quadrature Oscillator

Quadrature oscillators produce sine waves 90° out of phase, so they output sine/cosine, or quadrature waves.

When $R_1C_1 = R_2C_2 = R_3C_3$, the circuit oscillates at $\omega = 2\pi f = 1/RC$. Both op amps act as integrators causing two poles at 1/RC, thus the circuit oscillates when the loop gain crosses the 0-dB axis. The integrators ensure that gain is always sufficient for oscillation. There is a slight bit of distortion at the sine output, and it is very hard to eliminate this distortion.

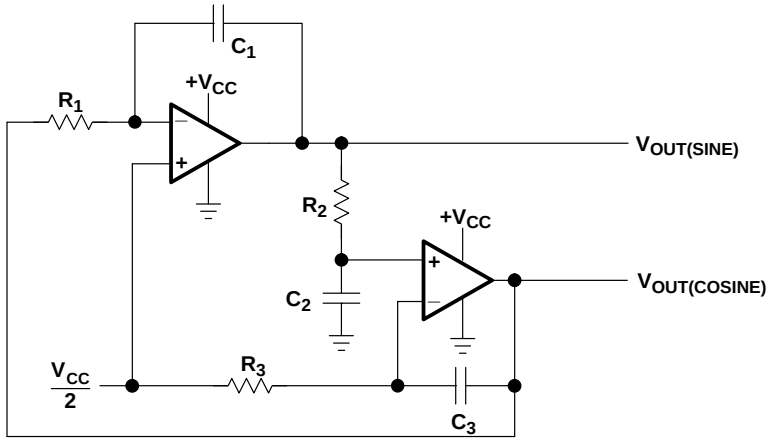

Figure A–40. Quadrature Oscillator

A.5.5 Classical Phase Shift Oscillator

Theoretically, the three RC sections do not load each other, thus the loop gain has three identical poles multiplied by the op amp gain.

The loop phase shift is –180° when the phase shift of each section is –60°, and this occurs when $\omega = 2\pi f = 1.732/RC$ because the tangent of 60° = 1.73. The magnitude of β at this point is $(1/2)^3$, so the gain, $A = R_F/R_G$, must be greater or equal to 8 for the system gain to be equal to 1.

The assumption that the RC sections do not load each other is not entirely valid, thus the circuit does not oscillate at the specified frequency, and the gain required for oscillation is more than 8. This circuit configuration was very popular when an active component was large and expensive, but now that op amps are inexpensive, small, and come quad packages, the classical phase shift oscillator is losing popularity.

The classical phase shift oscillator has an undistorted sine wave available at the output of the third RC section. This is not a low-impedance output, and the signal amplitude is smallest here, but these sacrifices have to be made to get away from distortion. An undistorted output can be obtained from the op amp if an AGC circuit similar to the one shown in Figure A–39 is employed. The reference voltage is set according to the equation $V_{REF} = V_{CC}/ 2(1+R_F/R_G)$ to center the output voltage at $V_{CC}/2$.

$$A\beta = \left(\frac{1}{RCs + 1}\right)^3 \qquad \text{A–46}$$

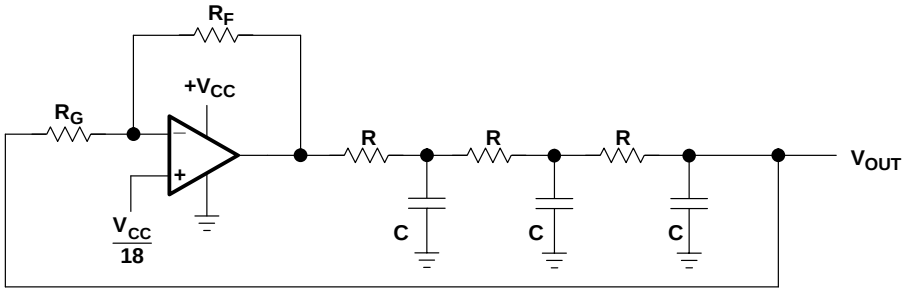

Figure A–41. Classical Phase Shift Oscillator

A.5.6 Buffered Phase Shift Oscillator

A noninverting op amp buffers each RC section in this oscillator. Equation A–46, repeated below, truly represents the transfer function of this circuit if $R_G >> R$.

$$A\beta = \left(\frac{1}{RCs + 1}\right)^3 \qquad \text{A–47}$$

The loop phase shift is –180° when the phase shift of each section is –60°, and this occurs when $\omega = 2\pi f = 1.732/RC$ because the tangent 60° = 1.73. The magnitude of β at this point is $(1/2)^3$, so the gain, $A = R_F/R_G$, must be greater or equal to 8 for the system gain to be equal to one.

The buffered phase shift oscillator has an undistorted sine wave available at the output of the third RC section. This is not a low-impedance output, and the signal amplitude is smallest here, but these sacrifices have to be made to get away from distortion. An undistorted output can be obtained from the op amp if an AGC circuit similar to the one shown in Figure A–39 is employed.

There are three op amps, so the gain can be distributed among the op amps at the expense of a few resistors, and the distortion is reduced. Another method of reducing distortion is to limit the output voltage swing softly with external components. The limiting technique does not yield as good results as the AGC technique does, but it is less expensive. The reference voltage is set according to the equation $V_{REF} = V_{CC}/ 2(1+R_F/R_G)$ to center the output voltage at $V_{CC}/2$.

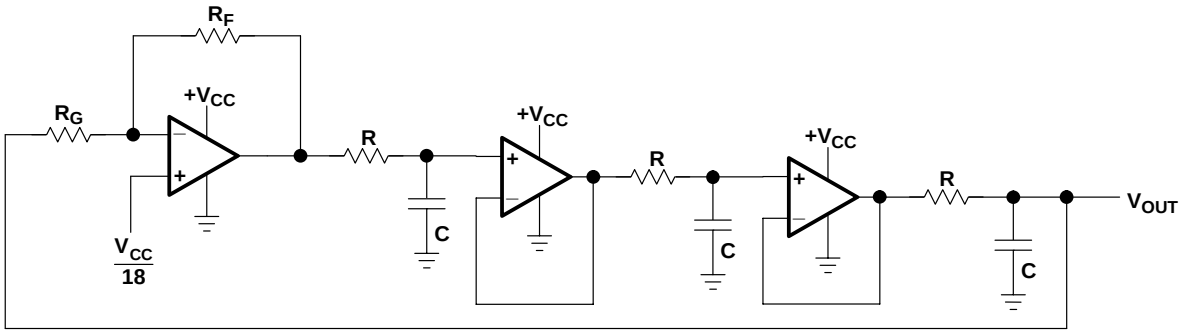

Figure A–42. Buffered Phase Shift Oscillator

A.5.7 Bubba Oscillator

The Bubba oscillator is another phase shift oscillator, but it takes advantage of the quad op amp package to yield some unique advantages. Each RC section is buffered by an op amp to prevent loading. When R_G >> R there is no loading in the circuit, and the circuit yields theoretical performance.

Four RC sections require –45° phase shift per section to accumulate –180° phase shift. Each RC section contributes –45° phase shift when $\omega = 1/RC$. The gain required for oscillation is $G \geq (1/0.707)^4 = 4$. Taking outputs from alternate sections yields low-impedance quadrature outputs. When an output is taken from each op amp, the circuit delivers four 45° phase-shifted sine waves.

The gain, A, must equal 4 for oscillation to occur. Very low distortion sine waves can be obtained from the junction of R and R_G. When low-distortion sine waves are required at all outputs, the gain should be distributed among the op amps. Gain distribution requires biasing of the other op amps, but it has no effect on the oscillator frequency. This oscillator has the best $d\phi/df$ of the phase shift oscillators, so it has minimum frequency drift. The reference voltage is set according to the equation $V_{REF} = V_{CC}/ 2(1+R_F/R_G)$ to center the output voltage at $V_{CC}/2$.

$$A\beta = \left(\frac{1}{RCs + 1}\right)^4 \qquad \text{A–48}$$

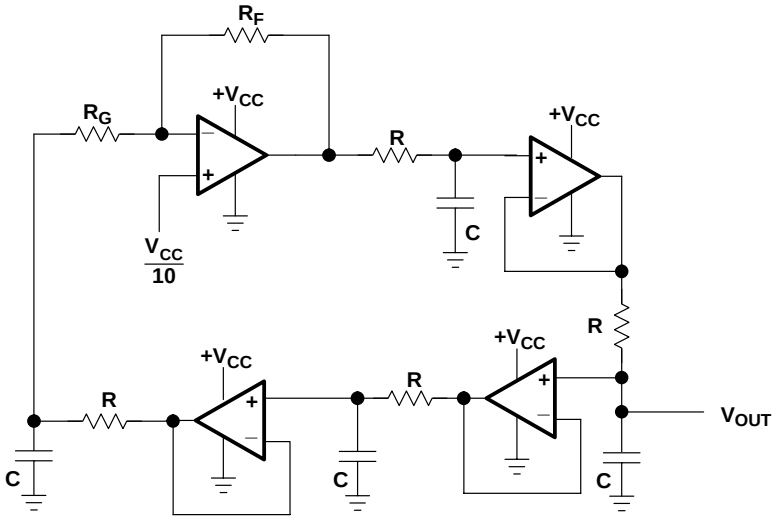

Figure A–43. Bubba Oscillator

A.5.8 Triangle Oscillator

The triangle oscillator produces triangle waves and square waves. The op amp functions as an integrator. When the output voltage of the comparator is low, the output of the op amp charges C until the output voltage exceeds the hysteresis voltage set by R_1 and R_F and the reference voltage ($V_{CC}/2$). At this point, the comparator output switches to a high state and the op amp integrates the voltage in a negative direction. The triangle wave (op amp output voltage swing) is given in Equation A–49. The frequency of oscillation is given in Equation A–50.

$$V_{OUT} = \frac{V_{CC}}{2} \pm \frac{V_{CC}R_1}{2R_F} \qquad \text{A–49}$$

$$f = \frac{R_F}{4CRR_1} \qquad \text{A–50}$$

The op amp reference voltage can be adjusted to equalize the triangle rise and fall times.

B

Band-pass filter
- Butterworth gain response graph, 16-36
- design, 16-27 to 16-37
- gain response graph, 16-29
- low-pass filter transition, 16-28, 16-37
- Sallen-Key circuit, 16-30
- second order, 16-29 to 16-39

Band-rejection filter, comparison graph active/passive, 16-41

Band-rejection filter
- active twin-T filter, 16-37 to 16-40
- active Wien-Robinson filter, 16-39 to 16-42
- design, 16-36 to 16-42

Bandwidth
- current feedback amp, 9-3 to 9-7
- current feedback amp graph, 8-10
- voltage feedback amp, 9-3 to 9-7

Bessel high-pass filter, circuit, 16-27

Bessel low-pass filter, 16-7 to 16-10

Bias circuit, 12-13

Binary bits, versus significant bits, 12-2

Black, Harry, Bell Labs, 1-1

Block diagram
- CDMA cellular base station, 13-5
- cellular base station receiver, 13-2
- dual IF receiver, 13-4
- feedback system, 6-2
- GSM cellular base station, 13-2
- loop gain, 6-4
- oscillator with positive feedback, 15-8

Block diagram math, 5-1 to 5-6
- control system terms, 5-3
- definition, 5-2
- feedback circuit, 5-3
- multiloop feedback system, 5-4
- summary points, 5-3
- transforms, 5-5

Blocks, block diagram math, 5-2

Bode analysis, feedback, 5-7 to 5-13

Bode plot
- compensated attenuator, 7-18
- current feedback amp, 8-7
- dominant-pole compensation circuit, 7-11
- feedback capacitance, 8-13
- lead compensation, 7-14
- lead-lag compensation, 7-19

Bode, H. W, 1-2

Broadcasting, from PCB traces, 17-9
Bridge, wheatstone, 12-8
Broadband noise, 11-18
Brown noise, 10-12
Bubba oscillator, 15-17 to 15-19
  circuit, 15-17
Burst noise, 10-9 to 10-11
Butterworth band-pass filter, gain response graph, 16-36
Butterworth low-pass filter, 16-6
  amplitude response graph, 16-6
  circuit with unity gain, 16-21
  graph, 16-51
  Tschebyscheff-type characteristic, 16-51

C

Cable amplifier, 3-9
Canonical equations, 6-2 to 6-5
Canonical feedback, 15-2
Capacitance
  effect on inverting op amp, 17-18
  trace to plane, 17-17
Capacitively-loaded
  loop-gain calculation circuit, 7-9
  op amp circuit, 7-9
Capacitor, 3-9 to 3-11
  high-frequency circuit, 17-12
  self resonance, 17-22
Cascading filter stages, 16-12
CDMA cellular base station, transmitter block diagram, 13-5
Cellular base station receiver, block diagram, 13-2
CFA. *See* current feedback amplifier
Characterization, transducer, 12-13 to 12-16
Circuit
  active full-wave rectifier and filter, 12-10
  active Wien-Robinson filter circuit, 16-39
  ADC singled-ended input drive, 13-20
  adder, 3-5
  AIA, 12-17
  analog interface, 12-21
  analysis done the hard way, 2-7
  automatic gain control, 15-13
  band reject filter, 5-9
  Bessel high-pass filter, 16-27
  bubba oscillator, 15-17
Butterworth low-pass filter circuit with unity gain, 16-21
canonical feedback, 5-6
capacitively-loaded op amp, 7-9
compensated attenuator, 7-17
complex feedback networks, 3-7
control canonical feedback, 5-6
current divider rule, 2-4
current feedback amplifier, 8-2
DAC current booster, 14-20
DAC current sink to actuator interface, 18-19
DAC current source to actuator interface, 18-17
DAC deglitch, 14-17
DAC voltage booster, 14-21, 14-22
differential amplifier, 3-6, 3-7
differential op amp, 6-8
dual-supply filter, 16-47
electronic canonical feedback, 5-6
feedback, 5-6
feedback loop broken, 6-7
first-order all-pass filter, 16-44
first-order high-pass filter, 16-23
first-order inverting high-pass filter, 16-23
first-order inverting low-pass filter, 16-13
first-order low-pass filter, 16-12
first-order noninverting low-pass filter, 16-14
first-order passive RC low pass filter, 16-2
fourth-order passive RC low pass filter, 16-3
high-frequency capacitor, 17-12
high-frequency inductor, 17-13
high-pass filter, 3-10
high-performance resistor, 17-11
high-speed analog input drive, 13-18 to 13-22
ideal current feedback amp, 9-3
ideal op amp, 3-2
input current, 11-10
input for an RRI op amp, 18-8
input for nonRRI op amp, 18-8
input offset voltage, 11-9
input offset voltage adjustment, 11-9
input parasitic elements, 11-13
inverting, 6-6, 6-7
inverting current feedback amp, 8-5
inverting op amp, 3-4
Kirchoff's current law, 2-3
Kirchoff's voltage law, 2-2
lead-lag compensation, 7-19
logic gate output, 17-21
long-tailed pair, 9-2
loop gain calculation, 7-9

low pass filter, 16-1
low-pass filter, 3-10, 5-8
low-pass filter circuit with unity gain, 16-19
maximum output voltage swing, 11-12
MFB band-pass filter, 16-31
MFB high-pass filter biasing, 16-50
MFB low-pass filter biasing, 16-49
Miller effect compensation, 7-2
noninverting current feedback amp, 8-4
noninverting op amp, 3-3, 18-7
nonlinear feedback, 15-12
Ohm's law, 2-2
op amp design, 12-16 to 12-23
op amp terminal model, 17-5
op amp with negative feedback, 15-8
op amp with positive feedback, 15-8
original amplifier, 2-5
passive twin-T filter, 16-37
passive Wien-Robinson bridge circuit, 16-39
phase shift oscillator, 15-14
phase shift oscillator, buffered, 15-16
photodiode amplifier, 12-8
phototransistor amplifier, 12-9
photovoltaic cell amplifier, 12-9
quadrature oscillator, 15-19
reference bias, 12-13
RRO output stage, 18-11
Sallen-Key band-pass filter, 16-30
Sallen-Key high-pass filter, 16-24
Sallen-Key high-pass filter biasing, 16-50
Sallen-Key low-pass filter, 16-15
Sallen-Key low-pass filter biasing, 16-48
Sallen-Key low-pass filter circuit, 16-20
saturated transistor, 2-9
second-order all-pass filter, 16-44
second-order low-pass filter, 16-17
second-order MFB high-pass filter, 16-25
second-order MFB low-pass filter, 16-18
second-order Tschebyscheff low-pass filter, 16-16
seventh-order all-pass filter, 16-46
simplified op amp, 11-17
simultaneous equation , 4-12, 4-15, 4-17, 4-20
single supply, 4-1, 4-3
common-mode voltage, 4-2
reference voltage input, 4-2
single supply inverting op amp, 4-4, 4-5
single supply noninverting, 4-7
single-ended to diff output, 13-18
single-pole reconstruction filter, 13-15
single-supply DAC, 14-23
single-supply filter, 16-47
slew rate, 11-16
split-supply op amp, 10-19
stability analysis, 8-2, 8-3
stray capacitance on inverting input, 7-16
superposition example, 2-8
T network, 3-8
Thevenim equivalent of the base circuit, 2-11
Thevenim's equivalent, 2-5, 2-6
TLC2201, 10-21, 10-23
traducer bias, 12-13
transducer to ADC interface, 18-15, 18-16
transistor, 2-10
video amplifier, 3-9
voltage divider rule, 2-3
voltage feedback amp, 9-2
voltage reference filter, 13-16
Wein bridge oscillator, 15-12
Wein bridge oscillator with AGC, 15-13
wheatstone bridge, 12-8
Wien bridge oscillator, 15-9, 15-11
Wien-Robinson bridge circuit, 16-39
Wien-Robinson circuit, 16-39
Circuit board layout, 17-1 to 17-30
component of op amp design, 17-1
noise sources, 17-2
prototype, 17-1 to 17-3
Circuit Theory, op amps, 2-1 to 2-13
Closed loop response, diff amp graph, 13-19
Colors, noise, 10-10 to 10-13
Common-mode range, op amp, 18-6 to 18-10
Common-mode rejection ratio, 11-15
Compensated attenuator, 7-16 to 7-19
circuit, 7-17
Compensation
comparison of schemes, 7-20 to 7-22
DAC, 14-18 to 14-20
dominant pole graph, 7-11
dominant-pole, 7-9 to 7-13
external, 7-8
feedback capacitance, 8-13 to 8-15
gain, 7-12 to 7-14
gain capacitance, 8-13
graph, 7-12, 7-13
internal op amp, 7-2 to 7-9
inverting op amp, 7-15
lead, 7-13 to 7-17
lead-lag, 7-18 to 7-21
Miller effect, 7-2 to 7-4

Miller effect circuit, 7-2
noninverting op amp, 7-16
Complex feedback network, 3-7 to 3-9
Thevenin's theorem, 3-7 to 3-9
Control system terms, block diagram math, 5-3
Corner frequency, 10-13 to 10-15
Current booster
circuit for DAC, 14-20
op amps, 14-20
Current divider rule, 2-4
Current drain, op amp, 18-12 to 18-14
Current feedback amplifier
analysis, 8-1 to 8-15
bandwidth, 9-3 to 9-7
bandwidth graph, 8-10
Bode plot, 8-7
circuit, 8-2
compensation, 8-13 to 8-15
equation comparison, 9-8 to 9-10
feedback capacitance, 8-12 to 8-14
feedback capacitance Bode plot, 8-13
feedback capacitance compensation, 8-13 to 8-15
feedback resistor graph, 8-10
feedback resistor selection, 8-9 to 8-12
frequency graph, 9-5
gain capacitance compensation, 8-13 to 8-15
gain graph, 8-10, 9-5
ideal circuit, 9-3
impedance, 9-7 to 9-9
input capacitance, 8-11 to 8-13
inverting, 8-5 to 8-7
inverting circuit, 8-5
model, 8-1 to 8-3
nonnverting, 8-3 to 8-6
noninverting circuit, 8-4
precision, 9-2 to 9-4
stability, 8-11 to 8-14, 9-6 to 9-8
stability analysis, 8-7 to 8-10
stability analysis circuit, 8-2, 8-3
stability equation, 8-2 to 8-4
stray capacitance graph, 8-12
voltage feedback amp comparison, 9-1 to 9-10
Current source, 12-7
Curve
band reject filter, 5-10
bode plot of low-pass filter, 5-9
Bode plot, no poles, 5-11
Bode plot, with single pole, 5-11
damping ratio vs overshoot, 5-16
damping ratio vs phase margin, 5-16
loop gain plot, 5-13, 5-14
low-pass filter, 5-9
overshoot vs damping ratio, 5-16
phase margin vs damping ratio, 5-16
single supply inverting op amp, 4-5
single supply noninverting op amp, 4-7
transfer, 4-12, 4-15, 4-18, 4-21

D

DAC
AC application error budget, 14-8
AC errors, 14-14 to 14-18
AC loads, 14-2
AC parameters, 14-14 to 14-18
accuracy vs resolution, 14-7
actuator analog interface, 18-16 to 18-21
compensation, 14-18 to 14-20
current booster circuit, 14-20
DC application error budget, 14-7
DC errors, 14-10 to 14-14
DC loads, 14-1 to 14-3
DC offsets, 14-22
DC parameters, 14-10 to 14-14
deglitch circuit, 14-17
differential nonlinearity error, 14-12
differential nonlinearity error graph, 14-13
dynamic range, 14-9 to 14-11
ENOB, 14-14
error budget, 14-6 to 14-11
errors, 14-10 to 14-16
external ref circuits, 13-15 to 13-18
external voltage reference circuit, 13-17
gain error, 14-11 to 14-13
gain error graph, 14-12
integral nonlinearity error, 14-13 to 14-15
intermodulation distortion, 14-15 to 14-17
interpolation filter, 13-5
nonlinearity error, 14-12 to 14-15
offset error, 14-10 to 14-12
offset error graph, 14-11
parameters, 14-10 to 14-16
power booster, 14-22
power supply rejection ratio, 14-14
R/2R, 14-4 to 14-6
R/2R circuit, 14-5
R/R2 resistor array, 14-4
reconstruction filter, 13-5, 13-13 to 13-16

resistor ladder, 14-2 to 14-4
resistor ladder circuit, 14-2
RF application budget, 14-10
selection, 13-6 to 13-10
settling time, 14-16 to 14-18
sigma-delta , 14-5 to 14-7
SINAD, 14-14
single-supply operation, 14-22
specifications, 14-2 to 14-6
spurious free dynamic range, 14-15
THD, 14-8 to 14-10, 14-14
types, 14-2
voltage booster circuit, 14-21, 14-22
weighted resistor, 14-3 to 14-5
weighted resistor circuit, 14-3
DAC current sink, actuator interface circuit, 18-19
DAC current source, actuator interface circuit, 18-17
Damping ratio, graph, 7-4
DC loads, DAC, 14-1 to 14-3
DC offsets, DAC, 14-22 to 14-24
DC parameters, DAC, 14-10 to 14-14
Deglitch circuit, DAC, 14-17
Design, op amp circuit, 12-16 to 12-23
Design hints, 16-47 to 16-55
Design procedure, 12-11 to 12-13
Differential amp, closed loop response, 13-19
Differential input voltage range, parameter, 11-11
Differential nonlinearity error, 14-12 to 14-14
graph, 14-13
Differential op amp, 3-6 to 3-8, 6-8 to 6-10
circuit, 3-6, 6-8
common-mode input signal circuit, 3-7
noise, 10-18
Differential output drive, from single-ended circuit, 13-18
Differential voltage amplification, parameter, 11-13
Digital plane placement, 17-8
Distortion, total harmonic, 11-18 to 11-20
Dominant-pole compensation, 7-9 to 7-13
graph, 7-11
Dominant-pole compensation circuit, bode plot, 7-11
Dual IF receiver, block diagram, 13-4
Dual supply op amp, vs single supply, 4-1 to 4-4
Dual-supply filter, circuit, 16-47
Dynamic range
DAC, 14-9 to 14-11
low-voltage op amp designs, 18-3 to 18-6

E

Effective number of bits, DAC, 14-14
Elapsed time
graph for TL07x, 7-5
graph for TL08x, 7-6
ENOB, DAC, 14-14
Equivalent input noise, parameter, 11-17 to 11-19
Error sources, op amp, 18-4
External compensation, 7-8

H

High-frequency capacitor, circuit, 17-12
High-frequency inductor, circuit, 17-13
High-frequency resistor, circuit, 17-11
High-pass filter
Bessel circuit, 16-27
circuit, 3-10
design, 16-21 to 16-27
first order, 16-23 to 16-25
from a low-pass filter, 16-21
gain response graph, 16-22
higher order, 16-26 to 16-28
inverting circuit, 16-23
MFB circuit, 16-25
noninverting circuit, 16-23
Sallen-Key circuit, 16-24
Sallen-Key circuit with unity gain, 16-24
second order, 16-24 to 16-27
High-speed analog input drive circuits, 13-18 to 13-22

I

Ideal op amp
assumptions, 3-1
characteristics, 3-2
circuit, 3-2
IF receiver, block diagram, 13-4
Impedance
current feedback amp, 9-7 to 9-9
voltage feedback amp, 9-7 to 9-9
Inductive vias, 17-19 to 17-21
Inductor, high-frequency circuit, 17-13
Input capacitance, 11-14
current feedback amp, 8-11 to 8-13
Input common-mode range, op amp, 18-6 to 18-8
Input common-mode voltage range, parameter, 11-11
Input current, 11-10
circuit, 11-10
Input noise spectrum, graph, 11-18
Input offset voltage
adjust circuit, 11-9
circuit, 11-9
parameter, 11-8 to 11-10
Input parasitic elements, 11-13 to 11-15
circuit, 11-13
input capacitance, 11-14
input resistance, 11-14
output impedance, 11-14
output impedance circuit, 11-14
Input resistance, 11-14
Instrumentation amaplifiers, 12-1 to 12-24
Integral nonlinearity error, DAC, 14-13
Intermodulation distortion, DAC, 14-15 to 14-17
Internal compensation, op amp, 7-2 to 7-9
Inverting
current feedback amp, 8-5 to 8-7
current feedback amp circuit, 8-5
Inverting high-pass filter, circuit, 16-23
Inverting input, stray capacitance circuit, 7-16
Inverting low-pass filter, circuit, 16-13
Inverting op amp, 3-4 to 3-6, 6-6 to 6-8
capacitance effect, 17-18
circuit, 3-4, 6-6

feedback back loop broken circuit, 6-7

Elliott Sound Products **Project 48**

Active Sub-Woofer and Controller

Rod Elliott (ESP)
Updated 03 Feb 2004

PCBs are available for this project. Click the image for details.

Introduction

Sub woofers are very popular, with home theatre being one of the driving forces. However, a good sub adds considerably to normal hi-fi program material, and especially so if it is predictable and has good response characteristics.

The majority of sub woofers use a large speaker driver in a large box, with tuning vents and all the difficulties (and vagaries) that conventional operation entails. By conventional, I mean that the speaker and cabinet are operated as a resonant system, using the Thiele-Small parameters to obtain a box which will (if everything works as it should) provide excellent performance.

Photo of Completed Prototype

The principle of Extended Low Frequency™(or ELF™) [1] is surprisingly uncommon, with one manufacturer that I have found using it in their subs [2]. I suspect there is one other, but I am not certain that the same method is used - although the principle is the same. Since ELF is trademarked, I will not be using the term in this project, but will refer to my version as Electronically Assisted Subwoofer (EAS). I briefly thought about Electronic Subwoofer Principle (ESP) but decided that would be silly :-)

The basic principles were discovered by Edward Long and Ronald Wickersham (although there is a

possibility that others have used similar principles beforehand, there is little available literature), and they both point out that there are some major problems in the reproduction of low bass, highlighting the fact that the bass is the foundation upon which the sound image is created, and that the phase response of ported enclosures can cause "smearing" of the sound in the time domain. I don't know about "smearing", but I do know that my prototype provides bass that is deeper and tighter than anything I have heard before. Ported enclosures definitely cause problems with the sound, as the reproduction mechanism relies on two resonant systems, and it takes time for the sound to build up and decay.

Siegfried Linkwitz [3] developed a circuit that equalises the bottom end of the system, but does not affect the higher frequencies. This is shown and described fully in Project 71, and must be used with a crossover. Although it offers several advantages over the EAS system described here, it is also much more reliant on your detailed knowledge of the loudspeaker driver parameters.

The electronics to perform the necessary processing are easy to build, with the only hard part being a suitably high powered amplifier, and the correct choice of loudspeaker drivers. The cabinet is very easy, since it is small and sealed, so there are no issues with resonance and tuning to worry about.

What? A small, sealed box for a sub-woofer - that can't be right. Well, it is, and the principle is quite different from the conventional approach. When a loudspeaker is installed in a sealed box (or any box, for that matter), it will have a resonant frequency that is higher than in free air. The smaller the box, the higher the resonant frequency will be.

With the EAS approach, the idea is to operate the speaker below resonance, where all the impedance peaks have been left behind in the upper frequencies, leaving a very predictable performance driver to handle the low frequency range. With some experimentation, I determined that a 55 litre box was ideal (it turned out to be 60 litres without the speaker, so with the speaker installed it is about right) for the driver I have, a 4 Ohm, 250W 380mm monster, with a free air resonant frequency of 18Hz. In the small box, this is increased to 63Hz, and this defines the maximum frequency of operation. Resonance probably should have been a little higher, but it manages to sound right, so I shall not worry too much.

Below resonance, a loudspeaker in a sealed box has a response that falls at 12dB / octave, so a means is required to provide an amplifier drive signal that increases at the same rate. A very common circuit in electronics is an integrator, and these are used in many signal processing applications. An integrator has a frequency response that falls at 6dB / octave from DC, extending as far as one wishes. By using two integrators, we obtain a response that falls at 12dB / octave, and by adding resistors, we can cause the response to shelve at any frequency we select. By including capacitors, we can create a high pass filter, so that response to DC is not possible (and nor is it desirable - but more on this later).

It appears that for reasons that are a complete mystery to me (and others), the ELF™ process is patented. Since the basic theory is public domain, and has been discussed by others [3], [4], at some length, it is doubtful that a patent challenge would stand up in a court, however I must warn you of this. In theory, the construction of this project is possibly a violation of patent, however for individual use it is impossible to enforce. Commercial production is a different matter, but no-one would do this without my consent anyway (hmmm), naturally having read and understood my disclaimer and copyright notice.

Driver Selection and Hardware

A quick word is warranted here, to allow you to determine if the speaker you have will actually work in a small sealed enclosure. The EAS principle (or Linkwitz transform circuit) will allow any driver to extend to 20 Hz or even lower. A good quick test is to stick the speaker in a box, and drive it to 100W or so at 20 Hz - you should see a lot of cone movement, a few things will rattle, but you shouldn't actually hear a tone. A "bad" speaker will generate 60 Hz (third harmonic) - if you don't hear anything, the speaker will work in an equalised sub.

If a tone is audible, or the speaker shows any signs of distress (such as the cone breaking up with appropriate awful noises), then the driver cannot be used in this manner. Either find a different driver, or use a vented enclosure.

Before you can build your own EAS box, you will need to select a suitable driver, using the above as a guide. Cone excursion will be very high at the lowest frequencies, so the speaker needs to be capable of high power, good excursion, and of reasonable size (there is no substitute for cone area for moving air at low frequencies). I am using a 380mm (15") driver, but two smaller drivers (say 300mm - 12") can be used, or even a larger number of smaller drivers. I have also had excellent results with a single 300mm driver, which has lower sensitivity (as one would expect) but is perfectly adequate for normal usage.

The test methods I used are applicable to any combination, but in general I suggest either a single large driver or a pair of (say) 300mm units. The next hurdle is the amplifier needed to drive the speaker. This is not trivial. If the selected driver has a sensitivity of 93dB / W @ 1 metre, then you can safely assume that the efficiency will be less than this below resonance, by a factor of maybe 6dB or more. If you are used to driving a sub with 100W, this means that you have just increased the power to 400W - although this is an over-simplification.

If we are to operate the sub from 60Hz (my goal from the beginning), we will increase the power by 12dB for each octave, so if 20W is needed at 60Hz, then at 30Hz this has increased to 320W, and at 15Hz, you will need over 5kW.

Fortunately, the reality is a little different, and 400W or so will be more than sufficient for a fairly powerful system, due mainly to the fact that the energy content in the low bass region is not normally all that great. (Although some program material may have very high energy content, in general this is *not* the case). The EAS system augments the existing system, which is allowed to roll off naturally - contrast this with the normal case, where a crossover is used to separate the low bass from the main system, so existing speaker capability is lost.

This method of driving a sub is best suited to systems where the main enclosures are sealed rather than ported. While it will still work with ported systems, the phase response will be unpredictable, and overall performance may not meet your expectations. As an experiment, the port(s) can be blocked. This will not only make the EAS box work better with your main loudspeakers, but will also improve their bass transient response. Make sure that any modification you make is reversible!

One area where you do need to be very careful is the selection of bass driver and box size. These are critically tied to the characteristics of the selected subwoofer, and should be carefully matched for best

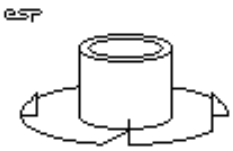
performance (and minimum power). If the box is too small, then the resonant frequency will be too high, causing a dramatic decrease in efficiency and a peaking response from the sub. If the box is too large, resonance will be lower than required, and the system will have a response that does meet the 12dB/ octave characteristics properly.

It is helpful if you know the -3dB frequency of your main speakers, and multiply by 0.75 to obtain the -6dB frequency. This is the frequency where you will actually cross over from the main speakers to the sub-woofer. The EAS box ideally needs to be tuned so that its resonance is between 1 and 1.4 times that of the main speakers. As part of my experiments, I checked the resonance of my EAS box, and found it to be 63Hz. What surprised me a little was the magnitude of the peak - at just over double the off-resonance impedance. This is very low, and is (presumably) a result of the small box and the fibreglass filling. A standard frequency scan shows a slight rise in output level at resonance, but this may be ignored (the room will have a far more profound effect anyway).

Let's assume that your main speakers are 3dB down at 60Hz - this is the resonant frequency of a sealed box. This means they will be 6dB down at 45Hz. The resonant frequency for the EAS box / loudspeaker combination therefore needs to be between 60Hz and 80Hz to obtain a good match. You will either need to experiment with actual boxes, or use a speaker box design program (BassBox, BoxPlot, etc.) - or just build it and have a listen.

There seems to be a fair bit of flexibility in the system, so it is unlikely that the unit you build will be completely unsuited - unless it has resonance at 60Hz and your main speakers roll off above 100Hz, for example. If you make the box a little too large, it is easy to reduce the volume by adding some suitable packing. If it is too small, this will be slightly more difficult :-)

The box I built is made from 25mm (1") MDF (Medium Density Fibreboard), and packed with fibreglass. Apart from the fact that it is very heavy (which is a good thing, because it wants to walk with low frequencies), the cabinet is acoustically dead, with no resonances in the low frequencies at all (completely unlike my house and furniture, dammit !). The woofer is recessed into the baffle, and sealed with weather sealing foam. When attaching the speaker, do NOT use wood screws, or any other screw into the MDF. I used "Tee" nuts. I have no idea what they are called elsewhere in the world, but they look like this ...



Tee Nut

The centre is tapped, and accepts a metal thread screw, and the little spikes mean that you just have to drill a hole, and hammer in the Tee nut. If you use a screw through the hole and screwed lightly into the Tee nut, you can hold it in place as you bash away at it, and can also see that it is straight when you are done. Just make sure that the end of the screw doesn't stick out the end, or you will never remove it again after the hammering! I suggest that you lock the tee nut into place with some construction adhesive (don't get any in the threaded section) so they don't fall out while you are installing the speaker.

The EAS Controller

The controller is quite (actually very) simple, and the circuit is shown in Figure 1. An input buffer ensures that the input impedance of the source does not affect the integrator performance, and allows summing of left and right channels without any crosstalk. The output provides a phase reversal switch, so that the sub can be properly phased to the rest of the system. If the mid-bass disappears as you advance the level control, then the phase is wrong, so just switch to the opposite position.

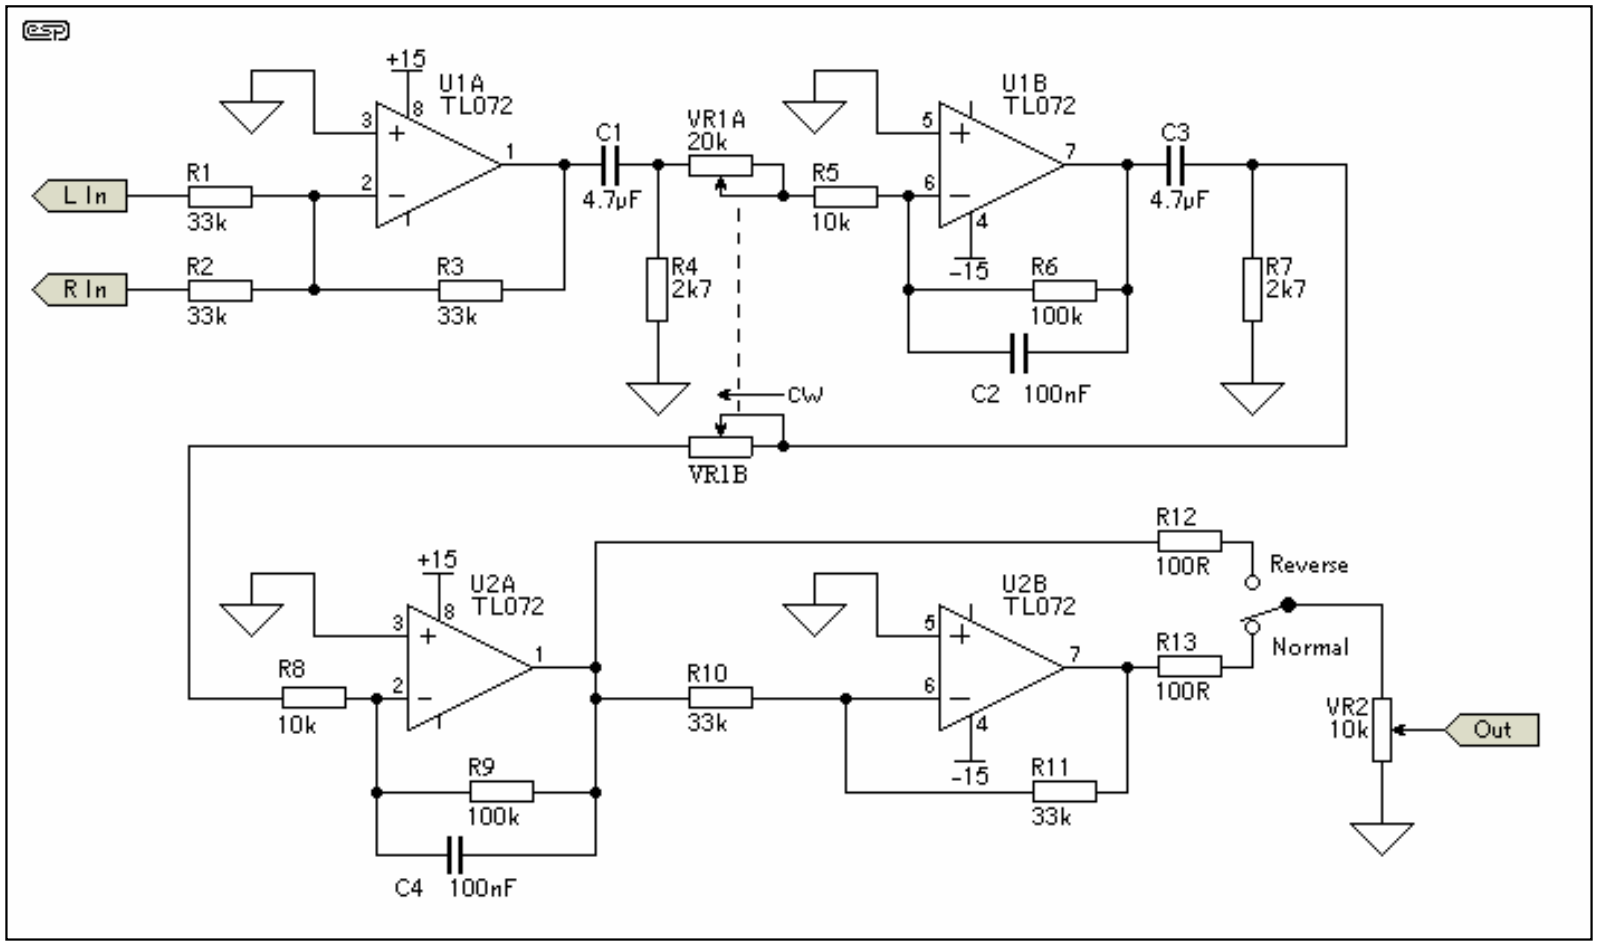


Figure 1 - The Original EAS Filter / Controller

It turns out that the controller can be simplified, but there really is no point. While the dual pot seemed like a good idea when I built my unit, it actually only changes the gain. Now, having experimented some more, this is a very good thing, since it means that the level through the controller can be set to make sure that there is no distortion - there can be a huge amount of gain at low frequencies, and if the gain is too high, distortion is assured!

The integrators (U1B and U2A) include shelving resistors (R6 and R9), and the capacitor / resistor networks (C1-R4, C3-R7) ensure that signals below 20Hz are attenuated. If you don't want to go that low, then the value of the caps (or the resistors R4 & R7) can be reduced. I used 4.7uF caps, and these are non-polarised electrolytics - a high value was needed to keep the impedance low to the integrators. I originally included the dual pot (VR1) to allow the upper frequency rolloff to be set - however it does no such thing (as described above). The final output level is set with VR2, which may be left out if your power amp has a level control.

It is OK to substitute different opamps, but there is little reason to do so. Any substitution device should be a FET input opamp, or DC offset may be a problem. Do not be tempted to use a DC coupled amp. If the one you are planning to use is DC coupled, the input should be isolated with a capacitor. Choose a value

to give a -3dB frequency of about 10Hz, as this will have little effect on the low frequency response, but will help to attenuate the subsonic frequencies.

The unity gain range (using a 20k pot as shown) is from 53Hz to 159Hz. This should be sufficient for most systems, but if desired, the resistors (R5 and R8) can be increased in value to 22k, or you can select a larger value pot. Using 22k resistors and the 20k pot will give a range from 36Hz to 72Hz.

The unity gain frequency is important in only one respect - it will determine the internal gain of the system, and needs to be set based on the input signal level. If the unity gain frequency is set to (say) 100Hz and there is a 1V RMS input, then a 1V RMS input at 20Hz will severely clip the integrators. I suggest that VR1 should be internal, and set when you know the signal level you will be using - this is determined by the input sensitivity of your power amplifier(s) used on the main system. It is probably easier to experiment a little than try to measure everything.

To allow lower frequencies, you can increase the 100k shelving resistors (R6 and R9) to 220k, and increase the high pass capacitors (4.7uF) with 10uF (or R4 & R7 may be increased - a maximum of 4.7k is recommended). This will give a turnover frequency of around 8Hz, but expect to use a lot more power, as there will likely be significant sub-sonic energy that will create large cone excursions with no audible benefit.

The input must be a normal full range (or for a biamped system, the complete low frequency signal). Do not use a crossover or other filter before the EAS controller. For final adjustment, and to integrate the system into your listening room, I recommend the Project 84 constant-Q equaliser. The end result using this is extraordinarily good - I have flat in-room response to 20Hz!

For the power supply, use the one in Project 05, or anything else will provide +/-15V at a few milliamps. My supply is not even regulated, and the entire system is as close to noiseless as you will hear (or not hear). Construction is not critical - I built mine on a piece of Veroboard (perforated prototype board), and managed to fit everything (including the power supply rectifier and filter) on a piece about 100 x 40 millimetres with room to spare.

The EAS system is surprisingly easy to set up with no instrumentation. Of course if you have an SPL meter and oscillator you can also verify the settings with measurements. Remember that the room acoustics will play havoc with the results, so unless you want to drag the whole system outdoors, setting by ear might be the easiest. Even if you did get it exactly right in an anechoic environment, this would change completely once it was in your listening room anyway.

It takes a little experimentation to get right, but is surprisingly easy to do. When properly set, a test track (or bass guitar) should be smooth from the highest bass note to the lowest, with no gross peaks or dips. Some are inevitable because of room resonances and the like, but you will find a setting that just sounds "right" with little difficulty.

Power Amplifier

I have had many requests for a high power amplifier (the 400W unit I am using was a kit - on special - so I couldn't pass it up :-) The easiest is to use the subwoofer amp (Project 68) which is designed specifically

for subwoofers.

Now, if you wanted a really powerful sub, use two 300mm (12") woofers, with one 250W amp per speaker. A system such as this would be excellent, especially since the effective cone area is greater than the 380mm woofer I am using. A typical 300mm speaker has a cone area of about 0.05 m² versus 0.085 m² for a 380mm unit, so two 300mm speakers will have a total effective cone area of 0.1 m². You could go all the way, with a 300mm driver on each face of a cube, with a 250W amp for each. 1500W of low bass should do the job, especially with a cone area of 0.3 m².

This idea is not as silly as it sounds. With six 200mm (8") drivers, you would get a cone area of nearly 0.13 m² (about the same as a single 450mm (18") driver), and the box would still only be quite small at about 60 litres (my guess). There is a lot of scope for experimentation, with far less chance of a box being completely useless than with conventional ported designs.

> Had the driver I am using not been on special, I probably would have used a pair of 300mm drivers for my own sub. As you may have guessed, I wanted to keep the cost of this down to a minimum. I even managed to get the MDF for AU$15 for the lot - as offcuts. The paint for the box cost more than that !

You must accept that for this project to work, you will need a bigger amp than you might have done otherwise. On the positive side, you will get performance that exceeds that of most subs - mine appears to give almost flat response down to less than 20Hz, except I can't actually hear it. My sound level meter can, and it confirms that the response is there. There is rolloff below 15Hz, but I suspect that is my meter, rather than the woofer, since the dual integrator was still working. This was before I built the unit properly, and I allowed the test circuit to go down to 1.5Hz - this caused some excessive cone excursions, to say the least !

Performance Of My Prototype

I measured 80dB SPL at 1 metre in my workshop (sub-woofer perched on a stool in more or less the centre of the space) with at 25Hz and 70W. This improved dramatically when the unit was installed in the listening room, but as I said earlier, there is generally not a lot recorded below around 35Hz. The longest pipe on the organ is about 16Hz, but I think it is not often used (they actually stopped the pipe in the Sydney Town Hall if I remember correctly, because when it was used, the interior trimmings in the building fell off !).

A couple of orchestral recordings revealed traffic (or perhaps underground railway) rumble that I was completely unaware of before (however this was before it was set correctly, and the bass was a tad louder than needed). Once set up properly, its presence is very unobtrusive - except I now have about one and a half octaves of additional bottom end.

I eventually decided on a 20Hz minimum frequency (-3dB), and this is reflected in the component values shown in Figure 1. The actual roll-over frequency is 16.5Hz, after which the output is attenuated at about 12dB / octave (see Figure 2). Without the rolloff capacitors, the gain would be 20dB at 20Hz. Unity gain frequencies are about 4Hz and 63Hz with the pot 20k centred.

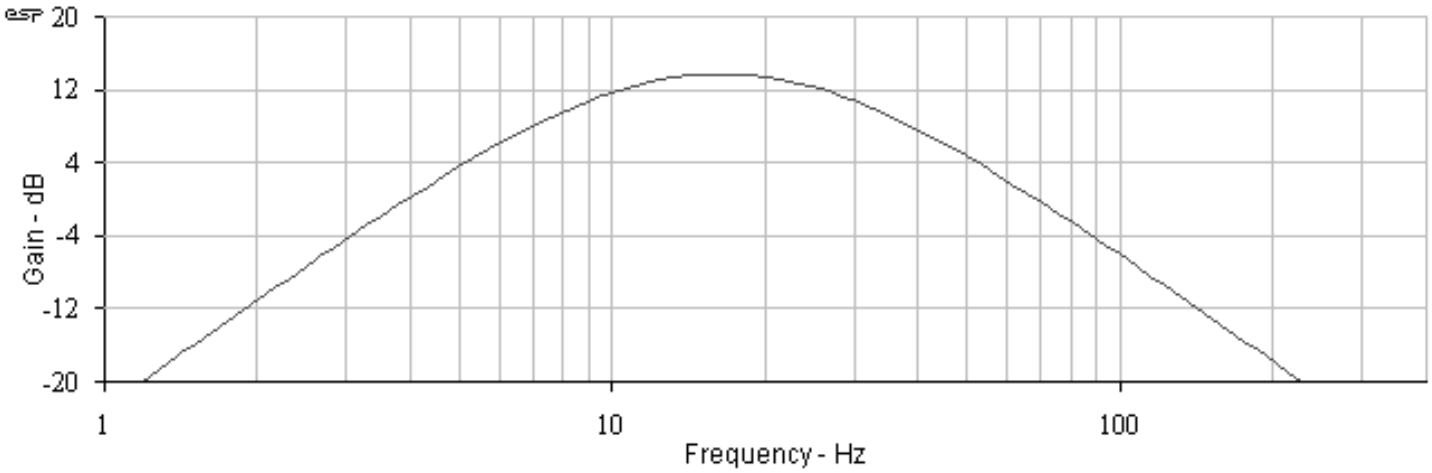

Figure 2 - Frequency Response of EAS Controller

Some Australian readers may recognise the woofer brand in the photo (Figure 3) of my completed unit. The compact size of the box can be seen from the fact that there is very little spacing around the speaker itself, and most of what is there is the top and sides - I used 25mm MDF, so it makes the outside of the box quite a bit bigger than the inside. Outside dimensions are 470W x 450H x 410D (18 1/2"W x 17 1/2"H x 16"D), which gives a capacity of 60 litres (about 2.1 ft³ - excluding the internal space occupied by the speaker. I think you would agree that this is a small box indeed for a 380mm loudspeaker that performs down to 15Hz.

Figure 3 - Photo of Completed EAS Cabinet

Overall, I would have to say that I doubt that any conventional design would be as compact, or would have such clarity and solidarity. Being a sealed box, there is none of the "waffle" that ported designs often give, and the speaker is protected against excessive excursion by the air pressure in the box itself (below the cutoff frequency, anyway).

The bottom end in my system is now staggering. It is rock solid, and absolutely thunders when called

upon. The 400W amp is more than sufficient for the job, considering it has to keep up with a biamped main system capable of very high SPL (up to 120dB at my listening position). In fact a quick test indicates that 200W would have been enough (but ... better to have it and not need it than need it and not have it).

The fact that the EAS design augments the existing speakers rather than taking over from them completely with a crossover goes a long way towards ensuring the power requirements do not get out of hand. As an added benefit, I have found that I get the same aural sensation at much lower SPLs - I can listen quite happily at 90dB, but it sounds much louder. I can even hear the phone ring while listening now !

All in all, I feel it is unlikely that anything other than an isobaric enclosure could give the same performance for a box size even close to the EAS box, and even then would be limited to about 35Hz. Added to this is the rather unpredictable combined response of the main speakers and the sub, which is not an issue with this design. With an EAS system, more power is needed than a conventional design, but for many people, power is much cheaper than space.

Given the performance, I would never consider a conventional sub again, except for the isobaric I have in my car - that only gets down to 40Hz (-3dB), but is acceptable considering the listening environment. The only other sub that takes my fancy is a dipole (i.e. open backed) arrangement [3], but I'm afraid that will have to wait for a while now - I have my EAS system, and am very happy with it.

Multiple Feedback Bandpass Filter

Rod Elliott - Elliott Sound Products

Introduction

The multiple feedback bandpass filter is a simple looking design, but it is difficult to calculate the values for a given set of parameters. These filters are useful for equalisation, analysis and other tasks such as the Sound to Light converter (Project 62) or even a fully functional Vocoder. For those who have not heard of the vocoder, it is a device that takes a music source as one input and vocals as the other, allowing a guitar, keyboard or complete ensemble to be made to speak or sing. The "speech" from a good vocoder is quite intelligible, and is "ear candy" of the very best kind for experimental musicians.

This is the first in a series of projects using this filter type, and I have included a small calculator programme to make it easier to determine the component values for different filter parameters.

Description

A schematic for the filter is shown in Figure 1. The source impedance must be low with respect to the input resistance, and normally these filters are driven from an opamp buffer. If a high impedance is used, it adds to the total input resistance, causing unpredictable centre frequency and response.

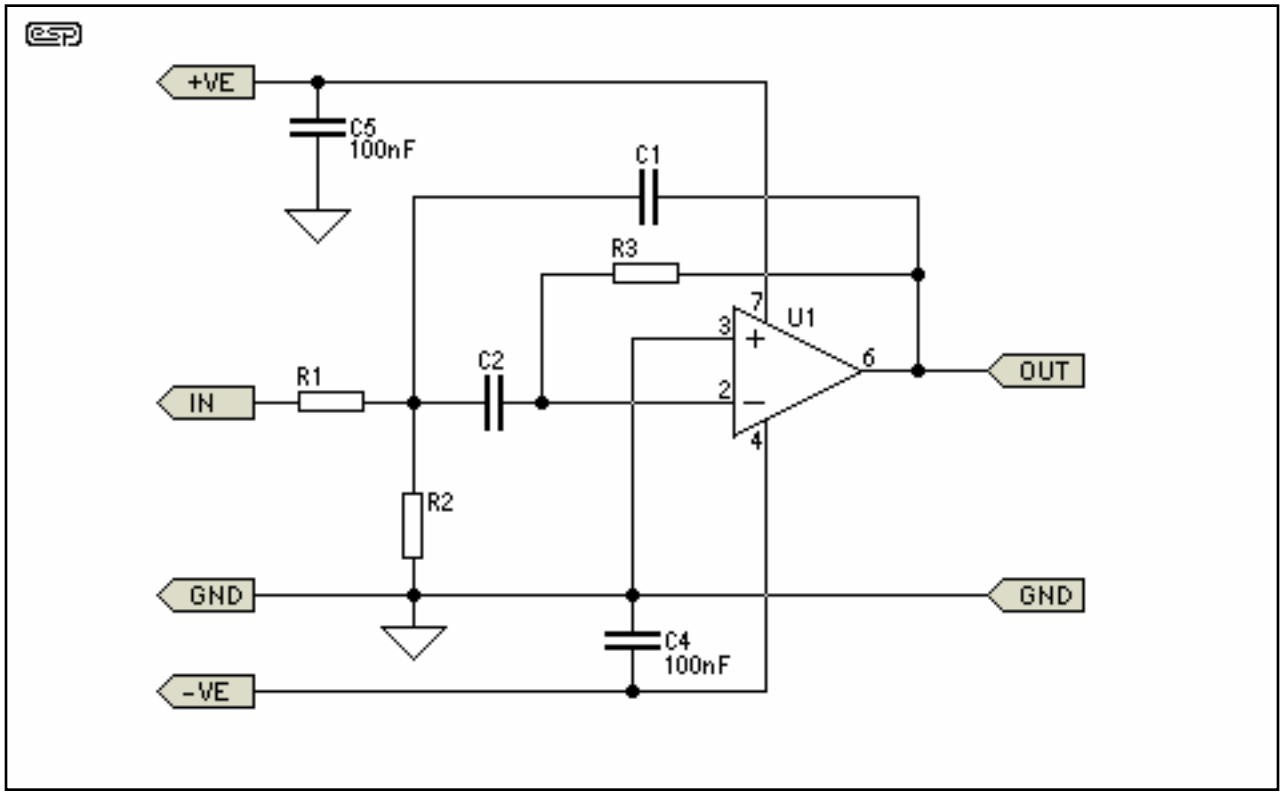

Figure 1 - Multiple Feedback Bandpass Filter

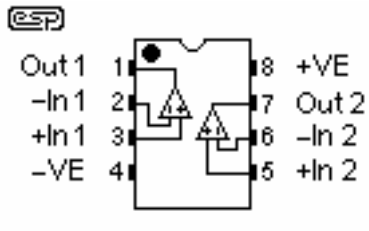
The resistor and capacitor values not shown are calculated from the formulae below, or by using the calculator program (see below for details). The opamp shown is a single device, but most commonly dual or quad opamps will be used for this kind of application. A resistance from the +ve input of the opamp is optional. If used, the resistor should be the same value as R3 to obtain minimum DC offset from the opamp output. A 100nF capacitor is highly recommended to bypass the non inverting input to earth for AC, and helps to reduce noise. If offset is not a problem for you, simply connect the non inverting input to the earth (GND) rail as shown. C4 and C5 are supply bypass capacitors, and should be used at each IC package. Ceramic capacitors are recommended for the most effective high frequency bypass. The opamp can be any common device for low frequencies, but at high frequencies (above about 2kHz) a high speed unit is required for best performance.



The pinout for a typical dual opamp is shown for reference. This is pretty much an industry standard, and nearly all dual opamps use this pin configuration. As always, I suggest that you download the data sheet for the device you intend to use to double check.

Octaves and Filter Q

With any bandpass design (or indeed any filter), one of the important parameters is Q, or 'Quality Factor'. The Q of a filter determines its bandwidth, and this is especially true of bandpass filters. Perhaps unexpectedly, bigger is not better. Most audio applications will require a maximum Q of about 4, which is suited to a 1/3 octave filter set. Few applications require closer filters than this, and to have 1/3 octave band filters covering the audio band requires 30 separate filters. Naturally, for even greater resolution this would increase dramatically.

At this point, a discussion about Q, bandwidth and even division of octaves is needed.

A filter with a Q of 10 (which is too high to be useful in most audio applications), has a bandwidth that is 1/10th of the centre frequency. Thus, a 1,000Hz filter with a Q of 10 has a bandwidth of 100Hz, measured at the -3dB frequencies on either side of the resonant peak. This is shown in Figure 2 for a filter having a centre (resonant) frequency of 123Hz. With -3dB frequencies of 116 and 149Hz, bandwidth is 33Hz, so Q is 132 / 33 = 4.

Note that beyond about 1.5 octaves either side of the resonant peak, the rolloff slope is 6dB / octave. This limits the usable range of the circuit in some respects, as the ultimate slope of 6dB / octave (20dB / decade) is only a first order filter response. Increasing the Q does nothing to solve this, the peak will be narrower and will extend more than the typical 8 to 10dB, but the ultimate slope is unaffected.

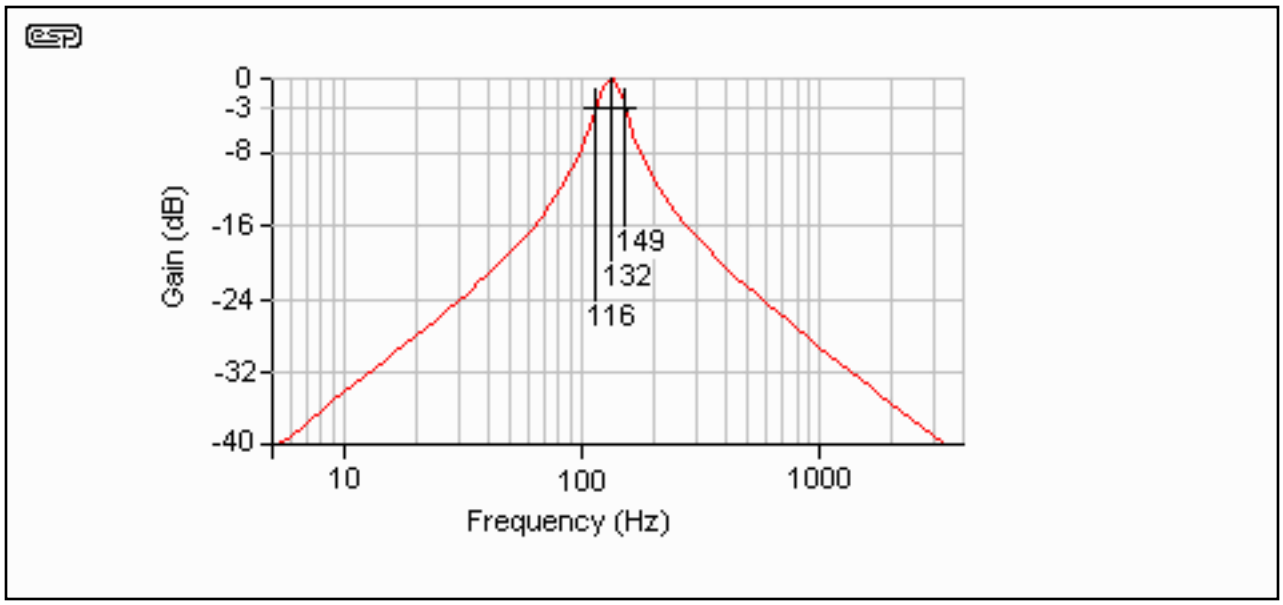


Figure 2 - Typical measurement of Q

Division of an octave is simple, once you see how it is done. An octave is the doubling (or halving) of a frequency, so for A440 (Concert Pitch), an octave above is 880Hz, and an octave below is 220Hz. All notes are "A", but in different octaves. If we want to divide an octave into 12 parts (the equally tempered scale, as used in most musical instruments) we will get 12 semitones. Using A220 as a starting point. we must divide the 220Hz bandwidth into 12 musically related frequencies. The trick here is that you can't divide 220Hz by 12 to find the interval, because our ears have a logarithmic frequency response.

Instead, we must find the 12th root of 2 (1.05946...). If you multiply 220 by 1.05946 twelve times, you will get 440 (well, near enough anyway). To divide an octave in half, we use the square root of 2 (tooth root of 2?) which is 1.414. So (for the sake of simplicity), a half octave division from 100Hz gives the halfway point at 141Hz, and the next octave at 200Hz.

To locate the 1/3 octave intervals, we use the 3rd root of 2 (1.26), so the frequencies will be 100Hz, 126Hz, 158.7Hz and 200Hz. By this means, an octave can be divided into as many frequencies as desired.

Calculating Frequencies

By far the easiest way is to use my program (download here), but since it is only applicable to Windoze machines, some of you will have to do it the hard way. Note that you will also need the Visual Basic 4 (VB4) runtime library, which can be obtained from Annoyances.org (easy) or the Microsoft support Website (less easy).

Based on the circuit above, select an appropriate capacitance first (both capacitors must be the same value), then these are the formulae ...

Input resistance	$R1 = Q / (G * 2 * \pi * f * C)$
Attenuator resistance	$R2 = Q / ((2 * Q^2 - G) * 2 * \pi * f * C)$
Feedback resistance	$R3 = Q / (\pi * f * C)$
Passband Gain	$G = 1 / ((R1 / R3) * 2)$
Centre Frequency	$f = (1 / (2 * \pi * C)) * \sqrt{((R1 + R2) / (R1 * R2 * R3))}$

This process can hardly be regarded as trivial, especially if there is a significant number of filters to design. The program also allows you to apply standard resistor values and

then calculate backwards to see how far out the final design will be from the design ideal. This applies to frequency, gain and Q. Capacitor selection will come with experience, but as a guide, the following table will help ....

$f_{(min)}$ (Hz)	$f_{(max)}$ (Hz)	Capacitance (nF)
20	80	330
80	300	82
300	1,200	22
1200	4,800	5.6
4,800	20k	1.5

Increasing capacitance decreases the resistance values, and especially with multiple filters, care must be taken to ensure that the loading on the input buffer opamp is not excessive. At the same time, low values of capacitance cause problems due to stray capacitance on the board, and resistor values become too high. The above is a reasonable set of values, and will give satisfactory results for most applications.

Equalisers and Analysers

For both equalisers and analysers, there are commonly accepted frequencies that are normally used. The exact frequencies depend on the octave division, the application and some degree of manufacturer preference, but nearly all share the basic octave boundaries which are based on a centre frequency of 1000Hz.

For an octave band EQ or analysis instrument (10 Band) the frequencies are usually as follows ...

31 63 125 250 500 1k0 2k0 4k0 8k0 16k

1/2 Octave band frequencies (20 Band) will be (typically) ...

31 44 63 87 125 175 250 350 500 700 1k0 1k4 2k0 2k8 4k0 5k6 8k0 11k 16k 20k

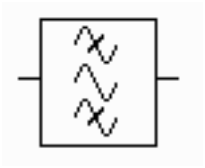
Finally, 1/3 Octave band instruments (30 Band) will typically follow this sequence ...

25 31 40 50 63 80 100 125 160 200 250 315 400 500 630 800 1k0 1k2 1k6 2k0 2k5 3k2 4k0 5k0 6k3

8k0 10k 12k 16k 20k

Naturally, it is possible to use wider bandwidth (and fewer filters) or narrower bandwidth and more filters. Although some 5 band 'graphic' equalisers have been made, they are of limited use for anything other than elaborate tone controls. Anything narrower than 1/3 Octave is rare, since the complexity of the filters increases for higher values of Q. This can get rather expensive, and in reality is of limited use for most applications in audio.

Projects Using MFB Filters



The symbol to the left is a standard representation of a band pass filter, and will be used in any future article or project using this building block. Following this description of the basic multiple feedback bandpass filter building block, projects will be offered that use it. The ones I am currently thinking of including are ...

- Graphic Equaliser (1) - a conventional boost / cut equaliser featuring constant Q at each frequency (see Project 84, a 1/3 octave subwoofer equaliser)
- Graphic Equaliser (2) - a frequency selective filter bank, with each band having its own volume control (project 64)
- Graphic Analyser - based on filters and LED VU meters, gives a display of the signal energy in each band (one day, perhaps)
- Vocoder - a proper vocoder circuit, using filters and voltage controlled amplifiers (VCAs) (maybe one day, maybe not - there is a lot of work involved)

The last two circuits will represent a considerable commitment in time and money, but you will be able to build a basic version of each first, and expand it later as your needs and/or funds allow.

Applications such as audio equalizers require bandpass filters with a constant maximum gain that's independent of the filter's quality factor, Q. However, all of the well-known filter architectures—Sallen-Key, multiple-feedback, state-variable, and Tow-Thomas—suffer from altered maximum gain when Q varies. **Equation 1** expresses the second-order bandpass transfer function of a bandpass filter:

$$H_{BP}(s) = K\frac{\left(\frac{s}{\omega_0}\right)}{\left(\frac{s}{\omega_0}\right)^2 + \frac{1}{Q}\left(\frac{s}{\omega_0}\right) + 1},$$

EQUATION 1

where K represents the filter's gain constant. When the input frequency equals ω_O, the filter's gain, A_{MAX}, is proportional to the product, KQ. Thus, modifying the quality factor alters the gain and vice versa.

This Design Idea describes a filter structure in which K is inversely proportional to Q. Altering Q also modifies K, producing a magnitude-plot set in which the curves maintain the same maximum gain at the central frequency ω_O —that is, KQ remains constant. **Figure 1** shows the filter, which comprises a twin T cell with an adjustable quality factor and a differential stage. The differential stage comprises op amp IC_3 and resistors R_{5A} through R_{5D}. This stage outputs the difference between the filter's input signal and the twin-T network's output. Capacitors C_1 and C_2 are of equal value, $C=C_1=C_2$, capacitor C_3 equals 2C, resistors R_1 and R_2 are also equal and of value $R=R_1=R_2$, and R_3 equals $R/_2$. **Equation 2** describes the twin-T circuit's transfer-function response as a notch filter producing output V_{BR} (t):

rotor connected to ground. The maximum gain is theoretically infinite, but, in practice, it's difficult to achieve a quality factor beyond 50. In most applications, Q ranges from 1 to 10.

Figure 2 shows the filter's magnitude and phase Bode plots for the frequency-notch output V_{BR} (t) (available at IC_1's output) for values of m from 0.1 to 0.9. **Figure 3** shows Bode plots for the filter's bandpass output, V_{OUT} (t), for the same values of m. In both graphs, frequency f_O equals 1061 Hz. To minimize frequency-response variations and improve response accuracy, you can build the filter with precision metal-film resistors of 1% or better tolerance. Likewise, use close-tolerance mica, polycarbonate, polyester, polystyrene, polypropylene, or Teflon capacitors. For best performance, avoid carbon resistors and electrolytic, tantalum, or ceramic capacitors.

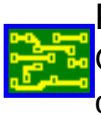
Elliott Sound Products **Project 37**

Minimalist Discrete Hi-Fi Preamp

Rod Elliott (ESP)



PCBs are available for this project. Click the image for details.
Click here to see a photo of the prototype - the actual boards have a silk screened overlay, but are otherwise identical.

Introduction

A preamp designed for the minimalist, and having no frills at all is the design goal for this project. It is designed as a preamp for the Death of Zen (DoZ) Class-A power amp (Project 36), and has very low levels of noise and distortion, in a minimum component count, fully discrete circuit.

This gain module can be used as the basis for any preamp - performance is exemplary, with low noise, wide bandwidth, and it sounds extremely good indeed.

You can add as many inputs as you need, and the only controls are volume and input selection. A power switch is also a good idea, but if you wanted to you could leave the preamp running all the time. This is not necessary, as it will reach a stable operating condition within a few seconds, and will not change its characteristics to any audible degree. An advantage of a power switch is that a +30V signal can be used to switch the power on the power amplifiers, so only a single switch is needed for the system. This can be expanded to switch power to the entire music centre, including CD player(s), tuner, etc.

The preamp can also be used with other amplifiers, and can drive an impedance of 2k Ohms with ease. Although shown using a single supply (to easily match the DoZ power amp), it can also be operated with a dual +/- 15V supply if desired, although this is not really recommended (and is not a trivial undertaking, either) partly because of the possibility of reverse biasing the output capacitors (which cannot be omitted), and partly because of other modifications that are needed for it to work properly.

As shown, frequency response is absolutely flat from 10Hz to 100kHz, without any frequency stabilisation required. The table below shows the rated performance of the gain module.

Distortion	< 0.01%
Output Voltage	6.0 V RMS
Output Impedance	< 100 Ohms
Minimum Load	2k Ohms
Frequency Response	10Hz - 100kHz (-0.5dB)
Voltage Gain	10dB nominal
Supply Voltage	30V
Supply Current	<10mA

Description

The circuit for the amplifier module is shown in Figure 1, and as can be seen is very simple. Two of these can easily be built on a piece of Veroboard, although the PCB makes it a lot easier. This preamp relies on a completely hum free power supply, as it is not an opamp, and cannot reject supply noise as well. This is not to say that the power supply rejection is especially bad, just that it is not as good as an opamp. The power supply is shown below, and this will have a ripple and noise of less than 10uV if built as specified.

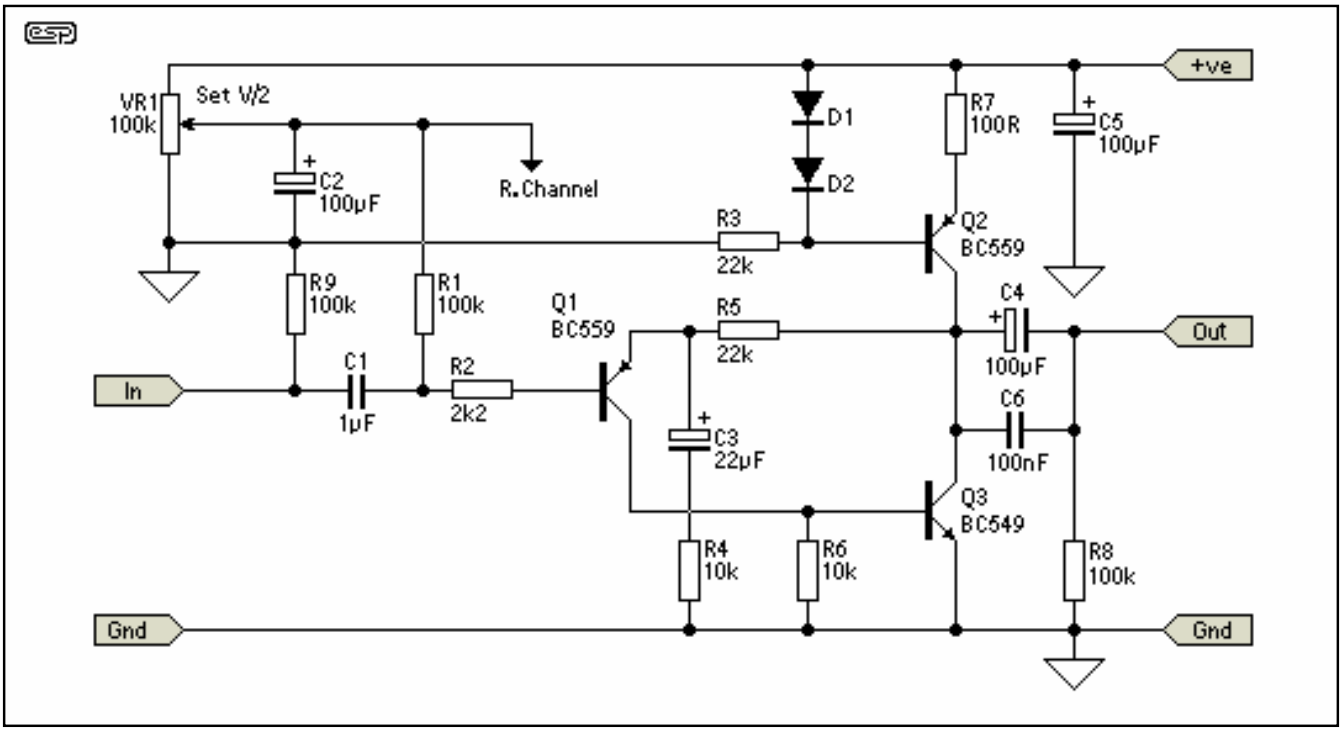


Figure 1 - Gain Module

D1 and D2 are 1N4148 (or 1N914), and together with Q2 form a current source providing a bias current of about 7mA. This stage is not an amplifier, but an active (and very linear) load, allowing the amplifying transistor Q3 to provide a high gain with excellent linearity. Feedback is applied through R5, with R4 setting the AC feedback ratio and thus the voltage gain of the amp. The transistors Q2 and Q3 operate at about 100mW and will get slightly warm in operation.

The trimpot VR1 is used to set the voltage at the collectors of Q2 and Q3 to 1/2 the supply voltage (15V), and a single unit can be used for a stereo pair with no interaction or other undesirable side effects. A 100k resistor is then used to supply bias for each preamp module. If you really don't want to use the pot, you can use a 10k resistor from the +ve of C2 to earth, and a 22k resistor to the supply. This will not allow you to set the quiescent voltage as accurately, but will be acceptable for normal use. R8 ensures that the output capacitor is properly charged with no output connected, and can be left out if the output is connected directly to the volume control as shown below.

The distortion of the preamp is reasonably consistent with frequency, and is less than 0.01%. I measured about 0.0075% - this is just above the residual of my signal generator (0.006%), so it is presumably much better than this, but I can't measure it. A rough guess would be the difference between the two, giving 0.0015%, but I prefer to err on the side of caution.

Frequency response is flat to within -0.2dB from 10Hz to 100kHz, and even at 100kHz, square wave performance is almost perfect, showing slight rounding and no ringing or instability of any kind. Measured output impedance is 84 Ohms, and the circuit can drive 6 Volts RMS into a 2.2k Ohm load easily. These are excellent figures, considering the simplicity of the circuit. The gain is nominally 3.2 (10dB) as shown, and is easily changed by varying R4 - increase the value to

decrease gain and vice versa. Because of the simplicity of the circuit, it can be made very small, even on Veroboard. My prototype measured less than 20mm x 40mm complete.

The preamp modules provide the only gain stage, and may be bypassed for high level signals (such as CD players) that have enough signal to drive the power amp directly. This is a great advantage for those who want the minimum number of components in line with the signal. The circuit cannot be direct coupled, however, since it operates on a single supply. This means that polyester caps can be used at the inputs, but for low impedance outputs, electrolytic capacitors must be used. These may be bypassed with 100nF polyester caps, but the frequency response is not altered to any significant degree (not measurable at 100kHz), and there is no measurable decrease in distortion with the bypass caps.

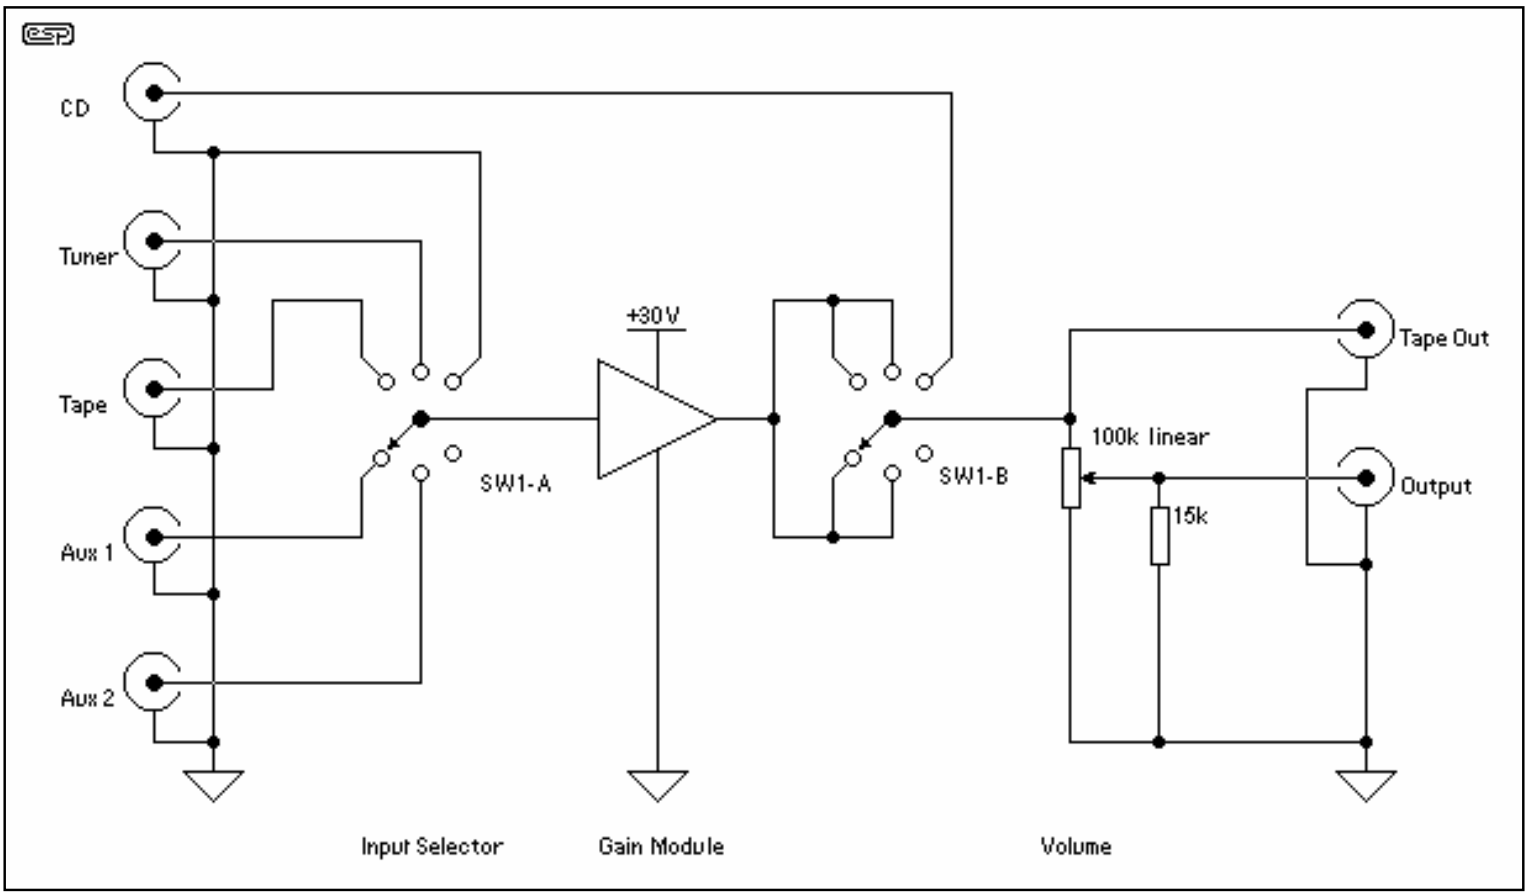

Figure 2 - Preamp Wiring Suggestion

Figure 2 shows one channel of a suggested wiring for the preamp. This is duplicated exactly for the other channel, and the switch and volume control are common to both. The CD input bypasses all electronics and is applied directly to the volume control, and the low level inputs use the gain of the modules to bring their level up to that of the CD player. This introduces a bit more switching, but many audiophiles will prefer this method. Note that when switched to CD, the input of the preamp is earthed to prevent any noise pick-up.

The switching requires a 4-pole, 5 position rotary switch for both channels, and a dual-gang pot. I strongly suggest that a linear pot is used, with the resistor as shown. Although this produces a

variable impedance to the source, it is a better approximation of a log pot than those you can buy at normal outlets, and has much better tracking between channels. If you can get a conductive plastic logarithmic pot, do not use the resistor, as these are generally much better than the normal carbon film types, and the resistor will ruin the log curve.

In some cases - due to an amplifier with unusually low input sensitivity for instance - an output gain stage might be needed. This would typically use another gain module using the circuit above, but generally with lower gain. It is expected that a gain of 2 (6dB) will be enough for any amplifier, since this will provide an output of 4V RMS for a CD players typical 2V output. I have found that with typical sources, a preamp gain of about 10dB is sufficient to drive a typical power amplifier, so the additional gain will probably not be needed.

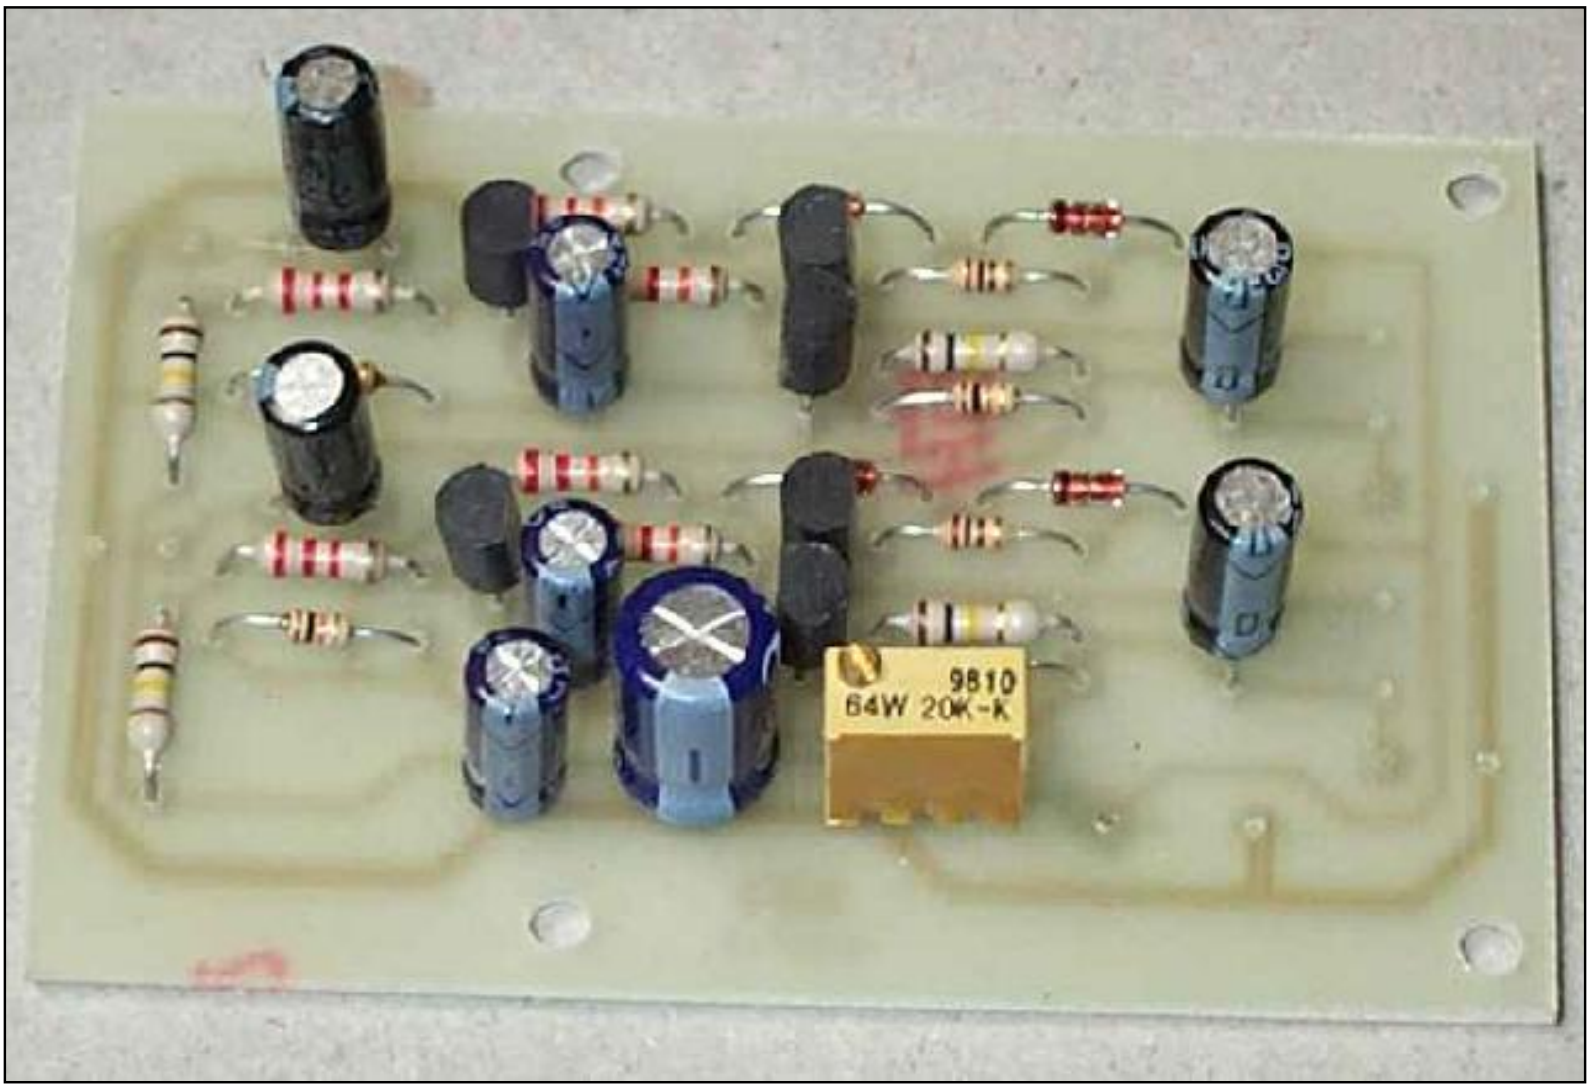

Photo of Prototype

The photo shows what the final unit looks like. Since this was taken of the prototype board, the silk screen component overlay is not present, and I used "ordinary" resistors for all my initial tests. Better noise performance will result from using metal film resistors.

Power Supply

The power supply must be free from hum and noise, and the circuit shown in Figure 3 should be used. Do not use 3 terminal regulators, as the applied voltage is too high, and they will fail. A discrete circuit is (usually) not quite as good, but is simple to build and reliable. The shunt regulator shown here will be hard to beat with any circuit though, mainly because of the filtering used, although the regulator does dispose of a lot of hum by itself.

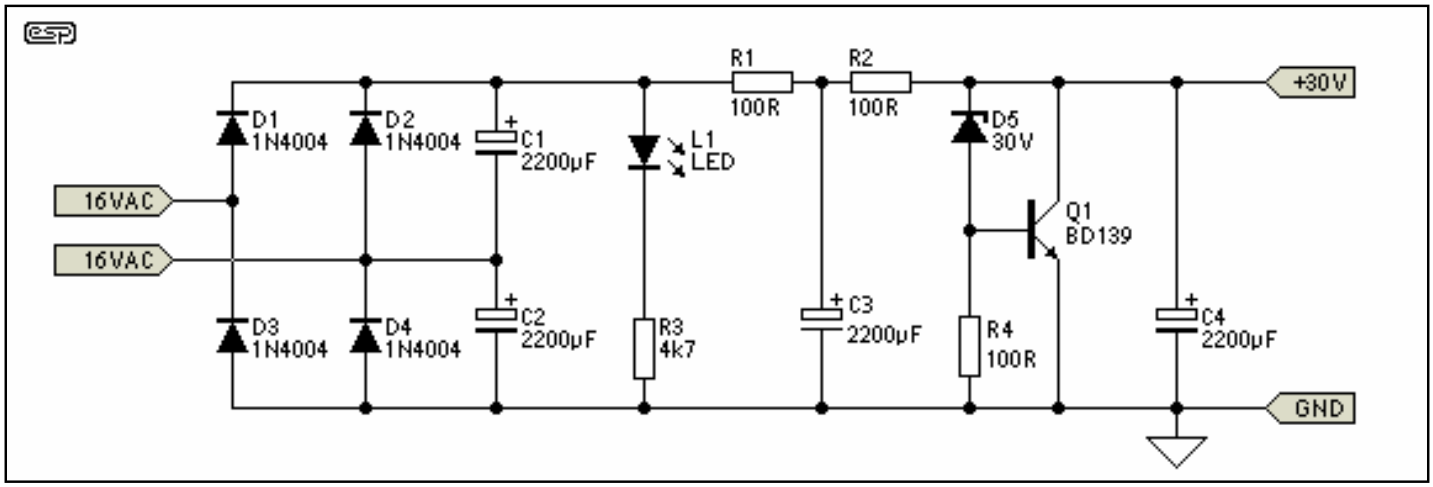

Figure 3 - Power Supply Circuit

This circuit is suitable for two gain modules as shown. If you want to use more, then R1 and R2 will have to be reduced in value. With a 40V input and a total of 200 Ohms, maximum current is 50mA for 30V output. I would suggest that a minimum of 20mA flows in the shunt regulator, so if you wanted to run 4 gain modules, reduce the value of R1 and R2 to about 82 Ohms. You can expect a very small increase in noise, but this will not be audible. The Zener diode must be a 30V device, and should be rated at 1 Watt. Your local electronics supplier will be able to tell you what type number you need. All electrolytic capacitors should be rated at 63V. If you cannot get a 16V transformer, you could use a unit with up to 20V AC output, but you will have to re-calculate the value of R1 and R2.

You can add decoupling between channels to prevent any possibility of crosstalk, but even without this it should be possible to obtain excellent channel separation, since the circuit operates in Class-A and does not vary the supply current with signal (as do opamps and many other circuits). The power transformer does not have to be high power - 20VA is more than enough due to the low current drain (about 50mA).

Because this is a shunt regulator, it has "automatic" protection against short circuits at the output. You should not test this though, because the discharge from the output capacitor will cause a very high peak current, and may damage the cap. Why the shunt regulator? Because in the interests of greatest simplicity, this is the ultimate. Since there is a resistor / capacitor "pi" filter, hum and noise are very low, and should be less than 10uV RMS under normal operation. The shunt regulator also acts to reduce hum, since this is "seen" by the circuit as a varying voltage, and the shunt circuit will try to compensate by modulating its shunt impedance to

minimise the fluctuating voltage.

The series 100 Ohm resistors (R1 & R2) carry the preamp + shunt current, which will typically be around 50mA, so dissipation is quite low. 5W resistors should be used to ensure reliability, especially in the event of an accidental short circuit on the output. In this event, dissipation will be about 7 to 8W, so the resistors will get very hot. The BD139 shunt transistor will operate at about 50mA when the supply is not loaded by the preamp modules, and will dissipate about 1.5 Watts. This must be mounted on a suitable heatsink, having a thermal resistance of no more than 10°C / Watt. This will keep the transistor nice and cool under worst case conditions, with a typical maximum temperature rise of 15°C.

If readers want an alternative with even less hum (the above circuit has about 5uV), let me know, and I'll publish the circuit of a shunt regulated supply with capacitance multiplier. I have only simulated this so far, but output noise is virtually unmeasurable. I don't really think that this is necessary, because even if all 5uV of hum from the circuit above found its way to the output (which it doesn't, by a wide margin), the signal to noise referred to 1V is 106dB (hum component only). This is unlikely to be achieved by the circuit itself, so the hum component can safely be ignored as completely inaudible.

As always, be very careful with the mains wiring. If possible, use a 16V AC power pack and mount it remotely from the preamp so that there is no possibility of inducing hum into the circuit from the transformer. Using the full wave voltage doubler as shown will provide about 40V minimum before regulation. This is more than enough to ensure that the preamp supply remains stable.

METER SHUNTS & MULTIPLIERS

How do you turn a 0-1mA panel meter into one that reads 1A full scale? Or one that reads 100mA full scale? Or into a voltmeter that reads 0-100V? It's not hard to adapt almost any panel meter in this way, once you understand the concepts of current shunts and voltage multipliers.

Let's look at current shunts first. A current shunt is basically just a resistor that is connected directly across the meter movement you want to adapt — so that it *shunts* a significant proportion of the total current around it. This is the way to adapt a meter into one that measures **higher currents**.

Fig.1 shows the basic idea. M is our basic meter movement, while Rs is the shunt resistor. As you can see it's connected directly across the meter's terminals, so that all of the current the meter can't handle is able to pass through the shunt instead.

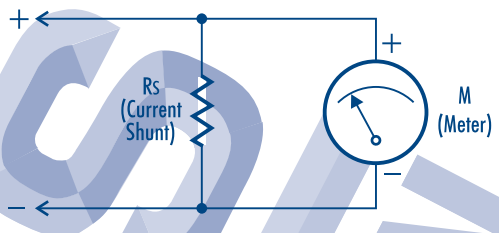

Fig.1: A current shunt is connected in parallel with the meter.

How do you work out the value of the shunt? It's easy once you understand exactly what a shunt does. Let's say we want to adapt our 0-1mA panel meter into one that measures 0-1A. That means that we want the meter to indicate full-scale deflection (FSD) when 1A is flowing — right? But the meter itself will read FSD when it has only 1mA flowing through its coil, of course. So the way we can make this happen is by arranging for the shunt to take **the remaining 999mA** of current. Or putting it in more general terms,

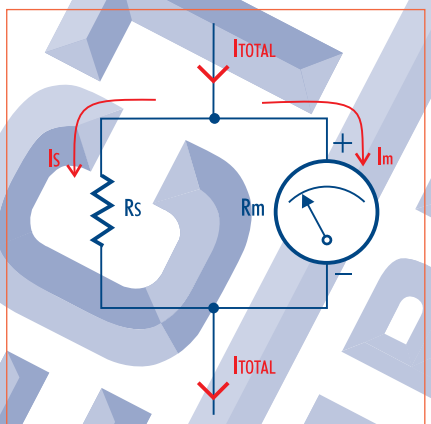

Fig.2: The shunt bypasses a large proportion of the total current around the meter, leaving it with only the current it can handle...

Is = ITOTAL - Im

where Is is the current taken by the shunt, ITOTAL is the total current equal to the new effective FSD we want to give the meter), and Im is the meter's own basic FSD.

So that's the easy way to work out how much current we want our shunt to carry, compared with the meter itself.

As another example, how much current would the shunt need to carry to turn our 0-1mA meter into one reading 100mA? That's right, 100mA minus 1mA, or 99mA.

Now what we have to do is work out the value of the shunt resistor in order to make it carry that proportion of the current. If you look at Fig.2, you see that because the meter and shunt are connected in parallel, they always have the same voltage across them. So how do we persuade say 999mA of the total current to go through the shunt, and only 1mA through the meter?

Right again — simply by making the resistance of the shunt 1/999th that of the meter. That's because in a parallel circuit, the current will always divide in proportions which are the reciprocal of the path resistances. Or in general terms here:

$$\frac{Is}{Im} = \frac{Rm}{Rs}$$

or in a more convenient form for our present purposes,

$$Rs = Rm \div \left(\frac{Is}{Im}\right)$$

In other words, the value of our shunt resistor Rs can be found by dividing the meter resistance Rm by the desired ratio of shunt current to meter current.

So in our example of turning the meter into one reading 0-100mA, the shunt would need to have a resistance of Rm divided by 99.

Meter resistance

Clearly, though, you need to know the resistance of the meter itself in order to work out the value of the shunt you're going to need.

Luckily the internal resistance of most meters is specified when you buy them new. For example the resistance of the MU-45 type 0-1mA meter movement sold by Electus (QP-5010) is specified as 200 ohms, while the more sensitive 0-50uA model (QP-5012) has a specified resistance of 3500 ohms. So it's not hard to work out the value of shunts needed to adapt either of these meters to read higher currents.

But what if you have a meter movement salvaged from a piece of equipment, and you don't know its resistance? Or even its current sensitivity? (It might already have an internal shunt, for example.) The simplest way is to measure it — but don't just slap a multimeter across it, because that could damage the meter by passing too much current through it. The best way is to use the simple test circuit shown in Fig.3.

Here the meter is connected to a 12V battery via a DMM (set to a suitable current range) and adjustable resistor RV1, which is carefully adjusted until the meter is just giving its full-scale reading. The DMM will then be showing the current needed to produce this current FSD — in other words, the meter's sensitivity.

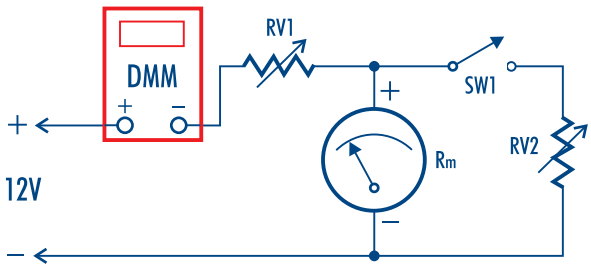

Fig.3: A simple circuit used to measure a meter's internal resistance.

ELECTUS DISTRIBUTION

Now switch SW1 is closed, to connect the second adjustable resistor RV2 directly across the meter, as a shunt. RV2 is then adjusted until the meter reading is reduced to **exactly half scale**, while monitoring the total current via the DMM, and if necessary adjusting RV1 to maintain it at the original FSD figure.

When the meter reading is exactly 50%, the value of RV2 will be equal to the meter's own resistance, because the current is being split equally through the two paths. So you can then disconnect the battery and use the DMM to measure the value of RV2 (by itself), to learn the meter's resistance.

Note that even if the meter should have a current shunt built inside it already, this test will still give you its *effective* sensitivity and resistance — **including** any internal shunt. So the figures you get will allow you to work out the value of any new shunt you need to adapt it for measuring higher currents, regardless of what may be inside the meter case.

Practical shunts

Because a current shunt is generally designed to take most of the current, leaving only a small amount to pass through the meter, most shunts need to have quite low resistance values. For example the shunt to adapt our 1mA/200Ω meter into one reading 0-1A needs a resistance of only 200Ω/999, or 0.20Ω. Similarly the shunt needed to adapt it for reading 0-100mA would need a resistance of only 200Ω/99, or 2.02Ω.

And these values need to be quite accurate, because the accuracy of the resulting 0-1A or 0-100mA meter depends directly on the shunt taking 999/1000ths or 99/100ths of the total current, respectively.

So practical shunts often have to have quite low values, yet be quite accurate. And of course they have to be able to carry the necessary current level (i.e., virtually all of the current being measured), without overheating.

For this reason, current shunts used to adapt meters for measuring very high currents are generally made from stout strips of nichrome or some similar metal with a very low temperature coefficient of resistance (tempco), carefully filed or machined until they reach the exact resistance needed.

This isn't very practical for hobbyist use. But if you only need moderately low shunt values, say for adapting a meter to read 0-10mA or 0-100mA, you can often achieve the value you need simply by using parallel combinations of standard low value resistors — preferably the metal film type, for stability.

For example to get a shunt of 2.02Ω, to adapt an Electus QP-5010 meter into one measuring 0-100mA, you could use a combination of six low value 1% metal film resistors in parallel: four of 10Ω value (RR-0524), one of 20Ω (RR-0531) and one of 22Ω (RR-0532). This combination will give a value very close to 2.02Ω.

You can use the same idea to make practical shunts for most common meters, to adapt them for measuring current up to about 500mA or so. It's really only when you want to make them measure significantly higher currents that you need to worry about pieces of nichrome wire or metal strip.

MULTIPLIERS

Now let's look at **multipliers**, which are used to adapt meters for measuring higher *voltages*. Unlike a current shunt, which as we've seen is wired in parallel with the meter, a multiplier is a resistor connected in *series* with the meter.

To understand how a multiplier works, first think about the meter itself. As we've already seen, a meter has two key parameters: its *sensitivity*, usually specified in terms of the current needed to indicate FSD, and its *internal resistance*.

Now using Ohm's law, it's easy to work out the voltage drop across the meter when it's carrying its FSD current:

$$V_m = I_m \times R_m$$

So when our 0-1mA meter with a resistance of 200Ω is reading FSD, for example, it will have a voltage drop of (1mA x 200Ω) or 200mV. Similarly a 50uA/3500Ω meter like the Electus QP-5012 will have a voltage drop of (50uA x 3500Ω) or 175mV.

These figures are sometimes called the **voltage sensitivity** of the meter movements, because they basically show the voltage that needs to be applied directly across the meter to produce its full-scale reading. As you can see the voltage sensitivity of most meter movements is typically quite low: 200mV or less.

To adapt such a meter for measuring much higher voltages — say 0-20V, or 0-50V — the simplest approach is to

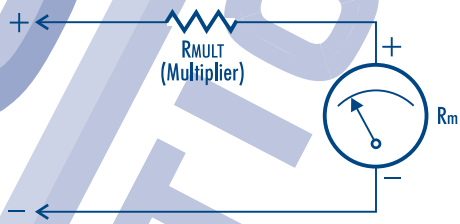

Fig.4: A multiplier is connected in series with the meter, not across it.

connect a resistor in **series** with it, to drop the excess voltage. This is exactly the idea of a *multiplier* resistor: it effectively 'multiplies' the voltage sensitivity of the basic meter to allow measuring higher voltages, without affecting its current sensitivity.

But how do we work out the value of the multiplier resistor? It's not hard.

First, work out the total resistance necessary to pass the FSD current of the meter, knowing the full-scale voltage we want our voltmeter to read:

$$R_T = V_{FSD} / I_m$$

where R_T is the total resistance, V_{FSD} is the FSD voltage we want for our voltmeter, and I_m is the meter's current sensitivity.

For example, let's say we want to turn our 0-1mA meter into a 0-50V voltmeter. R_T will need a value of 50V/1mA, or 50kΩ — right?

Similarly if we want to use a 0-50uA meter as a 0-20V voltmeter, the value of R_T will need to be 20V/50uA, or 400kΩ.

Now the meter itself has its own internal resistance, of course. And this will form part of the total resistance, whether we like it or not. So in order to find the required value of multiplier resistance as accurately as possible, we need to *subtract* the meter resistance from the total resistance we just worked out:

$$R_{MULT} = R_T - R_m$$

So because our 0-1mA meter has a resistance of 200Ω, the actual value of multiplier we'll need to turn it into a 0-50V voltmeter will be (50kΩ - 200Ω), or 49.8kΩ. Similarly the multiplier needed to turn our 50uA/3500Ω meter into a 0-20V voltmeter will be (400kΩ - 3.5kΩ) or 396.5kΩ. Get the idea?

ELECTUS DISTRIBUTION

Needless to say these multiplier values again need to be quite accurate, because the accuracy of the resulting voltmeter will depend on them quite heavily. Luckily because multiplier resistor values are much higher than those for current shunts, it's generally much easier to make up the value you need using standard 1% metal film resistors — this time series combinations.

For example to make up our 49.8kΩ multiplier, you'd use say a 47kΩ resistor (RR-0612) and a 2.7kΩ (RR-0582) in series, giving very close to the correct value. Similarly to make up the 396.5kΩ multiplier you'd use say two 180kΩ (RR-0626) resistors and a 36kΩ (RR-0609) in series, again giving very close to the correct value.

If you work out the exact figures, you'll find that they're within 0.2% or so of the correct figure. There's no point in striving for higher accuracy, because meter movements themselves are generally only rated to an accuracy of 2.5%, and metal film resistors have a tolerance of 1%.

When you want to make the meter into a voltmeter for high voltages, it's actually a good idea to split the multiplier into two or more physical resistors so they share the voltage drop. Metal film resistors are generally not designed to drop more than 200V or so, and they may break down if more than this is applied. So bear this in mind too when you're choosing the resistor values.

Choosing a meter

It's not difficult then, to turn almost any meter into a voltmeter, simply by connecting a suitable multiplier resistance in series. But does this mean that we can choose any meter we like for use as a voltmeter — is a 0-1mA meter just as good as a 50uA meter, given the appropriate multiplier?

No, for a very simple reason. In most circuits when we want to measure a voltage, we want do so while causing the absolute minimum disturbance to the circuit itself. And not surprisingly there will be less disturbance when less current needs to be drawn by the meter. So if a choice of meters is available, it's always better to use the one that needs less current: say the 50uA meter instead of the 1mA meter.

Remember when we worked out those multiplier values, for example. To turn the 1mA meter into a 0-50V voltmeter we ended up with a total resistance of 50kΩ, while for the 50uA we needed a total resistance of 400kΩ just to produce a 0-20V voltmeter. If we wanted to use the 50uA meter to read 0-50V, we'd end up with a total resistance of 1MΩ — much higher than 50kΩ, and therefore much less likely to disturb the circuit we're measuring in.

On the other hand for use as a **current** meter, it's generally better to use a less sensitive meter like a 1mA movement. This is because these movements have a lower internal resistance (like 200Ω instead of 3500Ω), so they will generally need a lower shunt resistance to adapt them for higher current measurement. And the lower the shunt resistance, the lower the voltage drop or 'voltage burden' that will be produced in the circuit when the meter and shunt are being used. Remember that to measure a current, the circuit must be generally be *broken* to connect the meter in series — so in this case, it's the voltage drop of the meter and shunt that will cause the disturbance.

Digital panel meters

Until now, we've been looking at what you need to adapt traditional moving-coil (or moving iron) meters so they will measure higher currents or voltages. But more and more, you might prefer to use a digital panel meter (DPM) instead. They're not much dearer nowadays, after all.

So what's different about DPMs? Can you use current shunts and multipliers with them, in the same way? Not quite, but there are similarities.

The main thing to realise is that a DPM is basically a digital voltmeter, not a current activated device like a meter. Most of them have a voltage sensitivity of 200mV, which is very similar to that of a meter movement, but on the other hand like a DMM they tend to have an internal resistance of 10MΩ or higher — much higher than a meter movement. As a result of this much higher resistance, we need to change the way we adapt a DPM for either current or voltage measurement. But often it makes things easier rather than harder.

When you want to measure a current, for example, you don't have to worry about the DPM's internal resistance any more. It's now so much higher than the shunt that you can ignore it. All you need to do is work out the value of 'shunt' resistor necessary to drop the DPM's full-scale reading voltage, when the desired full-scale current is flowing through it (Fig.5). So by Ohm's law:

$$R_S = V_{FSR} / I_{FSR}$$

Where R_S is the required shunt resistor value, V_{FSR} is the DPM's voltage sensitivity for full-scale reading, and I_{FSR} is the full-scale current reading we want to give it.

So to adapt either the Electus QP-5570 or QP-5580 DPMs (both of which have a voltage sensitivity of 200mV) to read say 0-100mA, for example, you'd need a shunt resistor of (200mV/100mA) or 2.00Ω. Similarly to make them read 0-10mA, you'd need a shunt of 20.0Ω. As you can see, it's even easier to work out the shunt value than it was before. The values are likely to be 'rounder numbers' too, and easier to achieve as a result.

There's even more reason to be accurate in achieving the right shunt value, though, because DPMs are much more accurate themselves than meter movements — typically 0.1%. So it's worth going to a bit more trouble to get the correct shunt value, to make sure that this higher accuracy isn't degraded.

When it comes to adapting your DPM for measuring higher voltages, though, things are a little more complex. In most cases we can't use a simple series multiplier resistor any

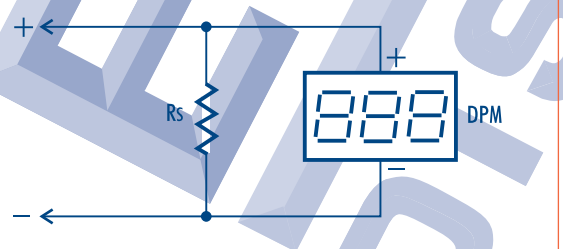

Fig.5: A shunt is also used to adapt a DPM for current measurement, but its value is easier to work out...

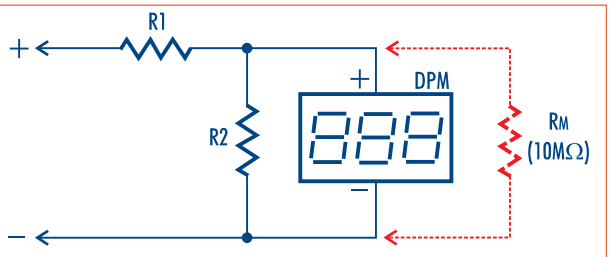

Fig.6: For voltage measurement, though, you need a resistive divider rather than a simple multiplier.

ELECTUS DISTRIBUTION

This table will save you having to work out common shunt and multiplier values for the meters and DPMs stocked by Electus.

ELECTUS METER	SHUNT VALUE (FOR CURRENT RANGE)					MULTIPLIER VALUE (FOR VOLTAGE RANGE)					
	10mA	20mA	50mA	100mA	500mA	5V	10V	20V	50V	100V	500V
QP-5010 (0-1mA/200Ω)	22.2Ω	10.53Ω	4.08Ω	2.02Ω	0.40Ω	4.80kΩ	9.80kΩ	19.8kΩ	49.8kΩ	100kΩ	500kΩ
QP-5012 (0-50uA/3500Ω)	17.6Ω	8.77Ω	3.50Ω	1.75Ω	0.35Ω	96.5kΩ	197kΩ	397kΩ	1MΩ	2MΩ	10MΩ
QP-5570 (LCD DPM. 200mV/10MΩ)	20.0Ω	10.0Ω	4.00Ω	2.00Ω	0.40Ω	R1= 1MΩ R2= 41.8kΩ	R1= 1MΩ R2= 20.5kΩ	R1= 1MΩ R2= 10.1kΩ	R1= 1MΩ R2= 4.00kΩ	R1= 1MΩ R2= 2.00kΩ	R1= 1.53MΩ R2= 612.2Ω
QP-5580 (LED DPM. 200mV/10MΩ)	20.0Ω	10.0Ω	4.00Ω	2.00Ω	0.40Ω	R1= 1MΩ R2= 41.8kΩ	R1= 1MΩ R2= 20.5kΩ	R1= 1MΩ R2= 10.1kΩ	R1= 1MΩ R2= 4.00kΩ	R1= 1MΩ R2= 2.00kΩ	R1= 1.53MΩ R2= 612.2Ω

more, because the DPM's own internal resistance is already so high (10MΩ). You'd need a whopping 40MΩ series resistor just to turn it into a 0-1V meter, for example. The circuit loading would be absolutely negligible, but finding or making up an accurate and stable 40MΩ multiplier wouldn't be easy.

So with a DPM, we need to use a **voltage divider** to adapt it for measuring higher voltages, rather than a simple multiplier. It's still fairly straightforward, though: see Fig.6.

If you like, you can think of resistor R1 as our original multiplier resistor, and R2 as an extra resistor added across the DPM to bring its 10MΩ internal resistance down to a suitably lower value. Or if you prefer, you can think of R1 and R2 simply as a voltage divider across the input voltage, and designed to 'break it down' to the 200mV needed by the DPM. To make the DPM read 0-20V you need a divider ratio of 20V/200mV or 100:1, for example.

The formula relating division ratio to R1 and R2 is:

$$V_R = (R1 + R2)/R2$$

where V_R is the divider ratio, expressed as a number, and R1 and R2 are the resistor values — although strictly speaking R2 here is really the parallel combination of resistor R2 and the DPM's own input resistance R_M.

The only thing you have to bear in mind is that to minimise the voltmeter's loading on the circuit you're measuring, the total resistance of the voltage divider should be as high as possible. But that may call for impractically high resistor values, especially for R1, and also mean that you *will* need to take the DPM's resistance R_M into account when you're working out the value for R2 (because of its shunting effect). So there's a bit more to it than simply picking a pair of resistors to give the right voltage division ratio.

Often, though, it *can* be that simple. If you want to make your DPM into a 50V meter, for example, it would probably be quite acceptable in terms of circuit loading to have the total divider resistance around 1MΩ. So since the divider ratio would be (50/0.2) or 250, you could pick a 1MΩ resistor for R1, and a value of 4.0kΩ for R2. Since R_M is 10MΩ, it'll have a very small shunting effect on R2 — about 0.04%. This can probably be ignored.

In fact with R1 fixed at 1MΩ, you can probably ignore the effect of R_M across R2 for any division ratio larger than 150 — corresponding to a 0-30V range or higher. You only need to take R_M into account for lower ratios; i.e., lower voltage ranges.

Finally, you again need to remember resistor voltage ratings when you're making a voltage divider to adapt a DPM into a voltmeter. So when you're building a divider for very high input voltages (say above 200V), it's again a good idea to split R1 into a number of series-connected resistors so they share the voltage drop.

Obviously most of the divider's voltage drop is across R1 (i.e., all but 200mV), and as we mentioned before metal film resistors generally aren't designed to withstand more than about 200V. So for a voltmeter designed to measure up to say 500V full scale, it would be a good idea to use say three 510kΩ resistors in series for R1, giving it a value of 1.53MΩ but with the three resistors able to share the load. Your corresponding value for R2 would be 612.2Ω, so the shunting effect of R_M would of course be negligible. Using a 620Ω resistor in parallel with one of 47kΩ would probably be close enough.

To save you time and effort, the table above shows the shunt and multiplier values for adapting Electus meters and DPMs for many common current and voltage ranges.

ELECTUS DISTRIBUTION

Moving Coil Meters

The design of a voltmeter, ammeter or ohmmeter begins with a current-sensitive element. Though most modern meters have solid state digital readouts, the physics is more readily demonstrated with a moving coil current detector called a galvanometer. Since the modifications of the current sensor are compact, it is practical to have all three functions in a single instrument with multiple ranges of sensitivity. Schematically, a single range "multimeter" might be designed as illustrated.

Voltmeter

A voltmeter measures the change in voltage between two points in an electric circuit and therefore must be connected in parallel with the portion of the circuit on which the measurement is made. By contrast, an ammeter must be connected in series. In analogy with a water circuit, a voltmeter is like a meter designed to measure pressure difference. It is necessary for the voltmeter to have a very high resistance so that it does not have an appreciable affect on the current or voltage associated with the measured circuit. Modern solid-state meters have digital readouts, but the principles of operation can be better appreciated by examining the older moving coil meters based on galvanometer sensors.

HyperPhysics***** Electricity and Magnetism *R Nave* Go Back

Ammeter

An ammeter is an instrument for measuring the electric current in amperes in a branch of an electric circuit. It must be placed in series with the measured branch, and must have very low resistance to avoid significant alteration of the current it is to measure. By contrast, an voltmeter must be connected in parallel. The analogy with an in-line flowmeter in a water circuit can help visualize why an ammeter must have a low resistance, and why connecting an ammeter in parallel can damage the meter. Modern solid-state meters have digital readouts, but the principles of operation can be better appreciated by examining the older moving coil meters based on galvanometer sensors.

A meter for volume flowrate must be in series to measure the flow, but must not appreciably affect the flow.

Details about ammeter design

HyperPhysics***** Electricity and Magnetism *R Nave* Go Back

Ohmmeter

The standard way to measure resistance in ohms is to supply a constant voltage to the resistance and measure the current through it. That current is of course inversely proportional to the resistance according to Ohm's law, so that you have a non-linear scale. The current registered by the current sensing element is proportional to 1/R, so that a large current implies a small resistance. Modern solid-state meters have digital readouts, but the principles of operation can be better appreciated by examining the older moving coil meters based on galvanometer sensors.

Voltmeter/Ammeter Measurements

The value of electrical resistance associated with a circuit element or appliance can be determined by measuring the voltage across it and the current through it and then dividing the measured voltage by the current. This method works even for non-ohmic resistances where the resistance might depend upon the current.

How Many?

A Dictionary of Units of Measurement

For information on a specific unit, click on the first letter of its name:

A B C D E F G H I J K L M N O P Q R S T U V W X Y Z

Answers to the three most frequently asked questions:

How many micrograms (µg, ug or mcg) in a milligram (mg)?
1000 micrograms = 1 milligram, and 1000 milligrams = 1 gram.

How can I convert from international units (IU) to milligrams or micrograms?
Generally speaking, you can't. IU's measure the potency of a drug, not its mass or weight.

What countries besides the U.S. have not adopted the metric system?
Many U.S. teachers think the answer is "Liberia and Burma" (make that Myanmar). Let's give Liberia and Myanmar a break! *All* countries have adopted the metric system, including the U.S., and most countries (but not the U.S.) have taken steps to eliminate most uses of traditional measurements. However, in nearly all countries people still use traditional units sometimes, at least in colloquial expressions. Becoming metric is not a one-time event that has either happened or not. It is a process that happens over time. Every country is somewhere in this process of going metric, some much further along than others.

Introduction

Americans probably use a greater variety of units of measurement than anyone else in the world. Caught in a slow-moving transition from customary to metric units, we employ a fascinating and sometimes frustrating mixture of units in talking about the same things. We measure the length of a race in meters, but the length of the long jump event in feet and inches. We speak of an engine's power in horsepower and its displacement in liters. In the same dispatch, we describe a hurricane's wind speed in knots and its central pressure in millibars.

Furthermore, our English customary units do not form a consistent system. Reflecting their diverse roots in Celtic, Roman, Saxon, and Norse cultures, they are often confusing and contradictory. There are two systems for land measurement (one based on the yard and the other on the rod) and a third system for distances at sea. There are two systems (avoirdupois and troy) for small weights and two more (based on the long and short tons) for large weights. Americans use two systems for volumes (one for dry

commodities and one for liquids) and the British use a third (British Imperial Measure).

Meanwhile, only a few Americans know that the legal definitions of the English customary units are actually based on metric units. The U. S. and British governments have agreed that a yard equals exactly 0.9144 meter and an avoirdupois pound equals exactly 0.453 592 37 kilograms. In this way, all the units of measurement Americans use every day are based on the standards of the metric system. Since 1875, in fact, the United States has subscribed to the International System of Weights and Measures, the official version of the metric system.

This dictionary began as a collection of notes describing the relationship between various English and metric units. It gradually grew until it finally became too large a word-processing document; I couldn't find my way around in it any more. So I turned it into a folder of html documents and added it to my Internet site. For many months, no one looked at the site except me and my students. Then, gradually, the dictionary began to attract users from around the world. Many users were kind enough to point out errors; others suggested additions and improvements. Questions about units began to appear in my email inbox. Sometimes I could answer the questions, sometimes not.

Today the dictionary has become a kind of interactive resource. It grows slowly and steadily, mostly through suggestions from readers and my efforts to answer questions posed by readers. You can participate in this process! Please let me know if you find any errors on the site, or if you can't find what you wanted to know, or if you know of units used in your field of study or in your part of the world that aren't included.

I hope you find the dictionary useful and informative.

Field descriptions for TRAFO7 Excel spreadsheet ...

Field	Type	Description
Ud	Input	Si diode voltage at high current (change this voltage for using valve (tube) rectifiers, or special diodes)
Ubrss	Input	max. allowed typical peak-peak ripple voltage
Ia	Input	desired nom. DC output current per coil (ohmic load)
alpha	Input	current form factor (RMS > average!) 1.5 ... 2
Uaminn	Input	desired minimum nominal output voltage, to remember your goal
Uamin	Input	minimum nominal output voltage for computation
rho	constant	Copper thermal specific resistance
L	Input	line length from house mains entry to transformer,one way (metres)
A	Input	wire cross section area of this line with length *L*
Rk	computed	resulting line resistance for both ways
Unetz	Input	nominal effective mains voltage
fn	Input	mains frequency
tolup	Input	upper limit of mains voltage variation
tolow	input	lower limit of mains voltage variation
ü	computed	transformation ratio
ü2	computed	impedance transformation ratio
Rks	computed	line resistance transformed to secondary, usually very small
f	Input	actual used transformer loss factor
f	computed	heuristical determined loss factor, no large difference with actually used, unless reason for this is known!
U0eff	computed	nominal sine AC effective transformer voltage per coil with no load
Ineff	computed	nominal sine AC effective transformer current per coil
In	computed	nominal sine AC transformer peak current per coil, compare with *Imax* for a hint for *alpha* (value is doubled in case of Center circuit, since only one coil at a time is conducting in this rectifier circuit, while both are conducting with pure resistive load)
Imax	computed	secondary peak current per coil, also current through diodes, compare with *In* to avoid core saturation
Idm	computed	average diode current
Pa	computed	total power per winding delivered to load resistor
Pn	computed	total transformer power, including rectifier power, load power, all coils and factor alpha
Pns	computed	*Pn* divided by number of coils (1, 2)
Ua0+	computed	idle voltage on capacitor, including mains upper *Ua0+* tolerance

Ua0	computed	idle voltage on capacitor, nominal mains
Ua0-	computed	idle voltage on capacitor, including mains lower tolerance
Usper+	computed	idle voltage stress on diodes, including mains upper *usper+* tolerance
Ua8+	computed	infinite capacitor voltage with load and mains upper *Ua8+* tolerance, can be used to estimate e.g. amplifier losses
Ua-	computed	capacitor voltage (capacitance value *Cl*), including mains lower tolerance and line losses and ripple, lowest instantaneous value
Ua8	computed	infinite capacitor voltage with load, nominal
Ua8ber	computed	tryed infinite capacitor voltage with load
r	computed	ratio between *Ua8* and *Ua8ber* in %, error of iteration, minimise to 0.0!
Uneff	iteration input	nominal effective transformer secondary voltage, this value must be iterated to minimise *r*
Rv	computed	load resistor that would draw *Ia* with infinite capacitor
Ri	computed	transformer resistance for each coil
Ri +main	computed	effective transformer resistance for each coil, including line losses
Cl	computed	capacitor size for give ripple, frequency, load
Pd	computed	power loss per diode
Pg	computed	total power loss, sum for all diodes

OOoCon 2006 Call for Papers

Almost Final Call : Just Days Left! Send in your abstract now.

We have issued our Call for Papers, and are inviting you, the community, to submit abstracts on a range of topics. The deadline is **1 June**.

OOoCon will be held in Lyon, France, from 11-13 September. All are welcome. Past conferences have been fun, important, memorable, and have dealt with technical as well as business and social concerns.

What Is .NET?

Updated: February 1, 2005

.NET is the Microsoft Web services strategy to connect information, people, systems, and devices through software. Integrated across the Microsoft platform, .NET technology provides the ability to quickly build, deploy, manage, and use connected, security-enhanced solutions with Web services. . NET-connected solutions enable businesses to integrate their systems more rapidly and in a more agile manner and help them realize the promise of information anytime, anywhere, on any device.

The Microsoft platform includes everything a business needs to develop and deploy a Web service-connected IT architecture: servers to host Web services, development tools to create them, applications to use them, and a worldwide network of more than 35,000 Microsoft Certified Partner organizations to provide any help you need.

What Are Web Services?

If you ask a developer what Web services are, you'll hear something like, "self-describing software modules, semantically encapsulating discrete functionality, wrapped in and accessible via standard Internet communication protocols like XML and SOAP."

But if you ask a business leader who has implemented Web service-based solutions, you'll get a different kind of answer. You'll hear that Web services are an approach that helps the business connect with its customers, partners, and employees. They enable the business to extend existing services to new customers. They help the business work more efficiently with its partners and suppliers. They unlock information so it can flow to every employee who needs it. They reduce development time and expense for new projects. You'll hear less about what

Web services are and more about what they enable the business to do.

Top of page

Benefits of Web Services

By enabling applications to share data across different hardware platforms and operating systems, Web services provide many benefits, including:

- Opening the door to new business opportunities by making it easy to connect with partners.
- Delivering dramatically more personal, integrated experiences to users through the new breed of smart devices—including PCs.
- Saving time and money by cutting development time.
- Increasing revenue streams by enabling businesses to easily make their own Web services available to others.

Top of page

Connecting Applications Through Web Services

Web services are revolutionizing how applications talk to other applications—or, more broadly, how computers talk to other computers—by providing a universal data format that lets data be easily adapted or transformed. Based on XML, the universal language of Internet data exchange, Web services can communicate across platforms and operating systems, regardless of the programming language in which the applications are written.

Each Web service is a discrete unit of code that handles a limited set of tasks. However, although Web services remain independent of each other, they can loosely link themselves into a collaborating group that performs a particular task.

Top of page

Example: Your Inventory System

Say you have a stand-alone inventory system. If you don't connect it to anything else, it's not as valuable as it could be. The system can track inventory, but not much more. You may have to enter inventory information twice—once in your accounting system and once in your customer relationship management system. The inventory system may be unable to automatically place orders to suppliers. The benefits of such an inventory system are diminished by high overhead costs.

However, if you connect your inventory system to your accounting system, it gets more interesting. Now, whenever you buy or sell something, the implications for your inventory and your cash flow can be tracked in one step. If you go further, and connect your warehouse management system, customer ordering system, supplier ordering systems, and your shipping company, suddenly that inventory management system is worth a lot. You can do end-to-end management of your business while dealing with each transaction only once, instead of once for every system it affects. That's a lot less work—and a lot less opportunity for errors.

These connections can be made easily using Web services. Web services allow the applications to share information through the Internet, regardless of the operating system or back-end software that the application is using.

Top of page

Web Services Use Industry-Standard Protocols

Web services also make it possible for developers to choose between building all pieces of their applications, or consuming (using) Web services created by others. This means that an individual company doesn't have to supply every piece for a complete solution. The ability to expose (announce and offer) your own Web services creates new revenue streams for your company.

Web services are invoked over the Internet by means of industry-standard protocols including SOAP; XML; and Universal Description, Discovery, and Integration (UDDI). They are defined through public standards organizations such as the World Wide Web Consortium (W3C).

SOAP is an XML-based messaging technology standardized by the W3C, which specifies all the necessary rules for locating Web services, integrating them into applications, and communicating between them. UDDI is a public registry, offered at no cost, where one can publish and inquire about Web services.

Microsoft

Audio Millivoltmeter

Rod Elliott - ESP (Original Design)

Introduction

When performing any tests on an audio system, some form of measuring device is essential. Digital multimeters are not useful, since they will not give the true picture of what is happening, and most have a fairly limited frequency range. An oscilloscope is the ideal tool, but not all hobbyists can afford the outlay for a scope, and would find justifying the not inconsiderable cost a tad difficult.

An AC millivoltmeter - calibrated in dB - with a range of 30V down to 3mV full scale (80dB range) would be extremely useful. Attach a microphone (electret mic capsules are quite good), and you have a relative sound level meter, even better if you have some way of calibration.

The meter presented here has a very wide frequency range, and uses a switched attenuator for range adjustment. The attenuator uses the 30-10-3 sequence, which provides 10dB steps between ranges. The standard attenuator provides an input impedance of over 2M Ohms, but is a nuisance because with such high impedances stray capacitance causes havoc with the calibration, so a parallel capacitive attenuator is also needed. If you expect to work with valve amplifiers, you will want the high impedance, but otherwise the low impedance attenuator should do nicely.

The Attenuators

The two attenuator networks are shown in Figures 1 and 2, and as you can see the Hi-Z version requires all those capacitors. They must be accurate, too. Otherwise high frequency performance will be all over the place, so you need a capacitance meter or a

source of close tolerance caps. The resistors are standard E24 series 1% metal film types, and the caps (if used) should ideally be polystyrene or polyester, but if ceramic is all you can get, then ceramics are what you use. If you do have to use ceramic caps, make sure that they have low thermal drift - NPO or similar.

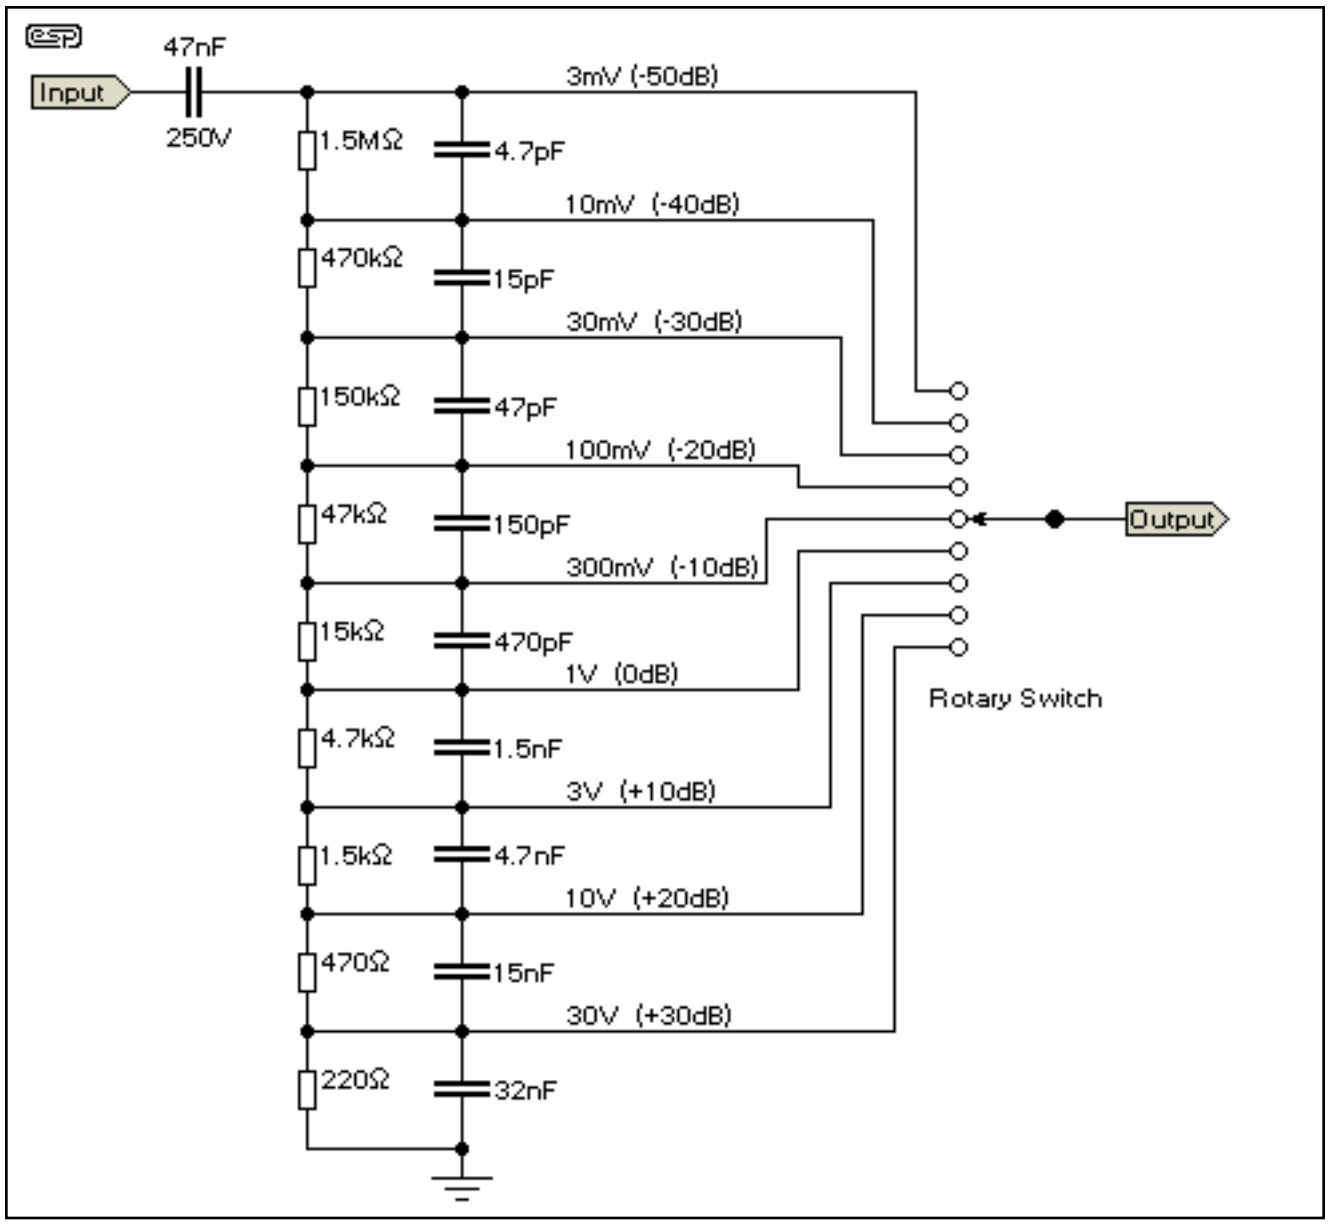

Figure 1 - High Impedance Attenuator (> 2M Ohm)

Note that the 32nF capacitor really is 32nF, and will have to be built up from smaller caps or selected from a batch. The capacitor tolerance ideally should be the same as that for the resistors - 1% is suggested to get acceptable accuracy.

With the Lo-Z attenuator, performance can be expected to be quite linear up to at least 80kHz before stray capacitance starts to influence the measurement. Without the paralleled capacitive attenuator, the Hi-Z version will start to show incorrect readings above 10kHz, which is unacceptable. The stray capacitance comes from the switch

contacts and the proximity of the resistors to each other, and only a few pF will cause havoc at high frequencies.

To minimise capacitance, mount all resistors (and capacitors) directly off the rotary switch, and keep them as separated from each other and the remainder of the circuitry as possible. Do not be tempted to try to make the arrangement nice and neat (with all the components nicely aligned with each other), for this will increase the capacitance of the circuit and ruin the high frequency performance. All component leads must be as short as possible.

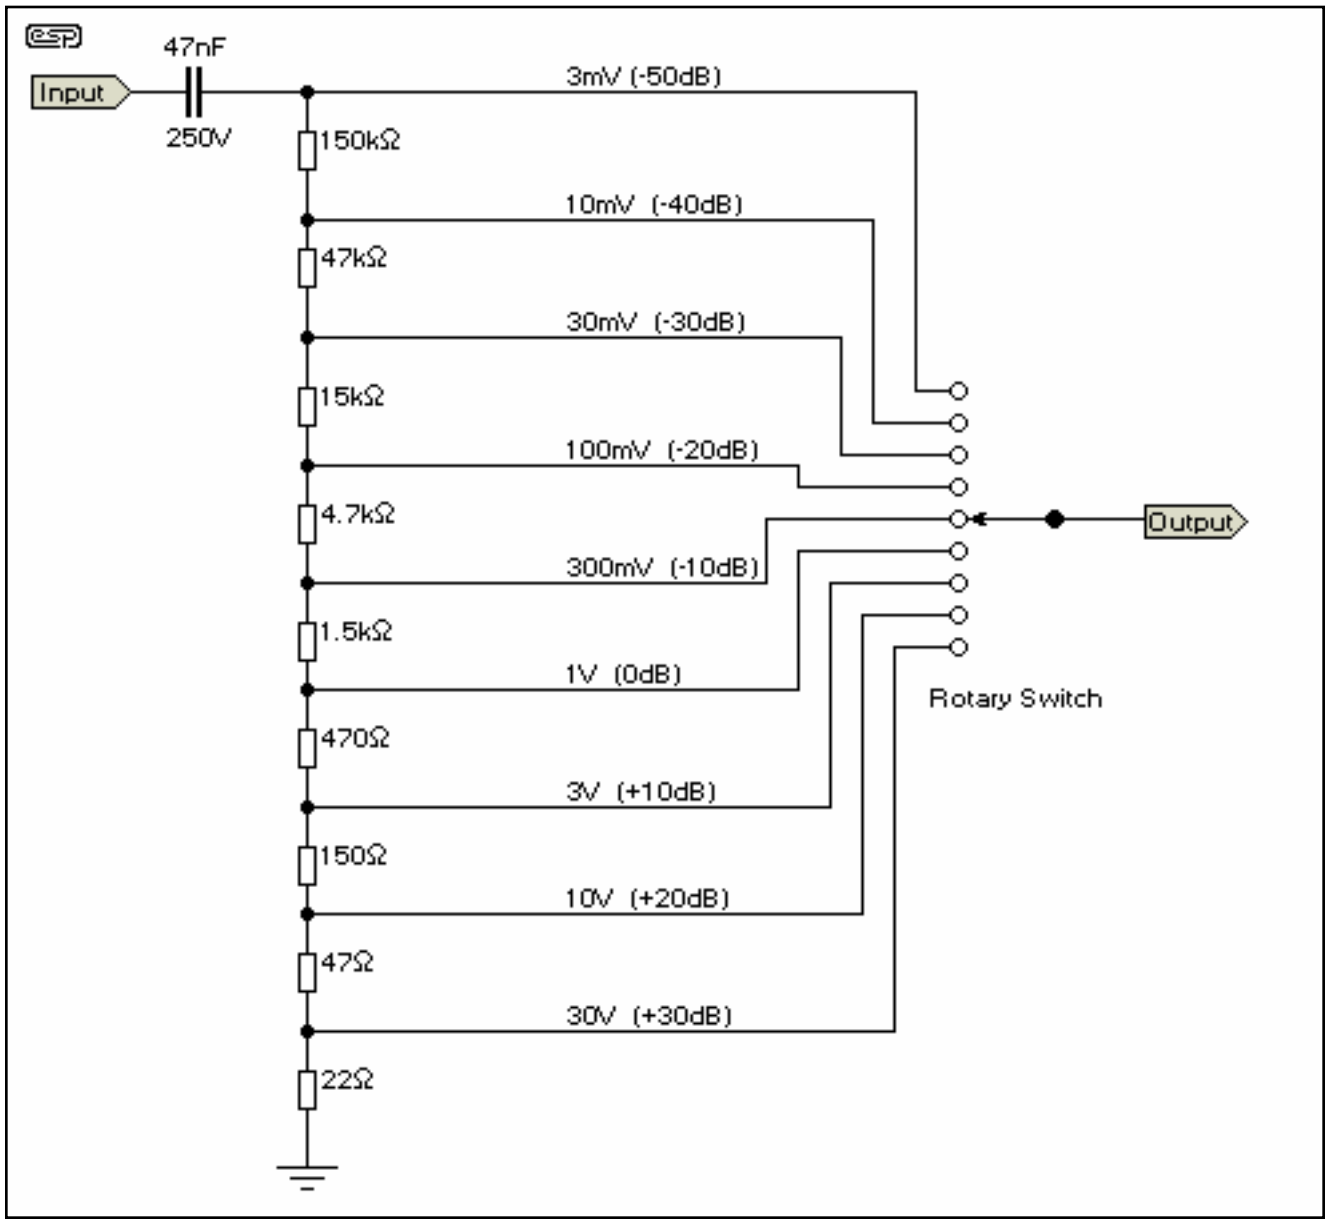

Figure 2 - Low Impedance Attenuator (> 200k Ohm)

The low-Z version is less susceptible to stray capacitance, but even at 150k (the highest value resistor in the circuit), only a few pF is needed to start to have an adverse influence at 100kHz or so. Again, do not strive for neatness, as this will only degrade

performance.

As can be seen, both attenuators have the same ranges - from 3mV to 30V in 10dB steps. Because 10dB is a ratio of 3.16, the scale must be calibrated with two voltage scales, 0-1 and 0-3. If you are very fortunate, it may be possible to find a meter with these ranges already (I have used about 3 of them in various projects), but they are now rather scarce. We can blame digital technology for this, but some analogue multimeters might have the scales you need - such a meter will not be cheap, however.

Amplifier

The amplifier(s) used in such a project are critical - we need wide bandwidth and low noise, coupled with low current drain, since we want to be able to run the meter on a 9V battery. The meter amplifier also requires high input impedance - especially for the high impedance attenuator version.

Consequently, a discrete opamp is the device of choice, since it can be built to satisfy all the desirable features we need. The input sensitivity of the meter amp is 3mV for full scale deflection on the meter, so it requires a fair bit of gain. In the final circuit, a JFET is used to provide the necessary high impedance input, and has the added benefit of supplying extra gain - this helps to reduce the demands on the opamp, since a typical 2N5459 JFET in the circuit shown (Figure 4) provides a gain of about 15, raising the input voltage to the opamp circuit to about 45mV for 3mV input.

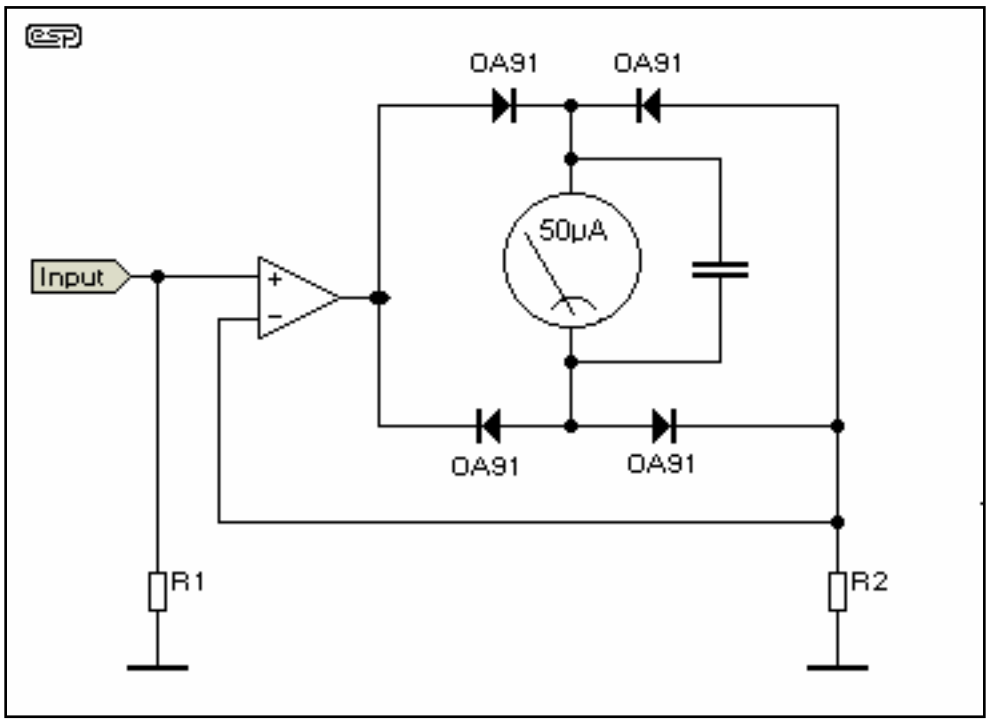

Figure 3 - Basic Meter Amplifier Scheme

Another requirement is simplicity and good linearity. The basic meter amplifier shown in Figure 3 satisfies all our requirements, but as you can see uses germanium diodes. Although these are harder to get and more expensive than silicon (and have higher leakage current), they also have very wide bandwidth and significantly less voltage drop than silicon, which reduces the requirement of the opamp to have an infinite slew rate.

This basic design has been around for many years, and is still one of the easiest to make, having the minimum of parts. The voltage across R2 must be the same as the input voltage (basic law of opamps) for the amp to be stable, so all losses in the meter and diodes are 'restored' by the opamp. The capacitor will need to be selected for the meter movement you use, since different meters have different damping. Initially this can be left out, but if excessive meter swings cause problems (or oscillation at low frequencies), then the capacitor will be needed. A value of 10uF is always a good starting point.

The input sensitivity is simply set by changing the value of R2 (In Figure 3), with lower values providing higher sensitivity and vice versa. Typically, R2 will be a multi-turn trimpot to allow for calibration.

Complete Meter Amplifier

The entire circuit can be built easily on a piece of perforated board (Veroboard or similar is good for this type of circuit), and a printed circuit board is quite unnecessary. Lay the physical circuit out following the schematic layout as closely as possible. This nearly always works well with discrete circuits, and makes it easy to follow 10 years later when you need to fix it. (I have had mine for nearly 20 years, and have not had to fix it yet.)

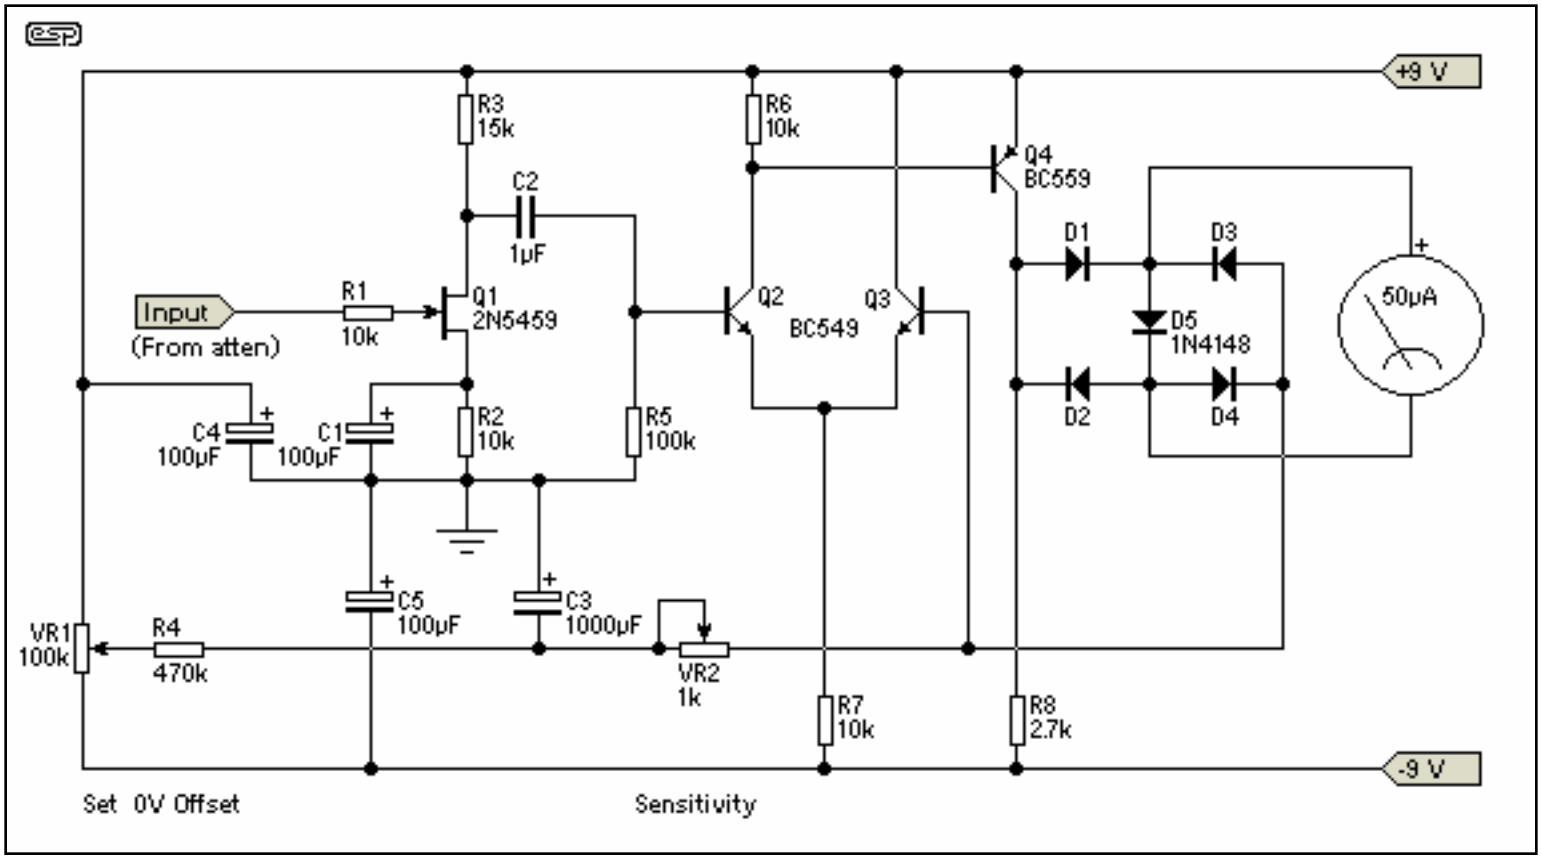

Figure 4 - The Complete Meter Amplifier

Figure 4 shows the complete meter amplifier, and uses a 2N5459 J-FET for the input. This provides a very high input impedance as well as some useful gain (about 15), allowing the entire unit to use a single discrete opamp - a discrete design is used to obtain optimum performance (frequency response) not readily obtainable with standard opamps for this application. The distortion characteristics are relatively unimportant, but the requirement for wide bandwidth and high gain over the entire frequency range excludes most conventional opamps. Use OA91 or similar germanium diodes for D1-D4 for best results. D5 *must* be silicon.

Note that the FET has no gate resistor, but relies on the voltage divider (attenuator) for its earth reference. This is not generally considered good practice, but will cause only minor 'flicks' of the needle when changing ranges. Also be aware that there is minimal input protection, so if you have the meter set to the 3mV range and connect it to the speaker output of an amplifier, you will probably cause damage. A resistor (10k) in series with the gate is be used, but will not offer full protection. A resistor which would offer full protection at any voltage will also cause problems at high frequencies because of its high value. Likewise, the capacitance of protection diodes will also adversely affect the high frequency performance (which is why there aren't any).

The discrete opamp is only a simple design, but manages a frequency response to well

over 100kHz (-1dB) with the 50uA meter load, and will operate satisfactorily with battery voltages down to 8V (the lower limit for a 9V battery before its internal impedance rises significantly). 100uF capacitors are used to ensure that the battery supply is bypassed, to help counteract the impedance rise as the battery ages.

I used BC549 (NPN) and BC559 (PNP) transistors, but any high gain, reasonably wide bandwidth, low current device will (should) work fine. As always, all resistors should be metal film, and the two pots should be multi-turn to allow accurate setting.

For those who find the 2N5459 JFET difficult to obtain, you can use a BF244, which a reader tells me works very well. During assembly, it is extremely important to keep stray capacitance to the minimum. The amplifier has very high gain and wide bandwidth, and oscillation will (not might) occur if you are not careful. In particular, keep the leads of C2 short, and make certain that the output (meter) leads are kept well separated from inputs and the attenuator.

If you use Veroboard, make sure that the track strips are cut at each end, so that they cannot act as antennas at high frequencies - this will cause oscillation or poor high frequency response, and neither will add to the instrument's usefulness.

Test and Calibration

The initial test involves connecting the meter amp to the attenuator, and applying power. All wiring must be carefully checked before you do this - the 9V batteries can supply enough current to damage the transistors, but batteries are more expensive than the transistors, and a wiring mistake may place a heavy discharge on the batteries rendering them dead before their time. Normally, batteries should last for quite a while, since the current drain is only about 4.5mA.

The meter is provided with protection by D5, a 1N914 (or 1N4148) which will conduct if too much voltage (or current) is applied - the meter will be hard against the stops though, and may still be damaged if the condition is allowed to persist. When power is applied, the meter should flick to full scale, then quickly settle back to near 0 volts. If it remains at full scale, you have made a mistake, so remove power immediately and locate (and fix) the error.

Calibration involves first setting the Set 0V Offset pot to its midway position, then carefully adjusting until the meter reading is as close as possible to the zero voltage mark. Any remaining offset must be removed using the meter's mechanical zero

adjustment - this is a little crude, but there is not much choice with this type of circuit. You will find that the meter reading will drop to some minimum value then start to climb again - this is because of the full-wave rectifier in the meter and feedback circuit.

Next, an accurate voltage at somewhere between 100 to 2,000 Hz is used to calibrate the meter. Select a suitable range on the attenuator, then adjust the Sensitivity control until the meter shows a reading that is identical to the applied voltage. Where possible, this should be done with the millivoltmeter at full scale on the 1V range. Remember that the scales are different for 1V and 3V ranges. The sensitivity pot will have more than enough range to allow the unit to be calibrated, provided no wiring mistakes have been made.

If by some chance your version decides it wants to oscillate at a MHz or three, you will need to add a small capacitance between collector and base of Q4 - I would not expect that more than 10pF should be needed, and even this will reduce the high frequency response slightly. Mine has a -1dB upper frequency limit of about 250kHz, a frequency which is more than adequate for audio use (by nearly an order of magnitude), but this is without a frequency limiting (miller or dominant pole) capacitor.

Meter Movement

It is important to obtain the best meter movement you can find, or the unit will be hard to read and possibly inaccurate. You will need to make a new scale for the meter, showing the two ranges and a dB scale. One possible reproduction is shown below, and there are links to a couple of others, one of which should suit whatever passes for a fairly standard 50uA movement - these should be available wherever you are, but you might need to look around a bit.

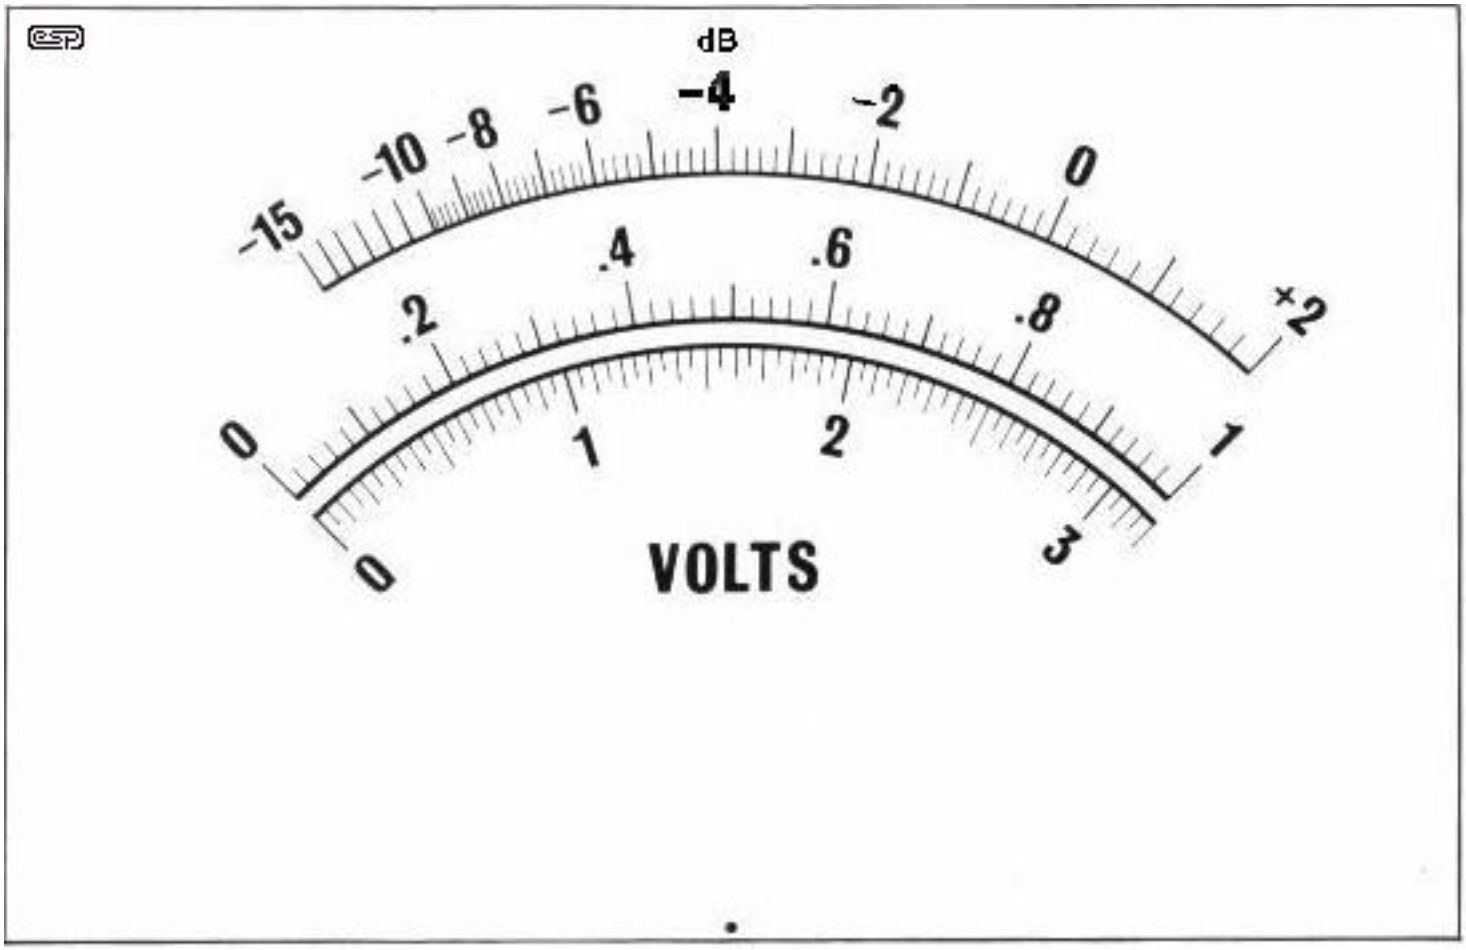

Figure 5 - Meter Face

The alternate meter faces are Meter Face 1 and Meter Face 3 - One of these should be able to be resized to suit the movement you use, but some experimentation is needed. You will notice that #3 appears to be hand-drawn in some areas - that's because it was. This is a scan from my own millivoltmeter, and when it was built, all these new-fangled scanners and computer thingies were a bit less common than today (you can gather from this that I have had the meter for a while).

To see what you are trying to find, check out this link to an Australian company called Jaycar Electronics. This is a link to the company website, and you will have to search for the movement (I used to have a link to the picture of the meter itself, but Jaycar has changed their website and the link will not work). Those available are not great meter movements, but are similar to the one I am using, and work quite well.

A typical 50uA movement will have a resistance of around 2k to 3k Ohms, and on average, expect to pay about AU$20 (or about US$15 or so) for a passably good movement.

When completed, the meter can be calibrated against a known accurate digital

multimeter, using a frequency of about 100Hz (most digitals will give an accurate reading at this frequency).

Optional Battery Check

If you would like to be able to measure the battery voltage without dismantling the instrument (I feel that this is a worthwhile addition), the switching shown in Figure 6 can be added. Note that both terminals of the meter must be switched, and the average of the two 9V batteries can be read on the 1V scale (so 0.9V would indicate 9V for each battery.

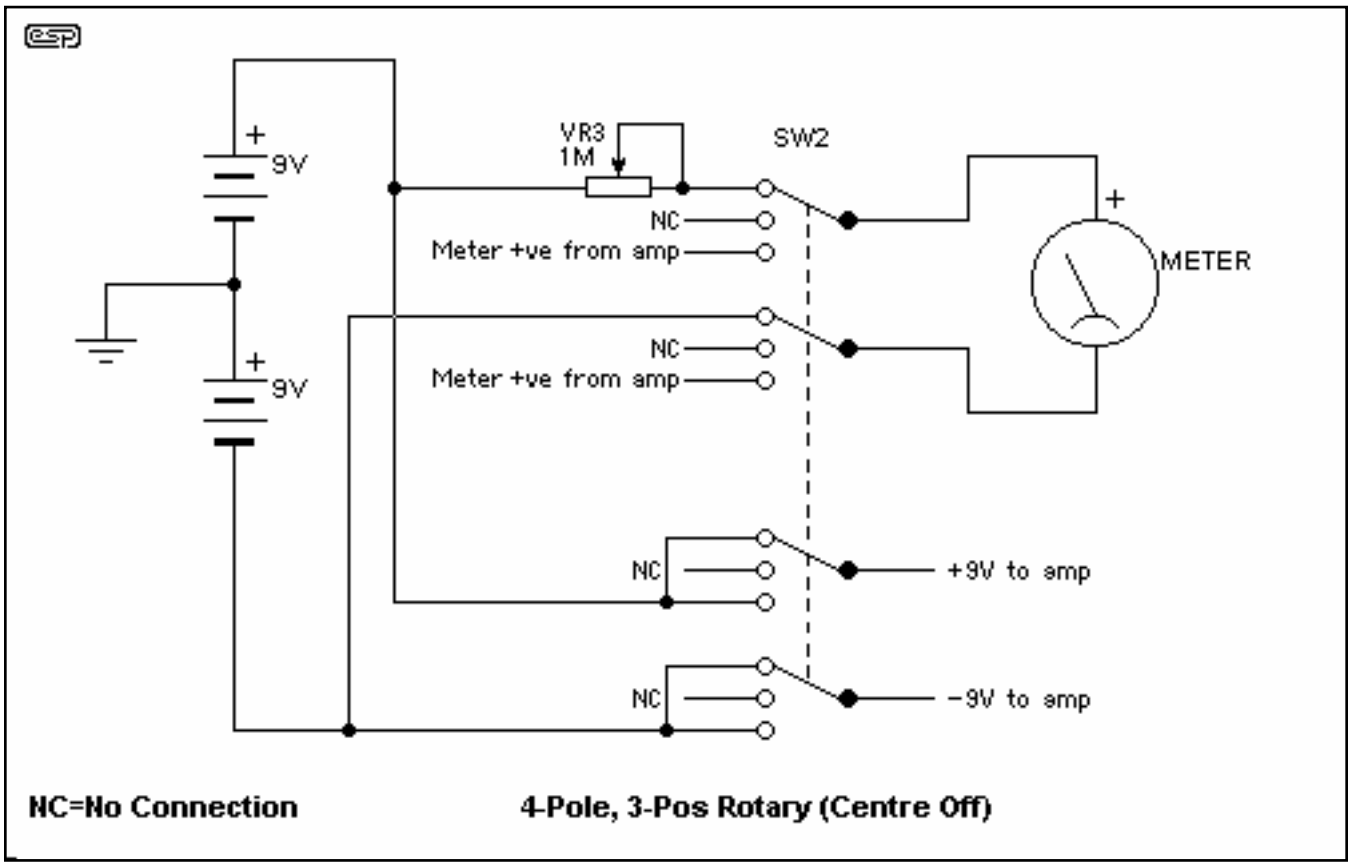

Figure 6 - Optional Battery Check Circuit

Use of a trimpot - preferably multi-turn - allows the voltmeter to be calibrated against an accurate multimeter, and the voltage shown is with the meter electronics switched on, so it will read the real loaded voltage. Both batteries are measured in series, so the nominal voltage read by the meter is 18V (R=18/50uA=360k, so a 1M trimpot should be near the middle of its travel). This option requires that the power switch be a 3-position 4-pole rotary, so it will cost a little more than a simple DPST mini-toggle.

WARNING: Make sure that the trimpot is set to approximately 1/2 way before attempting

calibration of the voltmeter. 2 x 9V batteries will destroy the coil of the meter *instantly* if the pot is set at minimum!

Enclosure

The case used must be all metal, since the attenuator and meter amplifier needs good shielding against noise pickup. This can be made from sheet aluminium or other metal (steel, brass, etc) if you have the tools to work with it, otherwise a suitable case may be obtainable from your normal parts supplier.

Another alternative is to use un-etched copper clad printed circuit board. Cut the panels to size, and solder together from the inside, filing off the outsides so the panels are all flush, and finally finishing the unit with a suitable coat or two of paint. There are many different finishes available in spray cans, so take your pick.

Cases built in this way can look surprisingly good if you take the time to finish them off well.

Construction

Make sure that the 0V line (the junction of the batteries, bottom of the attenuator string and earth input terminal are all tied to a common point on the front panel, and that the remainder of the case is in good electrical contact. If the case is not earthed properly, this is worse than using a non-shielded case!

It may also be necessary to add shielding between the FET stage and the main meter, and a small cap (10nF should be connected across the meter output, as close as possible to the diodes. Keep all leads short, and ensure that the output leads are kept well away from the input.

The meter amp is wide band, and has a full scale sensitivity of 3mV. It *will* oscillate if there is *any* feedback from O/P to I/P or between stages.

Front Panel

Drill all holes first for the two rotary switches, the meter and its mounting bolts and the input connectors. I always use a BNC connector, but for audio an RCA connector might

be better. One can also use "banana" sockets, so you can use ordinary multimeter leads, but being unshielded they will pick up noise - especially on the lower voltage ranges.

Make sure that all panel components fit properly, and de-burr the panel on both sides.

Mark the switch positions for each setting very carefully, since markings that do not line up with the pointer on the switch knobs look tacky, and can be confusing when you use the instrument.

Once you have the exact switch positions marked out, the front panel can be labelled any way you see fit. One method that works well is to use a graphics drawing package to create the label, and print it out onto ordinary paper. Carefully stick clear 'contact' film (as used for covering school books, etc) on both sides, ensuring that there are no air bubbles trapped under the film. Trim to the exact size of the front panel.

Use spray adhesive on both the panel and the label, leave for a few minutes then very carefully apply the label. You have to get this right first time - once stuck you will damage the label trying to move it ! The hole cutouts should then be very carefully removed using a hobby knife, scalpel or other suitable (sharp) instrument.

That's it - you are now the proud owner of a very useful piece of test equipment.

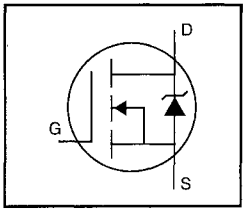
- Isolated Central Mounting Hole
- Fast Switching
- Ease of Paralleling
- Simple Drive Requirements



V_{DSS} = 200V

$R_{DS(on)}$ = 0.18Ω

I_D = 20A

Description

Third Generation HEXFETs from International Rectifier provide the designer with the best combination of fast switching, ruggedized device design, low on-resistance and cost-effectiveness.

The TO-247 package is preferred for commercial–industrial applications where higher power levels preclude the use of TO-220 devices. The TO-247 is similar but superior to the earlier TO-218 package because of its isolated mounting hole. It also provides greater creepage distance between pins to meet the requirements of most safety specifications.

Description

Third Generation HEXFETs from International Rectifier provide the designer with the best combination of fast switching, ruggedized device design, low on-resistance and cost-effectiveness.

The TO-247 package is preferred for commercial–industrial applications where higher power levels preclude the use of TO-220 devices. The TO-247 is similar but superior to the earlier TO-218 package because of its isolated mounting hole. It also provides greater creepage distance between pins to meet the requirements of most safety specifications.

APPLICATION NOTE AN-936

International Rectifier • 233 Kansas Street, El Segundo, CA 90245 USA

The Do's and Don'ts of Using MOS-Gated Transistors

In this application note, some of the most common do's and don'ts of using HEXFET® power MOSFETs are described. The objective is to help the user get the most out of these remarkable devices, while reducing "on the job" learning time to a minimum.

1. Be Mindful of The Reverse Blocking Characteristics of The Device

IGBTs have a limited reverse blocking capability of approximately 20-30 V, with high leakage. This is characterized in IR's data sheets with a Reverse Avalanche Energy (EARV). This rating is useful to absorb energy spikes due to the stray inductance in series with the anti-parallel diode. This is a significant advantage over bipolar transistors and power darlingtons. A feature of power MOSFETs is that they inherently have built into them an integral reverse body-drain diode. The existence of this diode is explained by reference to Figure 1. When the source terminal is made positive with respect to the drain, current can flow through the middle of the source cell, across a forward biased P-N junction. In the "reverse" direction, the HEXFET® power MOSFET thus behaves like a P-N junction rectifier. The integral body-drain diode is a real circuit element, and its current handling capability is typically as high as that of the transistor itself. Some circuits require an "inverse" rectifier to be connected across the switching device, and in these circuits it will often be possible to utilize the body-drain diode of the HEXFET power MOSFET provided the proper precautions are taken.

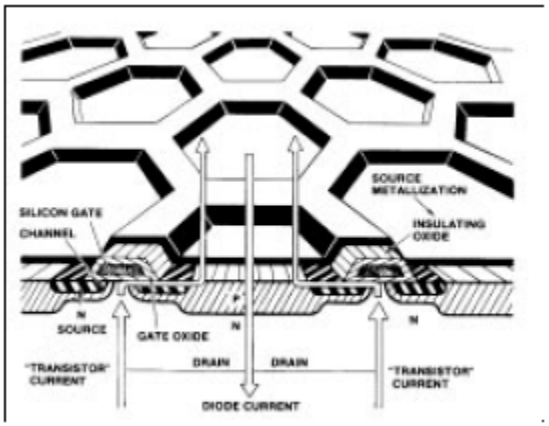

Figure 1. Basic HEXFET MOSFET Structure

2. Be Careful When Handling & Testing HEXFET® Power MOSFETs

The user's first "contact" with a MOS-gated transistor could be a package of parts arriving on his desk. Even at this stage, it behooves one to be knowledgeable about some elementary precautions. Being MOS devices, HEXFET power MOSFETs can be damaged by static charge when handling, testing or installing into a circuit. Power Devices have large input capacitance, and are able to absorb static charge without excessive buildup of voltage. In order to avoid possible problems, however, the following procedures should be followed as a matter of good practice, wherever possible:

- MOS-gated transistors should be left in their anti-static shipping bags, or conductive foam, or they should be placed in metal containers or conductive tote bins, until required for testing or connection into a circuit. The person handling the device should ideally be grounded through a suitable wrist strap, though in reality this added precaution is seldom essential.
- Devices should be handled by the package, not by the leads. When checking the electrical characteristics of the MOS-gated transistors on a curve tracer, or in a test circuit, the following precautions should be observed:
- Test stations should use electrically conductive floor and table mats that are grounded. Suitable mats are available commercially.

HEXFET® is the registered trademark for International Rectifier Power MOSFETs

- When inserting the device in a curve tracer or a test circuit, voltage should not be applied until all terminals are solidly connected into the circuit.
- When using a curve tracer, a resistor should be connected in series with the gate to damp spurious oscillations that can otherwise occur on the trace. A suitable value of resistance is 100 ohms.
- For repeated testing, it is convenient to build this resistor into the test fixture.
- When switching from one test range to another, voltage and current settings should be reduced to zero, to avoid the generation of potentially destructive voltage surges during switching.

The next step is to connect the device into an actual circuit. The following simple precautions should be observed:

- Work stations should use electrically grounded table and floor mats.
- Soldering irons *should be grounded.*

Now that the device has been connected into its circuit, it is ready for the power to be applied. From here on, success in applying the device becomes a matter of the integrity of the circuit design, and of what circuit precautions have been taken to guard against unintentional abuse of its ratings.

The following are the interrelated device and circuit considerations that lead to reliable, trouble-free design.

3. BEWARE OF UNEXPECTED GATE-TO-SOURCE VOLTAGE SPIKES

Excessive voltage will punch through the gate-source oxide layer and result in permanent damage. This seems obvious enough, but it is not so obvious that transient gate-to-source overvoltages can be generated that are quite unrelated to, and well in excess of, the amplitude of the applied drive signal. The problem is illustrated by reference to Figure 2.
If we assume that the impedance, Z, of the drive source is high, then any positive-going change of voltage applied across the drain and source terminals (caused, for example, by the switching of another device in the circuit) will be reflected as a positive-going voltage transient across the source and the drain terminals, in the approximate ratio of:

$$\frac{1}{1+\frac{C_{gs}}{C_{dg}}}$$

The above ratio is typically about 1 to 6. This means that a change of drain-to-source voltage of 300V, for example, could produce a voltage transient approaching 50V between the gate and source terminals. In practice this “aiming” voltage will not appear on the gate if the dv/dt is positive because the MOS-gated device goes in conduction at approximately Vgs = 4V, thereby clamping the dv/dt at the expense of a current transient and increased power dissipation. However, a negative-going dv/dt will not be clamped. This calculation is based upon the worst case assumption that the transient impedance of the drive circuit is high by comparison with the gate-to-source capacitance of the device. This situation can, in fact, be quite easily approximated if the gate drive circuit contains inductance—for example the leakage inductance of an isolating drive transformer. This inductance exhibits a high impedance for short transients, and effectively decouples the gate from its drive circuit for the duration of the transient.

The negative-going gate-to-source voltage transient produced under the above circumstances may exceed the gate voltage rating of the device, causing permanent damage. It is, of course, true that since the applied drain transient results in a voltage at the gate which tends to turn the device ON, the overall effect is to an extent self-limiting so far as the gate voltage transient is concerned. Whether this self-limiting action will prevent the voltage transient at the gate from exceeding the gate-source voltage rating of the device depends upon the impedance of the external circuit. Spurious turn-on is of itself undesirable, of course, though in practical terms one may grudgingly be able to accept this circuit operating imperfection, provided the safe operating area of the device is not violated.

Notice that a voltage clamp (a conventional zener diode is suitable for this purpose) to prevent the gate-source voltage rating from being exceeded will not prevent the dv/dt induced turn-on, as the gate will not reach the zener voltage. In many instances the zener is responsible for generating oscillations in the gate circuit, particularly when a significant amount of stray inductance is present. A more fundamental solution, of course, is to make the impedance of the gate circuit low enough that not only is the gate-source voltage rating not exceeded, but also the voltage transient at the gate is contained to a level at which spurious turn-on does not occur.

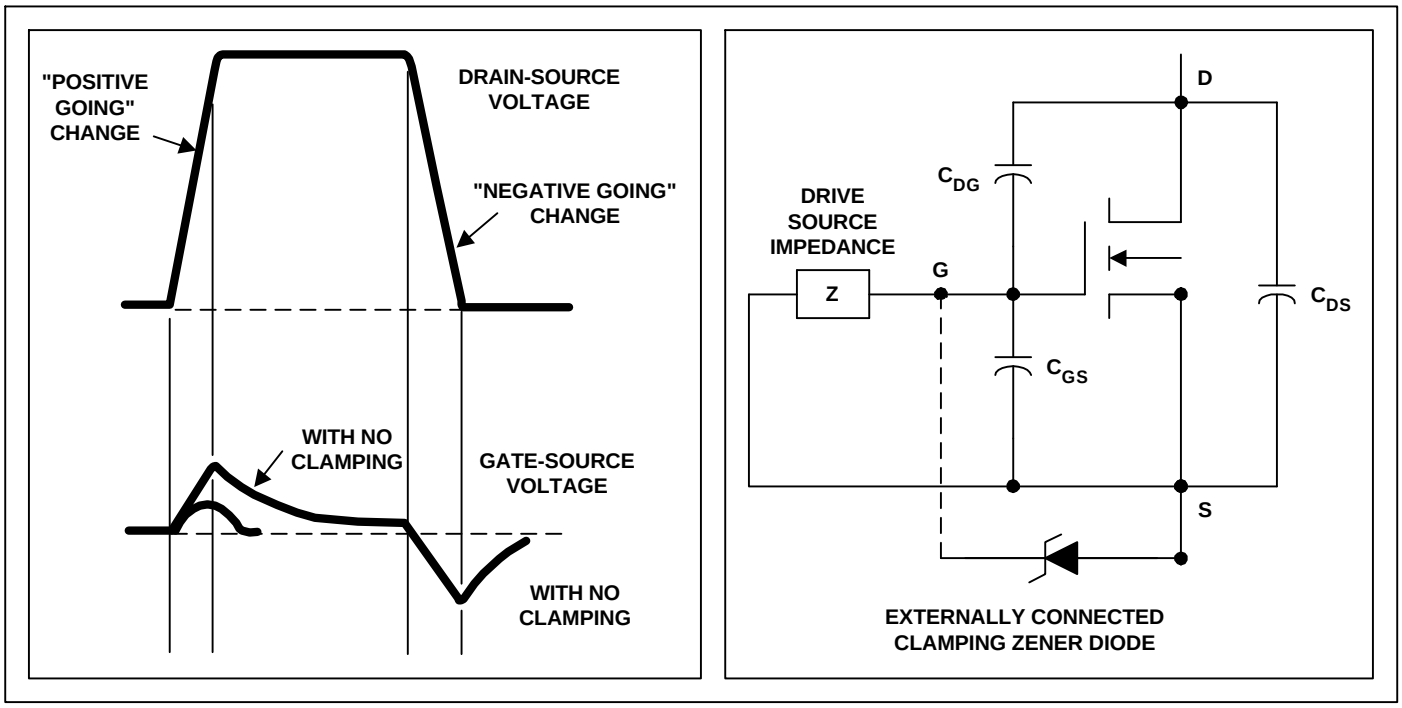

Figure 2. A Rapidly Changing Applied Drain-Source Voltage will Produce Gate-Source Transients

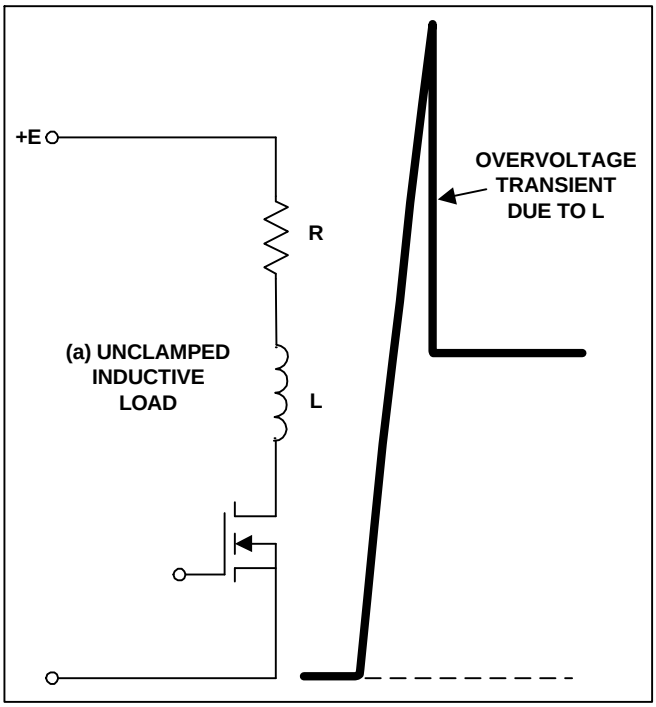

Figure 3. Drain-Source Overvoltage Transient when Switching Off with Unclamped Inductive Load

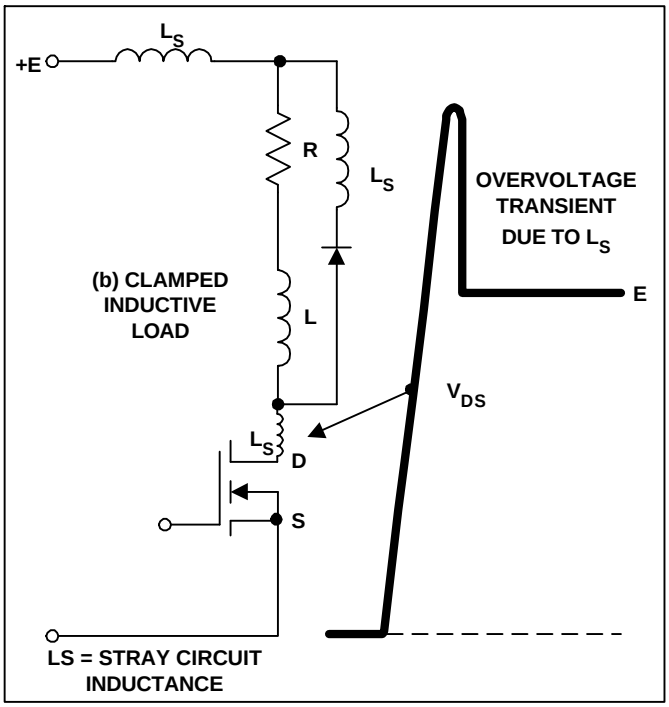

Figure 4. Drain-Source Overvoltage Transient Produced by Stray Circuit Inductance When Switching Off with Clamped, Inductive Load

It should be remembered that a collapse of voltage across the device (i.e., a negative-going dv/dt) will produce a transient negative voltage spike across the gate-source terminals. In this case, of course, there will be no tendency for the device to turn ON, and hence no tendency for the effect to be self-limiting. A zener diode connected to clamp positive transients will automatically clamp negative-going transients, limiting them to the forward conduction voltage drop of the zener.

4. BEWARE OF DRAIN OR COLLECTOR VOLTAGE SPIKES INDUCED BY SWITCHING

The uninitiated designer is often not aware that self-inflicted overvoltage transients can be produced when the device is switched OFF, even though the DC supply voltage for the drain circuit is well below the V_{DS} rating of the transistor.
Figure 3 shows how a voltage spike is produced when switching the device OFF, as a result of inductance in the circuit. The faster the device is switched, the higher the overvoltage will be.
Inductance is always present to some extent in a practical circuit, and therefore, there is always danger of inducing overvoltage transients when switching OFF. Usually, of course, the main inductive component of the load will be "clamped", as shown in Figure 4. Stray circuit inductance still exists, however, and overvoltage transients will still be produced as a result—to say nothing of the fact that the clamping diode may not provide an instantaneous clamping action, due to its "forward recovery" characteristic.

The first approach to this problem is to minimize stray circuit inductance, by means of careful attention to circuit layout, to the point that whatever residual inductance is left in the circuit can be tolerated. HEXFET®s have an inductive energy rating that makes capable of withstanding these inductive spikes, assuming that the data sheet limits for energy and temperature are not violated. IGBTs, however, do not have an avalanche rating, and a clamping device should be connected, physically as close as possible to the drain and source terminals, as shown in Figure 5. A conventional zener diode, or a "transorb" clamping device, are satisfactory for this purpose. An alternative clamping circuit is shown in Figure 6, depending on the voltage and current rating of the circuit.
The capacitor C is a reservoir capacitor and charges to a substantially constant voltage, while the resistor R is sized to dissipate the "clamping energy" while maintaining the desired voltage across the capacitor. The diode D must be chosen so that its forward recovery characteristic does not significantly spoil the transient clamping action of the circuit. A simple RC snubber can also be used, as shown in Figure 7. Note, however, that an RC snubber not only limits the peak voltage, it also slows down the effective switching speed. In so doing, it absorbs energy during the whole of the switching period, not just at the end of it, as does a voltage clamp. A snubber is therefore less efficient than a true voltage clamping device.

Note that the highest voltage transient occurs when switching the highest level of current. The waveform of the voltage across the device should be checked with a high-speed oscilloscope at the full load condition to ensure that switching voltage transients are within safe limits.

5. DO NOT EXCEED THE PEAK CURRENT RATING

All power transistors have a specified maximum peak current rating. This is conservatively set at a level that guarantees reliable operation and it should not be exceeded. It is often overlooked that, in a practical circuit, peak transient currents can be obtained that are well in excess of the expected normal operating current, unless proper precautions are taken. Heating, lighting and motor loads, for example, consume high in-rush currents if not properly controlled. A technique that ensures that the peak current does not exceed the capability of the device is to use a current sensing control that switches it OFF whenever the current instantaneously reaches a preset limit.

Unexpectedly high transient current can also be obtained as a result of rectifier reverse recovery, when a transistor is switched ON rapidly into a conducting rectifier. This is illustrated in Figure 8. The solution is to use a faster rectifier, or to slow down the switching of the transistor to limit the peak reverse recovery current of the rectifier.

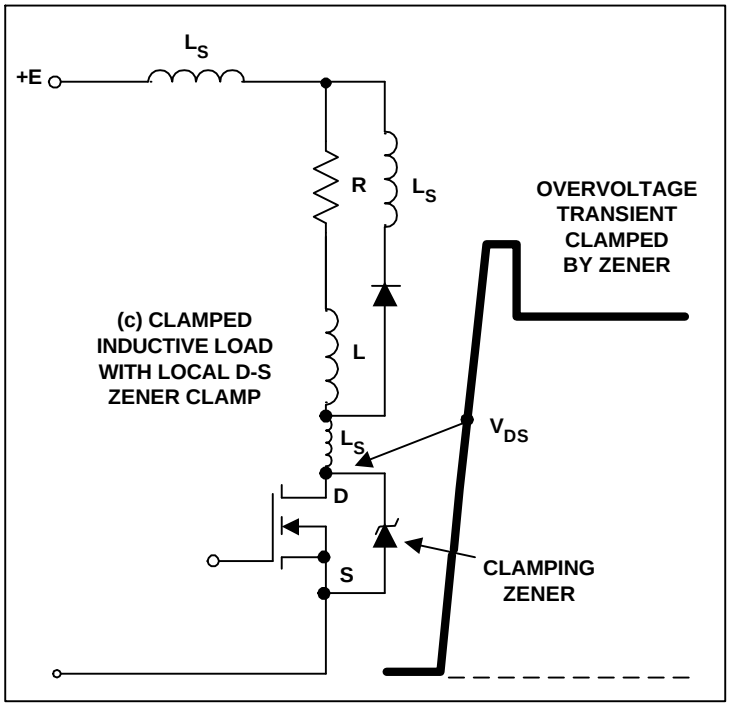

Figure 5. Overvoltage Transient at Switch-Off Clamped by Local Drain-Source Zener

6. STAY WITHIN THE THERMAL LIMITS

Power transistors are thermally limited. They must be mounted on a heatsink that is adequate to keep the junction temperature within the rated under the "worst case" condition of maximum power dissipation and maximum ambient temperature.

It must be remembered that in a switching application, the total power is due to the conduction losses and the switching loss. Switching time and switching losses of HEXFET®s are essentially independent of temperature, but the conduction losses increase with increasing temperature, because $R_{DS(on)}$ increases with temperature. IGBTs, on the contrary, have switching losses that highly dependent of temperature, while conduction losses are not. This must be taken into account when sizing the heatsink. The required thermal resistance of the heatsink can be calculated as follows:

The transistor conduction power, P_T, is given approximately by *P_T = On-state Voltage x Drain or Collector current*

The switching energy depends upon the voltage and current being switched and the type of load. The total switching loss, P_S, is the total switching energy, ε_T, multiplied by the operating frequency, f. e_T is the sum of the energies due to the individual switchings that take place in each fundamental operating cycle:

$$P_S = \varepsilon_T f$$

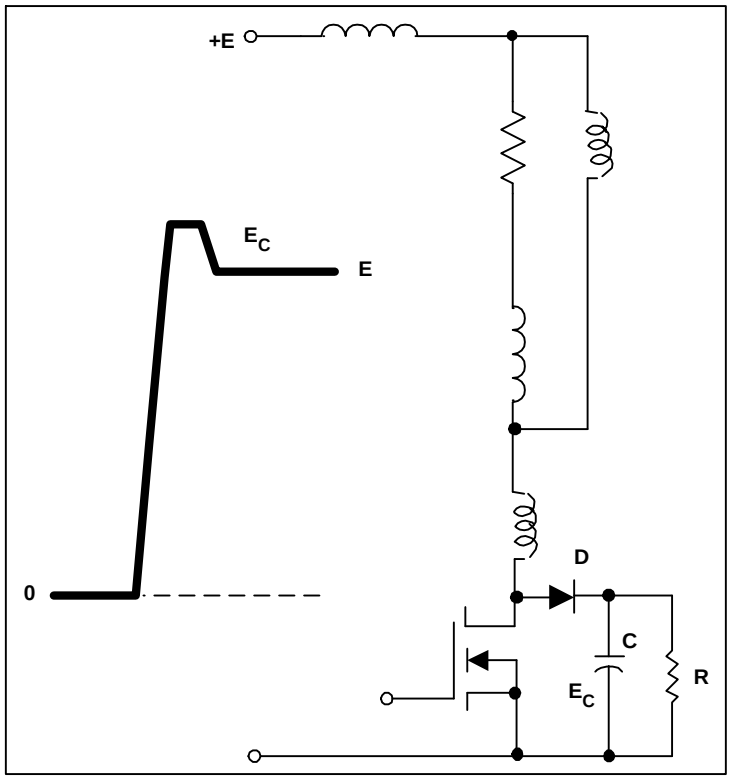

Figure 6. Overvoltage Transient at Switch-Off Limited by Local Clamp

The total power dissipation is the sum of the conduction power, P_T, and the switching power, P_S.

$$P = P_T + P_S$$

Since:

$$\Delta T_{JA} = PR_{th}$$

where:

R_{th} = junction-to-ambient thermal resistance

The junction-to-ambient thermal resistance, R_{JA}, is made up of the internal junction-to-case thermal resistance, R_{JC}, plus the case-to-heatsink thermal resistance, R_{CS}, plus the sink-to-ambient thermal resistance, R_{SA}. The first two terms are fixed for the device, and the required thermal resistance of the heatsink, R_{S-A}, for a given junction temperature rise DT_{J-A}, can be calculated from:

$$R_{S-A} = R_{J-A} - (R_{JC} + R_{C-S})$$

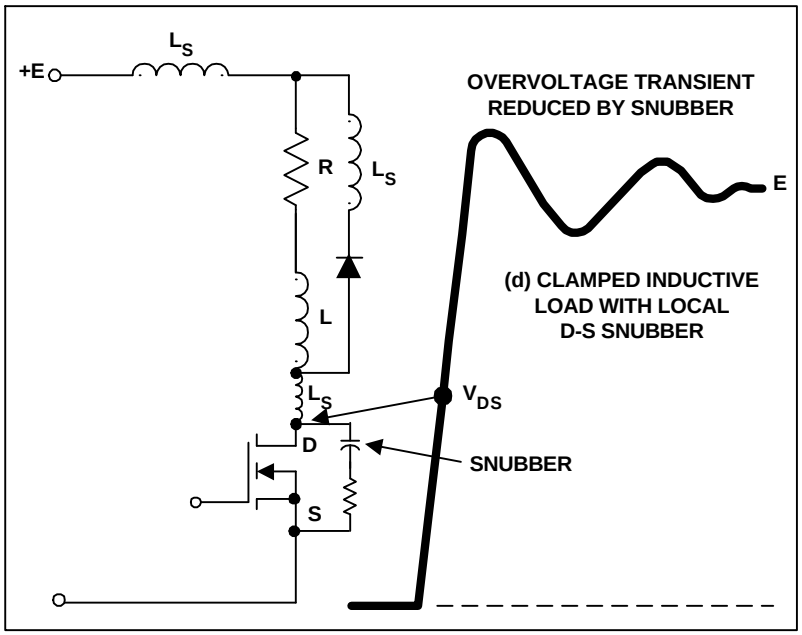

Figure 7. Overvoltage Transient at Switch-Off Limited by Local Capacitor-Resistor Snubber

7. PAY ATTENTION TO CIRCUIT LAYOUT

Stray inductance in the circuit can cause overvoltage transients, slowing down of the switching speed, unexpected unbalance of current between parallel connected devices, and unwanted oscillations.

In order to minimize these effects, stray circuit inductance must be minimized. This is done by keeping conduction paths as short as possible, by minimizing the area of current loops, by using twisted pairs of leads, and by using ground plane construction. Local decoupling capacitors alleviate the affects of any residual circuit inductance, once these measures have been taken. Circuit layout should be kept as symmetrical as possible in order to maintain balanced currents in parallel connected HEXFET®s or IGBTs. The gates of parallel connected devices should be decoupled by small ferrite beads placed over the gate connections, or by individual resistors in series with each gate. These measures prevent parasitic oscillations.

8. BE CAREFUL WHEN USING THE INTEGRAL BODY-DRAIN DIODE

The HEXFET®'s integral body-drain diode exhibits minority carrier reverse recovery. Reverse recovery presents a potential problem when switching any rectifier off; the slower the rectifier, the greater the problem. By comparison with the HEXFET® itself, the switching speed of the integral reverse rectifier is quite slow. The switching speed of a circuit which utilizes the body-drain diode of the HEXFET® may therefore be limited by the rectifier. Whether this will be so depends upon the circuit and the operating conditions.

Regardless of the overall circuit configuration, or the particular application, the "local" circuit operating situation that is troublesome occurs when the freewheeling current from an inductive load is commutated from the integral rectifier of one HEXFET® to the transistor of an "opposite" HEXFET®, the two devices forming a tandem series connected pair across a low impedance voltage source, as shown in Figure 8. This “local” circuit configuration occurs in most chopper and inverter schemes.

If the incoming HEXFET® switches ON too rapidly, the peak reverse recovery current of the integral body-drain diode of the opposite HEXFET® will rise too rapidly, the peak reverse recovery current rating will be exceeded, and the device may possibly be destroyed.

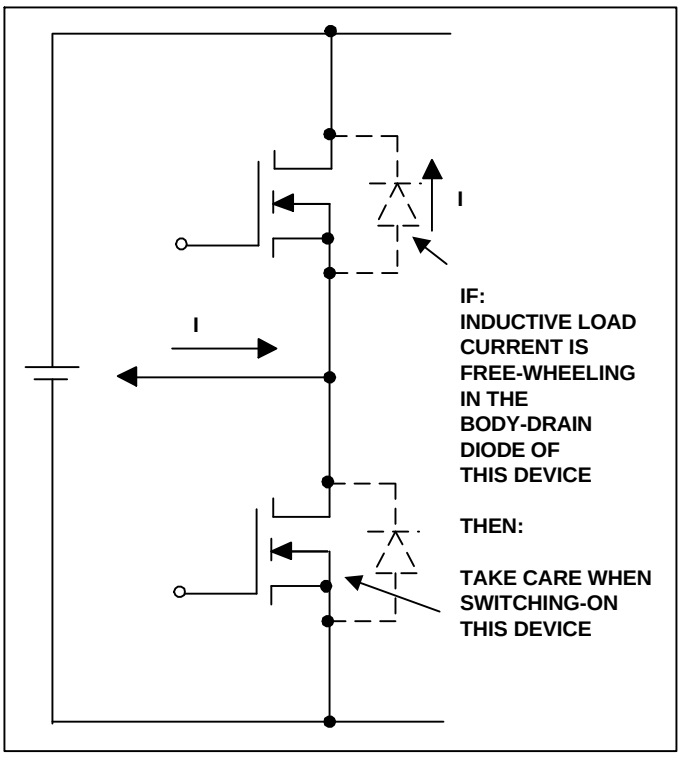

Figure 8. Local Circuit Configuration and Operating Condition Requiring Special Care When Using the HEXFET's Integral Body-Drain Diode.

The peak reverse recovery current of the rectifier can be reduced by slowing down the rate of change of current during the commutation process. The rate of change of current can be controlled by purposefully slowing down the rate of rise of the gate driving pulse. Using this technique, the peak current can be reduced to almost any desired extent, at the expense of prolonging the high dissipation switching period.

The oscillograms in Figure 9 illustrate the effect. By slowing the total switch-ON time from 300ns to 1.8ms, the peak current of the IRF330 has been decreased from 20A to 10A. The energy dissipation associated with the “unrestrained” switch-ON in Figure 9(a) is 0.9mJ, whereas it is 2.7mJ for the controlled switch-ON of Figure 9(b).

Note also that it is not necessary to slow the switching-OFF of the HEXFET®, hence the energy dissipation at switch-OFF will be relatively small by comparison with that at switch-ON. For operation at frequencies up to a few kHz, where ultra-fast switching is not mandatory, slowing the applied gate drive signal to reduce the peak reverse recovery current of the "opposite" rectifier offers a good practical solution.

9. BE ON YOUR GUARD WHEN COMPARING CURRENT RATINGS

The user can be forgiven if he assumes that the continuous drain current rating, that appears on the data sheet represents the current at which the device can actually be operated continuously in a practical system. To be sure, that's what it should represent; unfortunately it often does not.

Frequently a "continuous" current rating is assigned to the device which in practical terms cannot be used, because the resulting conduction power dissipation would be so large as to require a heatsink with an impractically low thermal resistance, and/or an impractically low ambient operating temperature. The best advice to the user is to compare different types *on the basis of high temperature conduction and switching losses*, and not of current rating. For MOSFETS, it is sufficient to compare $R_{DS(on)}$ at 25° C, and this provides a common basis for comparison. This parameter, taken in conjunction with the junction-case thermal resistance, is a much better indication of the power MOSFET true current handling capability.

(Note: Most of the gate drive considerations and circuits are equally applicable to IGBTs. Only MOSFETs are mentioned for the sake of simplicity. Special considerations for IGBTs are contained in INT-990)

1. GATE DRIVE VS BASE DRIVE

The conventional bipolar transistor is a current-driven device. As illustrated in Figure 1(a). a current must be applied between the base and emitter terminals to produce a flow of current in the collector. The amount of a drive required to produce a given output depends upon the gain, but invariably a current must be made to flow into the base terminal to produce a flow of current in the collector.

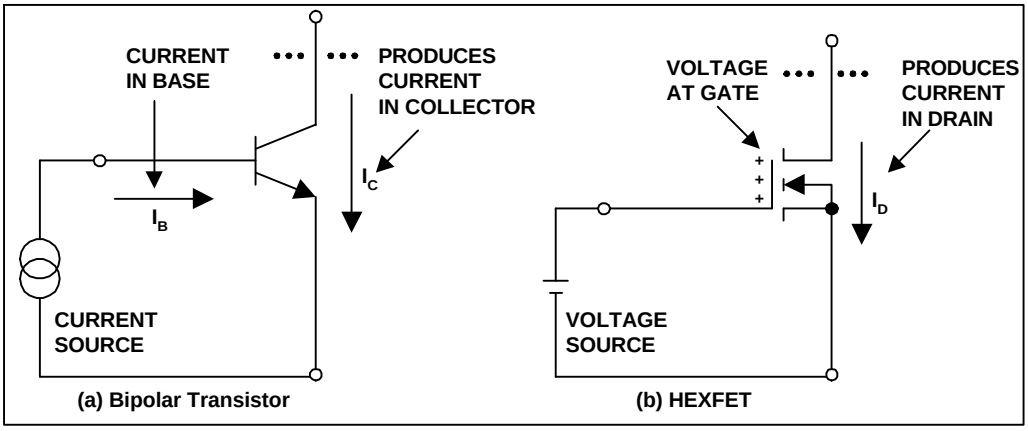

Figure 1. Bipolar Transistor is Current Driven, HEXFET is Voltage Driven

The HEXFET®is fundamentally different: it is a voltage-controlled power MOSFET device. A voltage must be applied between the gate and source terminals to produce a flow of current in the drain (see Figure 1b). The gate is isolated electrically from the source by a layer of silicon dioxide. Theoretically, therefore, no current flows into the gate when a DC voltage is applied to it - though in practice there will be an extremely small current, in the order of nanoamperes. With no voltage applied between the gate and source electrodes, the impedance between the drain and source terminals is very high, and only the leakage current flows in the drain.

When a voltage is applied between the gate and source terminals, an electric field is set up within the HEXFET®. This field "inverts" the channel (Figure 2) from P to N, so that a current can flow from drain to source in an uninterrupted sequence of N-type silicon (drain-channel-source). Field-effect transistors can be of two types: enhancement mode and depletion mode. Enhancement-mode devices need a gate voltage of the same sign as the drain voltage in order to pass current.

Depletion-mode devices are naturally on and are turned off by a gate voltage of the same polarity as the drain voltage. All HEXFET®s are enhancement-mode devices.

All MOSFET voltages are referenced to the source terminal. An N-Channel device, like an NPN transistor, has a drain voltage that is positive with respect to the source. Being enhancement-mode devices, they will be turned on by a positive voltage on the gate. The opposite is true for P-Channel devices, that are similar to PNP transistors.

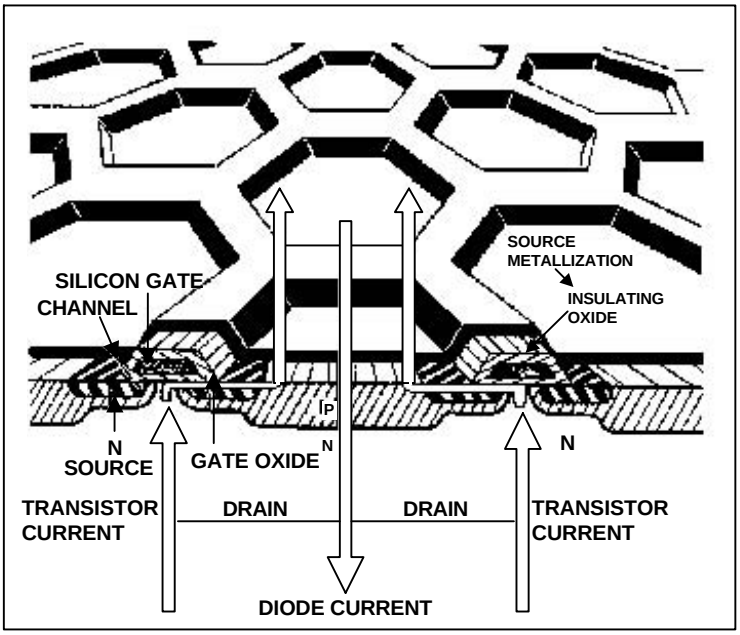

Figure 2. Basic HEXFET Structure

Although it is common knowledge that HEXFET®transistors are more easily driven than bipolars, a few basic considerations have to be kept in mind in order to avoid a loss in performance or outright device failure.

2. GATE VOLTAGE LIMITATIONS

Figure 2 shows the basic HEXFET®structure. The silicon oxide layer between the gate and the source regions can be punctured by exceeding its dielectric strength. The data sheet rating for the gate-to-source voltage is between 10 and 30 V for most HEXFET®s.

Care should be exercised not to exceed the gate-to-source maximum voltage rating. Even if the applied gate voltage is kept below the maximum rated gate voltage, the stray inductance of the gate connection, coupled with the gate capacitance, may generate ringing voltages that could lead to the destruction of the oxide layer. Overvoltages can also be coupled through the drain-gate self-capacitance due to transients in the drain circuit. A gate drive circuit with very low impedance insures that the gate voltage is not exceeded in normal operation. This is explained in more detail in the next section.

Zeners are frequently used "to protect the gate from transients". Unfortunately they also contribute to oscillations and have been known to cause device failures. A transient can get to the gate from the drive side or from the drain side. In either case, it would be an indication of a more fundamental problem: a high impedance drive circuit. A zener would compound this problem, rather than solving it. Sometimes a zener is added to reduce the ringing generated by the leakage of a gate drive transformer, in combination with the input capacitance of the MOSFET. If this is necessary, it is advisable to insert a small series resistor (5-10 Ohms) between the zener and the gate, to prevent oscillations.

3. THE IMPEDANCE OF THE GATE CIRCUIT

To turn on a power MOSFET a certain charge has to be supplied to the gate to raise it to the desired voltage, whether in the linear region, or in the "saturation" (fully enhanced) region. The best way to achieve this is by means of a voltage source, capable of supplying any amount of current in the shortest possible time. If the device is operated as a switch, a large transient current capability of the drive circuit reduces the time spent in the linear region, thereby reducing the switching losses.

On the other hand, if the device is operated in the linear mode, a large current from the gate drive circuit minimizes the relevance of the Miller effect, improving the bandwidth of the stage and reducing the harmonic distortion. This can be better understood by analyzing the basic switching waveforms at turn-on and turn-off for a clamped inductive load, as shown in Figures

3 and 5. Figure 3 shows the waveforms of the drain current, drain-to-source voltage and gate voltage during the turn-on interval. For the sake of simplicity, the equivalent impedance of the drive circuit has been assumed as purely resistive.

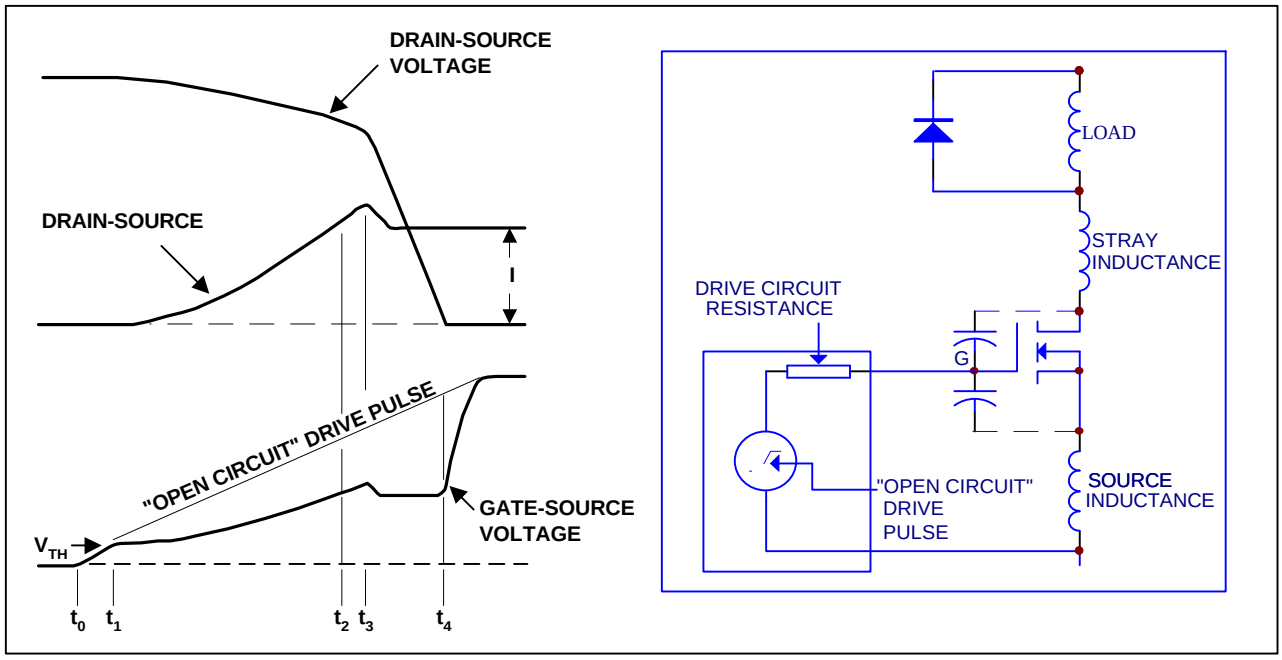

Figure 3. Waveforms at Turn-On

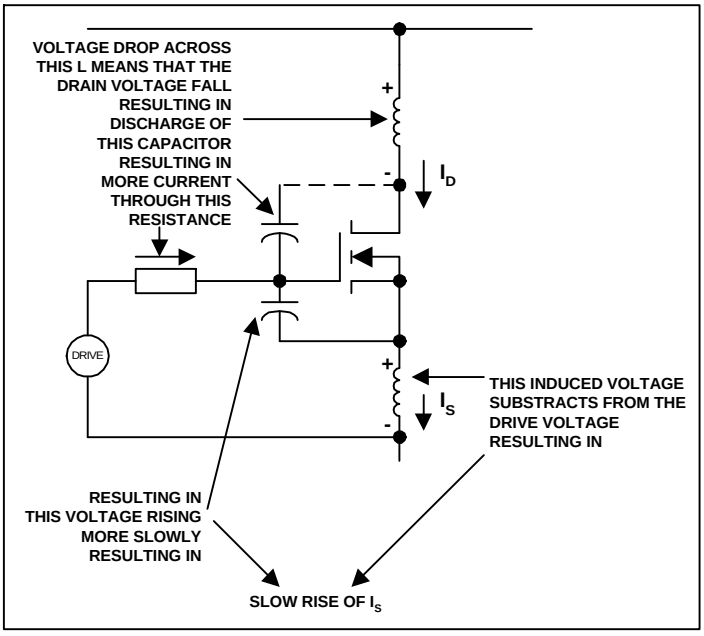

Figure 4. Diagrammatic Representation of Effects When Switching-ON

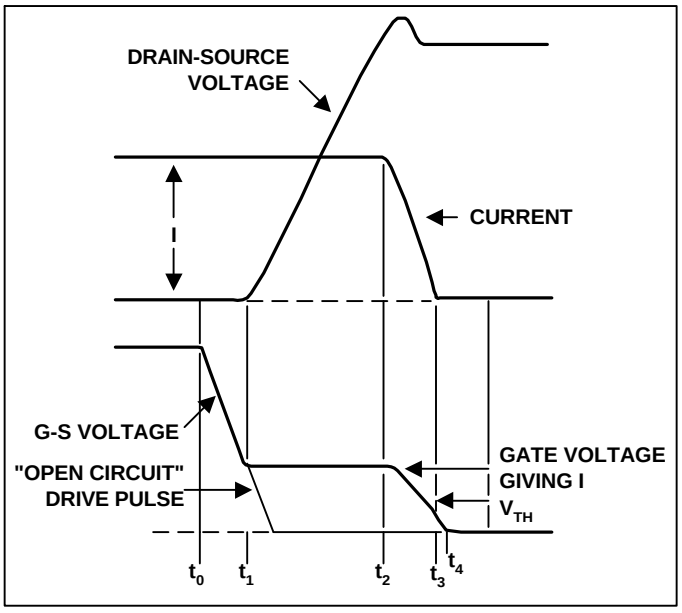

Figure 5. Waveforms at Turn-OFF

At time, t_0, the drive pulse starts to rise. At t_0 it reaches the threshold voltage of the HEXFET®s and the drain current starts to increase. At this point, two things happen which make the gate-source voltage waveform deviate from its original “path”. First, inductance in series with the source which is common to the gate circuit (“common source inductance”) develops an induced voltage as a result of the increasing source current. This voltage counteracts the applied gate drive voltage, and slows down the rate of rise of voltage appearing directly across the gate and source terminals; this in turn slows down the rate of rise of the source current. This is a negative feedback effect: increasing current in the source produces a counteractive voltage at the gate, which tends to resist the change of current.

The second factor that influences the gate-source voltage is the so called “Miller” effect. During the period t_1 to t_2 some voltage is dropped across “unclamped” stray circuit inductance in series with the drain, and the drain-source voltage starts to fall. The

decreasing drain-source voltage is reflected across the drain-gate capacitance, pulling a discharge current through it, and increasing the effective capacitive load on the drive circuit.
This in turn increases the voltage drop across the source impedance of the drive circuit, and decreases the rate of rise of voltage appearing between the gate and source terminals. Obviously, the lower the impedance of the gate drive circuit, the less this effect will be. This also is a negative feedback effect; increasing current in the drain results in a fall of drain-to-source voltage, which in turn slows down the rise of gate-source voltage, and tends to resist the increase of drain current. These effects are illustrated diagramatically in Figure 4. This state of affairs continues throughout the period t_1 to t_2, as the current in the HEXFET®rises to the level of the current, I_M, already flowing in the freewheeling rectifier, and it continues into the next period, t_2 to t_3, when the freewheeling rectifier goes into reverse recovery.

Finally, at time t_3 the freewheeling rectifier starts to support voltage and drain current and voltage start to fall. The rate of fall of drain voltage is now governed almost exclusively by the Miller effect, and an equilibrium condition is reached, under which the drain voltage falls at just the rate necessary for the voltage between gate and source terminals to satisfy the level of drain current estab-lished by the load. This is why the gate-to-source voltage falls as the recovery current of the freewheeling rectifier falls, then stays constant at a level corresponding to the drain current, while the drain voltage falls. Obviously, the lower the impedance of the gate-drive circuit, the higher the discharge current through the drain-gate self-capacitance, the faster will be the fall time of the drain voltage and the switching losses.

Finally, at time t_4, the HEXFET®is switched fully on, and the gate-to-source voltage rises rapidly towards the applied “open circuit” value.

Similar considerations apply to the turn-off interval. Figure 5 shows theoretical waveforms for the HEXFET®in the circuit of Figure 4 during the turn-off interval. At t_o the gate drive starts to fall until, at t_l , the gate voltage reaches a level that just sustains the drain current and the device enters the linear mode of operation. The drain-to-source voltage now starts to rise. The Miller effect governs the rate-of-rise of drain voltage and holds the gate-to-source voltage at a level corresponding to the constant drain current. Once again, the lower the impedance of the drive circuit, the greater the charging current into the drain-gate capacitance, and the faster will be the rise time of the drain voltage. At t_3 the rise of drain voltage is complete, and the gate voltage and drain current start to fall at a rate determined by the gate-source circuit impedance.

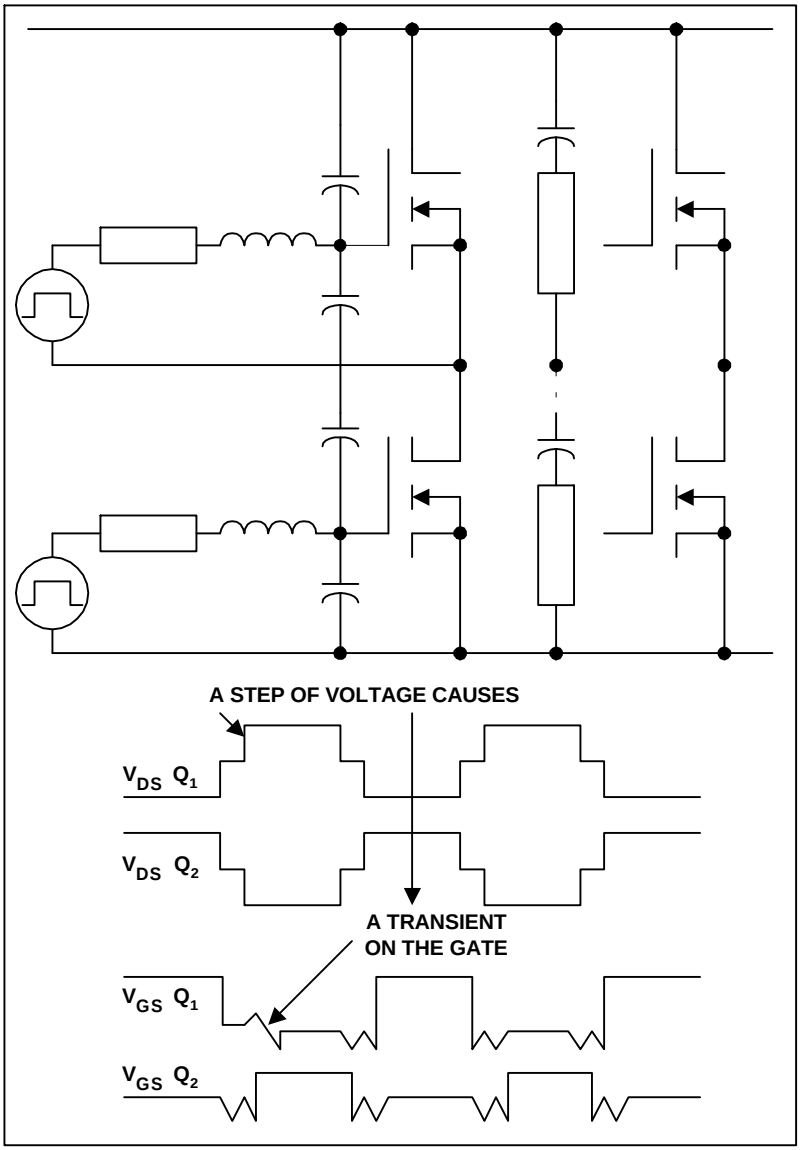

Figure 6. Transients of Voltage Induced on the Gate by Rapid Changes on the Drain-to-Source Voltage

We have seen how and why a low gate drive impedance is important to achieve high switching performance. However, even when switching performance is of no great concern, it is important to minimize the impedance in the gate drive circuit to clamp unwanted voltage transients on the gate. With reference to Figure 6, when one HEXFET®is turned on or off, a step of voltage is applied between drain and source of the other device on the same leg. This step of voltage is coupled to the gate through the gate-to-drain capacitance, and it can be large enough to turn the device on for a short instant (“dv/dt induced turn-on”). A low gate drive impedance would keep the voltage coupled to the gate below the threshold.

In summary: MOS-gated transistors should be driven from low impedance (voltage) sources, not only to reduce switching losses, but to avoid dv/dt induced turn-on and reduce the susceptibility to noise.

4. DRIVING STANDARD HEXFET®S FROM TTL

Table 1 shows the guaranteed sourcing and sinking currents for different TTL families at their respective voltages. From this table, taking as an example of the 74LS series, it is apparent that, even with a sourcing current as low as 0.4 mA, the guaranteed logic one voltage is 2.4V (2.7 for 74LS and 74S). This is lower than the possible threshold of a HEXFET®. The use of a pull-up resistor in the output, as shown in Figure 7, takes the drive voltage up to 5 V, as necessary to drive the gate of Logic Level HEXFET®s, but is not sufficient to fully enhance standard HEXFET®s. Section 8 covers the drive characteristics of the logic level devices in detail.

Logic Conditions	54 / 74	54H / 74H	(54L) / 74L	(54LS) / 74LS	74S
Logic Zero Min. sink current for V_{OL}	16mA ≤ 0.4V	20mA ≤ (0.4V) /	20mA ≤ (0.3V) / 0.4V	(4) / 8 ≤ (0.4V) / 0.5V	20mA 0.5V
Logic One Max. source current for V_{OH}	-0.4mA ≥2.4V	-0.5mA ≥2.4V	-0.2mA ≥2.4V	-0.4mA ≥ (2.5) / 2.7V	-1.0mA ≥2.7V
Typical Gate Propagation Delay	10ns	7ns	50ns	12ns	4ns

Table 1. Driving HEXFET®s from TTL (Totem Pole Outputs)

Open collector buffers, like the 7406, 7407, etc., possibly with several drivers connected in parallel as shown in Figure 9, give enough voltage to drive standard devices into "full enhancement", i.e. data sheet on-resistance. The impedance of this drive circuit, however, gives relative long switching times. Whenever better switching performance is required, interface circuits should be added to provide fast current sourcing and sinking to the gate capacitances. One simple interface circuit is the complementary source-follower stage shown in Figure 9. To drive a MOSFET with a gate charge of 60 nC in 60 ns an average gate current of 1 A has to be supplied by the gate drive circuit, as indicated in INT-944. The on-resistance of the gate drive MOSFETs has to be low enough to support the desired switching times.

With a gate charge of 60 nC and at a switching frequency is 100kHz, the power lost in the gate drive circuit is approximately:

$P = V_{GS} \times Q_G \times f = 12 \times 60 \times 10^{-9} \times 100 \times 10^{3} = 72mW$

The driver devices must be capable of supplying 1A without significant voltage drop, but hardly any power is dissipated in them.

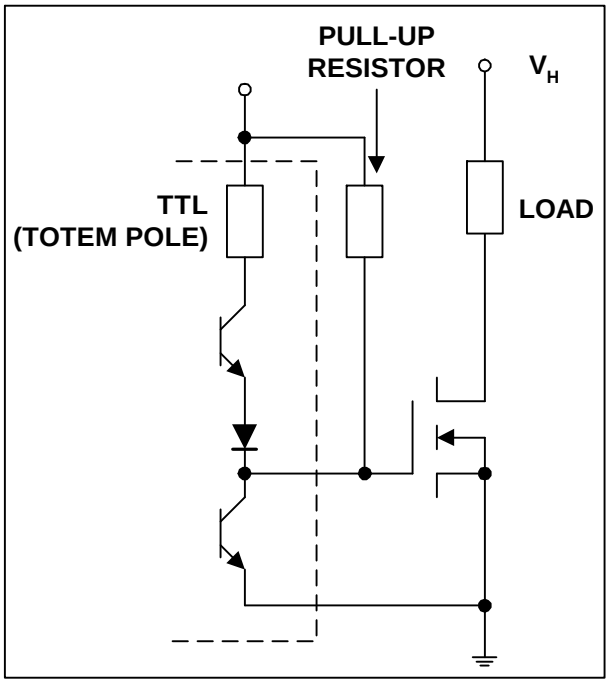

Figure 7. Direct Drive from TTL Output

5. DRIVING STANDARD HEXFET®S FROM C-MOS

While the same general considerations presented above for TTL would also apply to C-MOS, there are three substantial differences that should be kept in mind:

1. C-MOS has a more balanced source/sink characteristic that, on a first approximation, can be thought of as a 500 ohm resistance for operation over 8V and a 1k ohm for operation under 8V (Table 2).

2. C-MOS can operate from higher supply voltages than 5V so that HEXFET® saturation can be guaranteed.
3. Switching times are longer than those for TTL (Table 2).

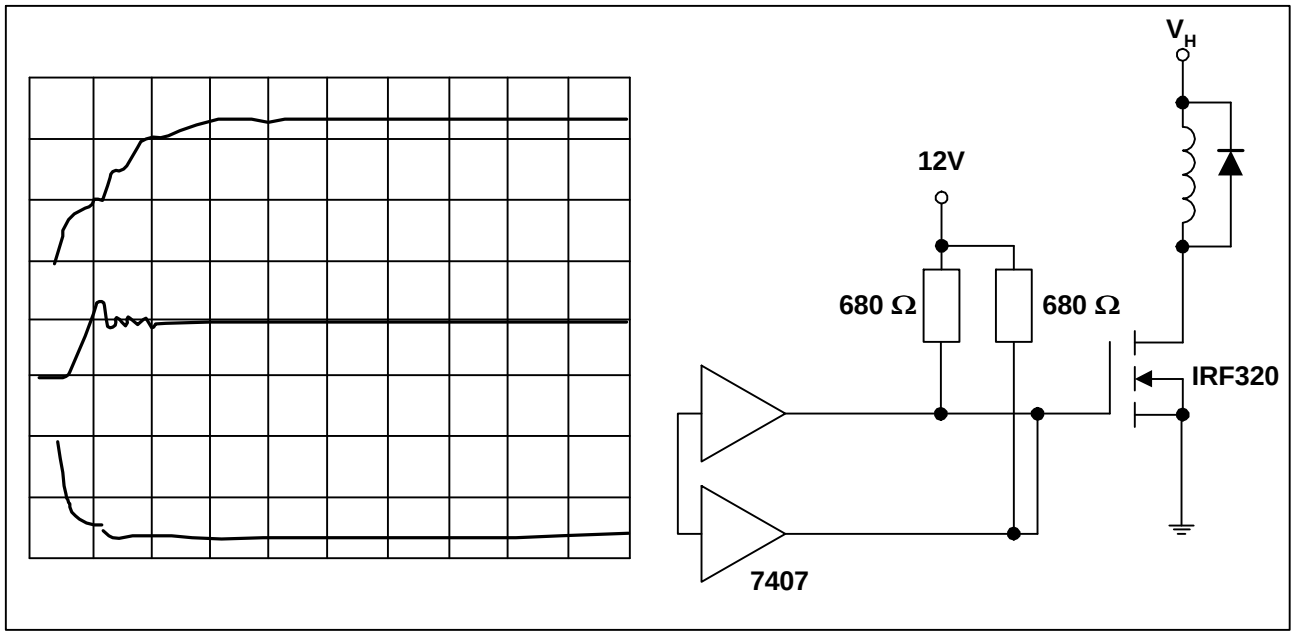

Figure 8. High Voltage TTL driver and its waveforms

When C-MOS outputs are directly coupled to the gate of a HEXFET®, the dominant limitation to performance is not the switching time, but the internal impedance (assuming that C-MOS are operated from a 10V or higher voltage supply). It will certainly not be able to turn OFF the HEXFET® as fast as the TTL, while the turn-ON waveform will be slightly better than what can be achieved with a 7407 with a 680 ohm pull-up resistor. Of course, gates can be paralleled in any number to lower the impedance and this makes C-MOS a very simple and convenient means of driving HEXFET®s. Drivers can also be used, like the 4049 and 4050 which have a much higher current sinking capability (Table 2), but they do not yield any significant improvement in current sourcing.

For better switching speeds, buffer circuits, like the one shown in Figure 9, should be considered, not only to provide better current sourcing and sinking capability, but also to improve over the switching times of the C-MOS output itself and the dv/dt noise immunity.

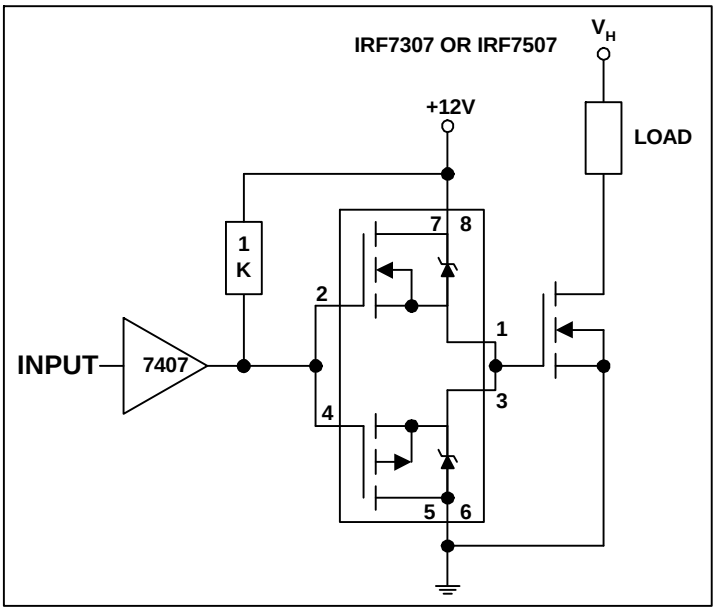

Figure 9. Simple Interface to Drive HEXFETs from TTL

6. DRIVING HEXFET®S FROM LINEAR CIRCUITS

The complementary source follower configuration of Figure 9 can also be used in linear applications to improve drive capability from an opamp or other analog source.

Most operational amplifiers have a very limited slew rate, in the order of few V/microsec. This would limit the bandwidth to less than 25kHz. A larger bandwidth can be obtained with better operational amplifiers followed by a current booster, like the ones shown in Figures 10 or 11. For a system bandwidth of 1MHz, the opamp bandwidth must be significantly higher than 1MHz and its slew rate at least 30V/μs.

Logic Supply Voltage / Logic Conditions	Standard Buffered Outputs			4049 / 4050 Drivers		
	5V	10V	15V	5V	10V	15V
Logic Zero: Approximate sink current for $V_{OL} \leq 1.5V$	1.5mA	3.5mA	4mA	20mA	40mA	40mA
Logic One: Minimum source current for V_{OH}	-0.5mA $\geq$ 4.6V	-13mA $\geq$ 9.5V	-3.4mA $\geq$ 13.5V	-1.25mA $\geq$ 2.5V	-1.25mA $\geq$ 9.5V	-3.75mA $\geq$ 13.5V
Typical switching times of logic drive signals:						
RISE	100ns	50ns	40ns	100ns	50ns	40ns
FALL	100ns	50ns	40ns	40ns	20ns	15ns

Table 2. Driving HEXFET®s from C-MOS (Buffered)

When analog signals determine the switching frequency or duty cycle of a HEXFET®, as in PWM applications, a voltage comparator is normally used to command the switching. Here, too, the limiting factors are the slew rate of the comparator and its current drive capability. Response times under 40ns can be obtained at the price of low output voltage swing (TTL compatible). Once again, the use of output buffers like the ones shown in Figures 9, may be necessary to improve drive capability and dv/dt immunity. If better switching speeds are desired. a fast op-amp should be used.

In many applications, when the HEXFET®is turned on, current transfers from a freewheeling diode into the HEXFET®. If the switching speed is high and the stray inductances in the diode path are small, this transfer can occur in such a short time as to cause a reverse recovery current in the diode high enough to short out the dc bus. For this reason, it may be necessary to slow down the turn-on of the HEXFET®while leaving the turn-off as fast as practical. Low impedance pulse shaping circuits can be used for this purpose, like the ones in Figures 12 and 13.

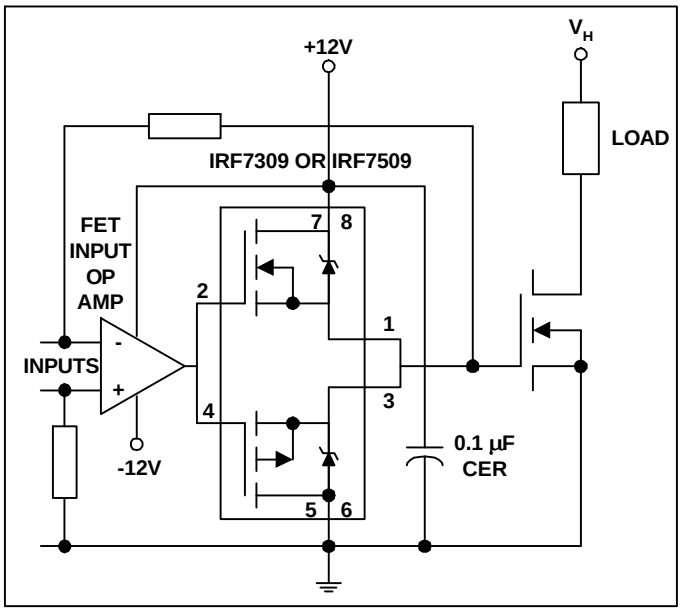

Figure 10. Dual Supply Op-Amp Drive Circuit

7. DRIVE CIRCUITS NOT REFERENCED TO GROUND

To drive a HEXFET®into saturation, an appropriate voltage must be applied between the gate and source. If the load is connected between source and ground, and the drive voltage is applied between gate and ground, the effective voltage between gate and source decreases as the device turns on. An equilibrium point is reached in which the amount of current flowing in the load is such that the voltage between gate and source maintains that amount of drain current and no more. Under these conditions the voltage drop across the MOSFET is certainly higher than the threshold voltage and the power dissipation can be very high. For this reason, the gate drive circuit is normally referenced to the source rather than to the ground. There are

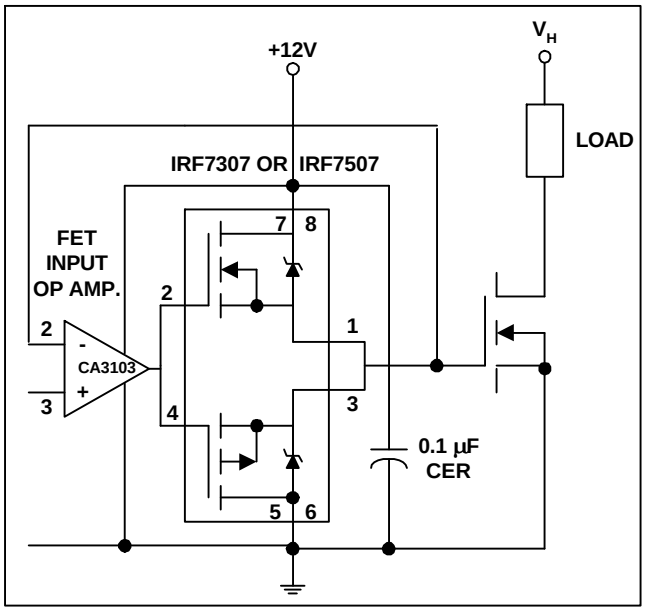

Figure 11. Single Supply Op-Amp Drive Circuit (Voltage Follower)

basically three ways of developing a gate drive signal that is referenced to a floating point:

1. By means of optically coupled isolators.
2. By means of pulse transformers.

By means of DC to DC chopper circuits with transformer isolation.

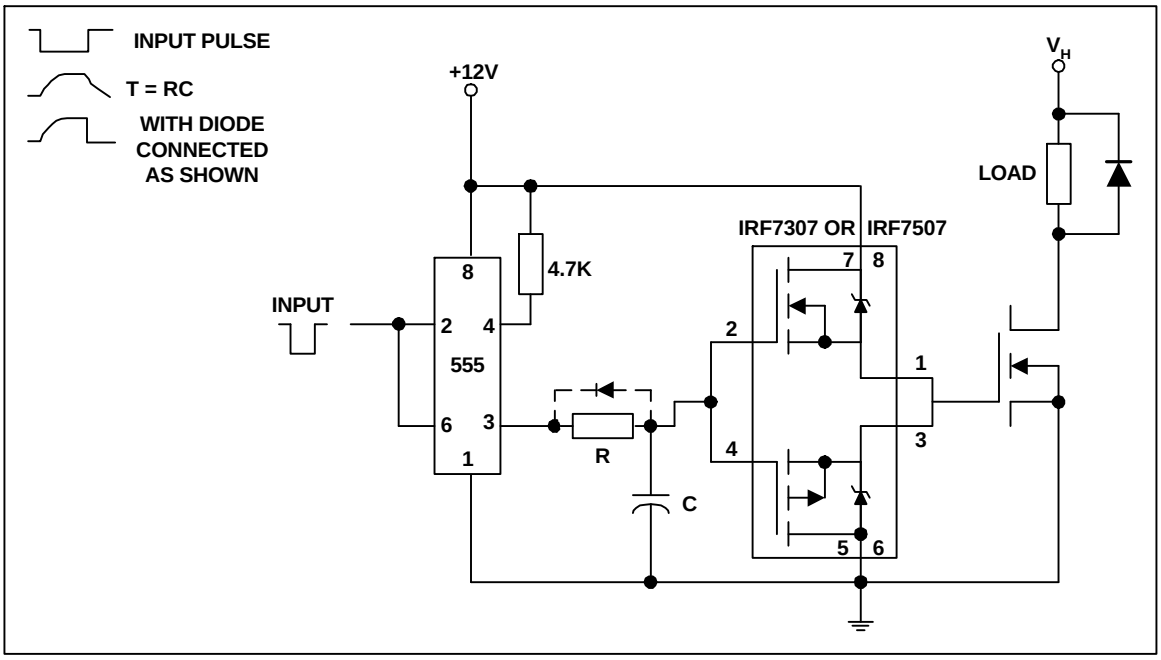

Figure 12. A pulse shaper. The 555 is used as an illustration of a Schmitt Trigger pulse shaper

7.1 MGDs with optocouplers

Most optocouplers require a separate supply grounded to the source on the receiving end of the optical link and a booster stage at the output, as shown in Figure 14a. One of the major difficulties encountered in the use of optocouplers is their susceptibility to noise. This is of particular relevance in applications where high currents are being switched rapidly. Because of the dv/dt seen by the V_{EE} pin, the optocoupler needs to be rated for high dv/dt, in the order of 10 V/ns.

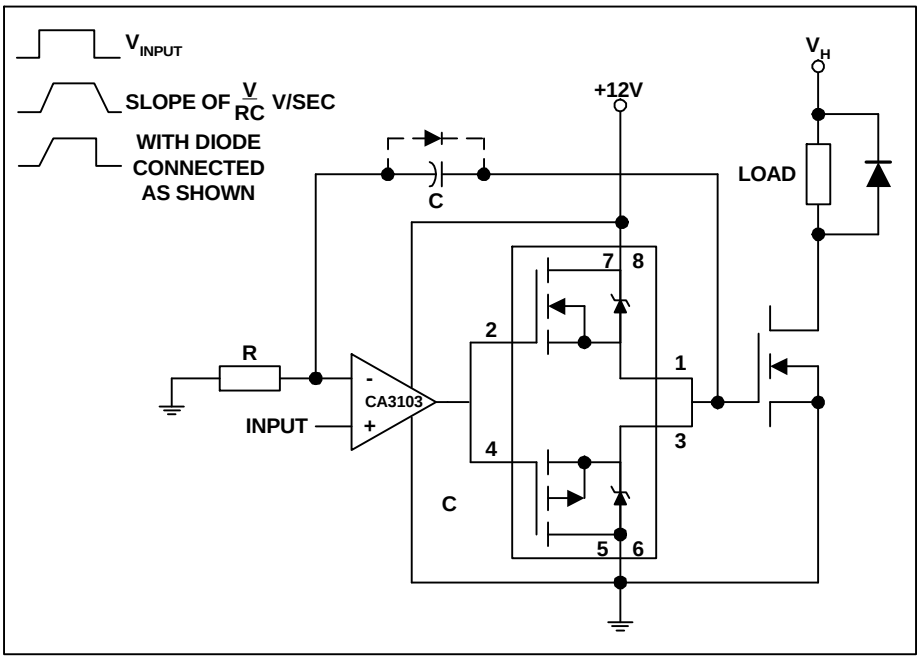

Figure 13. Pulse shaper implemented with an integrator

Figure 15a shows an MGD with under-voltage lockout and negative gate bias. When powered with a 19 V floating source, the gate drive voltage swings between +15V and -3.9V. D1 and R2 offset the emitter voltage by 3.9V. The switching waveforms shown in Figure 15b are similar to those in Figure 14b except for the negative bias. Q3, D2 and R5 form the under voltage lockout circuit.

The LED D2 is used as low voltage, low current reference diode. Q3 turns on when the voltage at the anode of D2 exceeds the sum of the forward voltage of LED and the base-emitter voltage of Q3. This enables the operation of the optocoupler. The tripping point of the under voltage lock-out circuit is 17.5V. The start-up wave forms are shown in Figure 16.

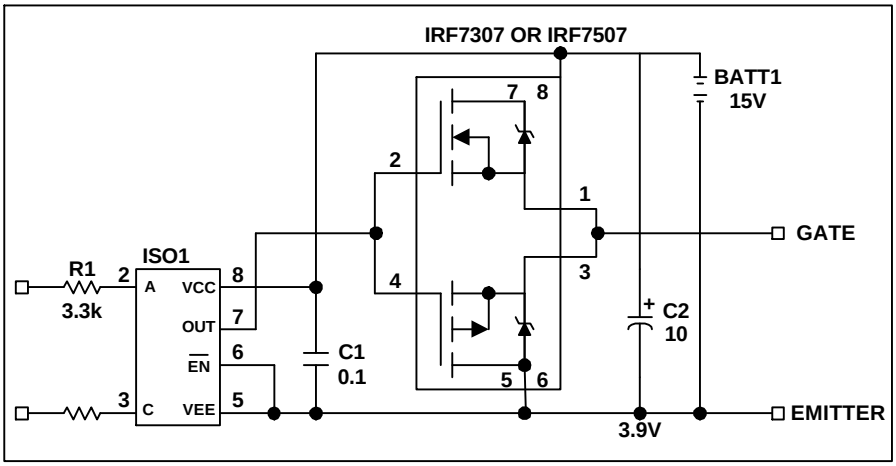

Figure 14a. Simple high current optoisolated driver

The auxiliary supply for the optocoupler and its associated circuitry can be developed from the drain voltage of the MOSFET itself, as shown in Figure 17, 18 and 19. This supply can be used in conjunction with the UV-lockout shown in Figure 15 to provide a simple high-quality optoisolated drive.

The circuit in Figure 17a can be modified to provide higher output current. By changing C1 to 680pF and R3 to 5.6k, its performance changes to what is shown in Figures 20, 21 and 22. Other methods of developing isolated supplies are discussed in Section 9.

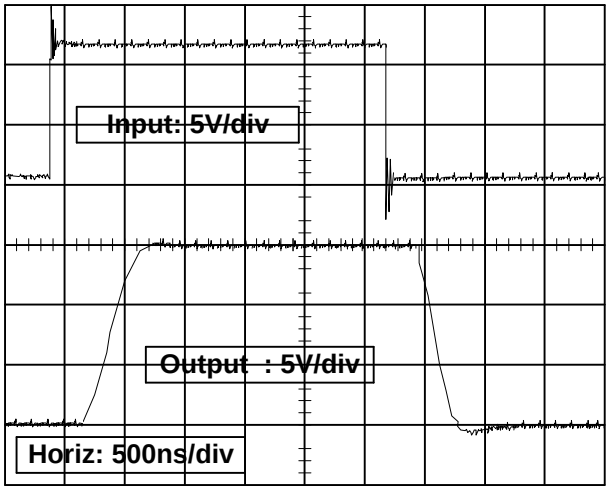

Figure 14b: Waveforms associated with the circuit of Figure 14a when loaded with 100nF

7.2 Pulse transformers

A pulse transformer is, in principle, a simple, reliable and highly noise-immune method of providing isolated gate drive. Unfortunately it has many limitations that must be overcome with additional components. A transformer can only transfer to the secondary the AC component of the input signal. Consequently, their output voltage swings from negative to positive by an amount that changes with the duty cycle, as shown in Figure 23. As a stand-alone component they can be used for duty cycles between 35 and 65%.

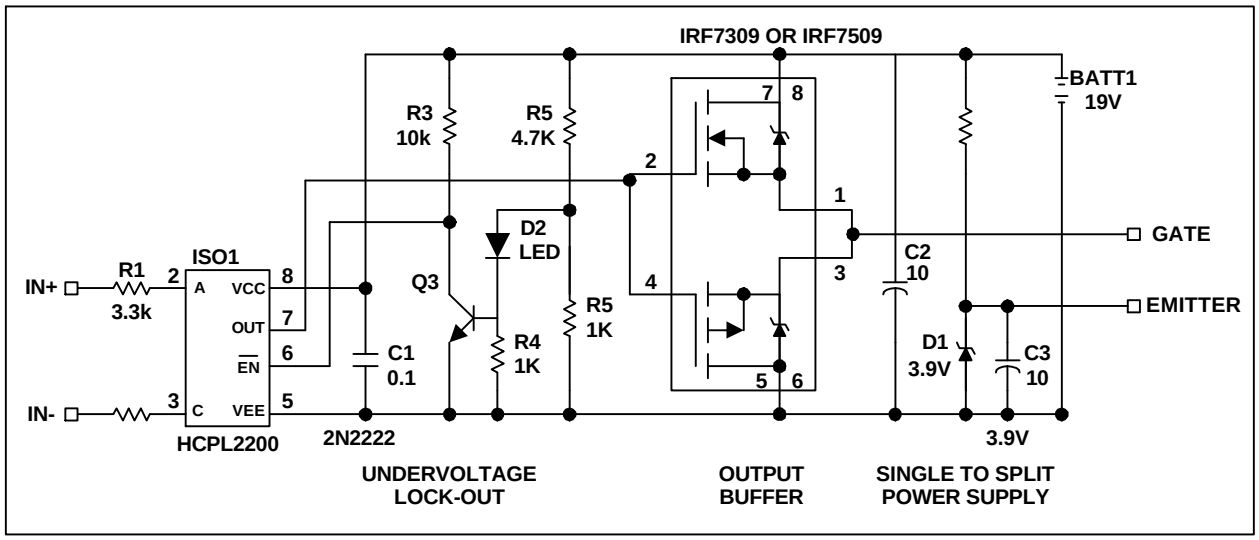

Figure 15a: Optoisolated driver with UV lockout and negative gate bias

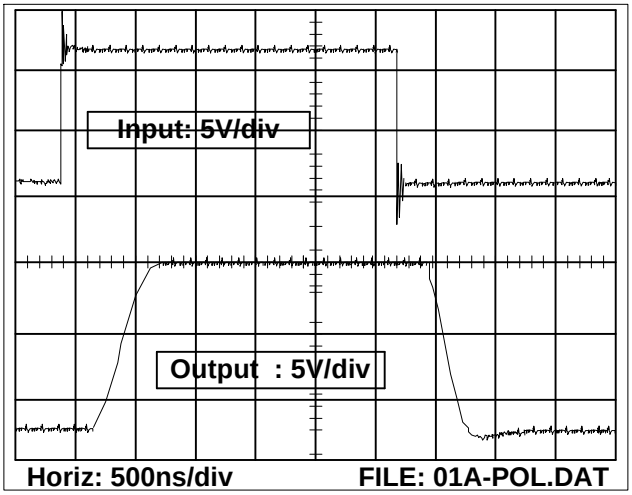

Figure 15b: Waveforms of the circuit in Figure 21a when loaded with 100nF

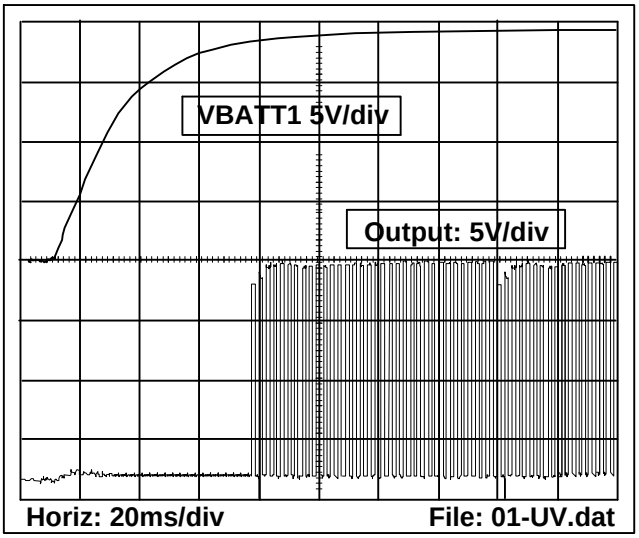

Figure 16. Start-up waveforms for the circuit of Figure 15a.

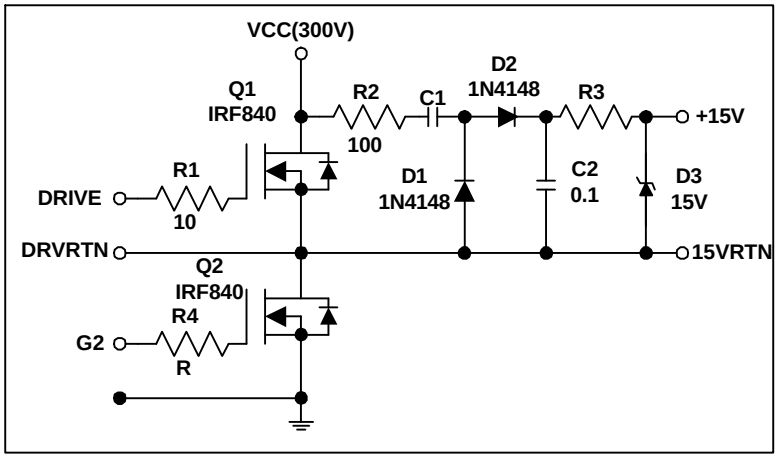

Figure 17a. Drive supply developed from the drain voltage

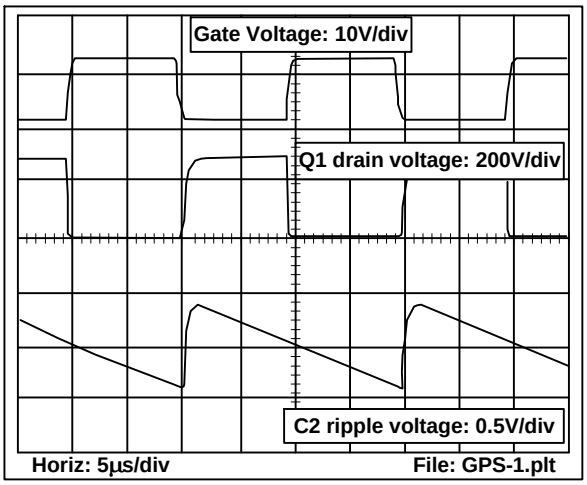

Figure 17b. Waveforms of the circuit in Figure 23a.C1 = 100 pF, R3 = 5.6 k, f = 50 kHz

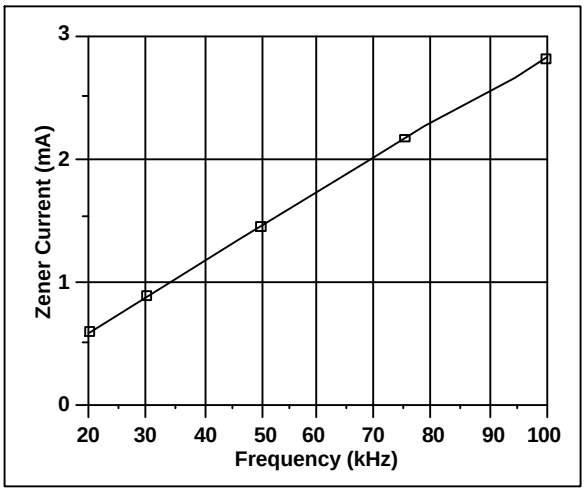

Figure 18. Zener current (max output current) for the circuit in Figure 23a.

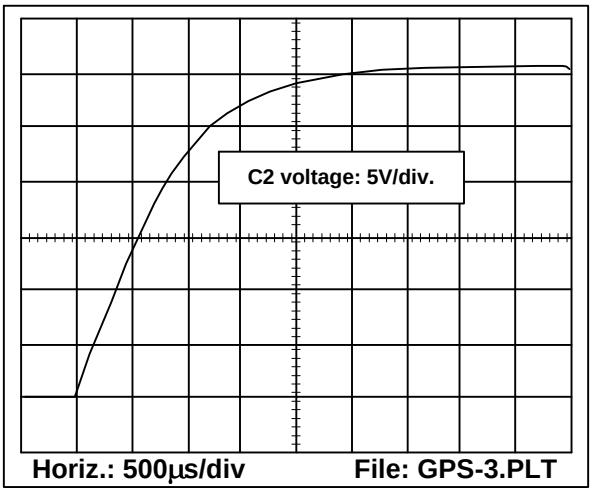

Figure 19. Start-up voltage at 50 kHz for the circuit in Figure 23a.

They have the additional advantage of providing a negative gate bias. One additional limitation of pulse transformers is the fact that the gate drive impedance is seriously degraded by the leakage inductance of the transformer. Best results are normally obtained with a few turns of twisted AWG30 wire-wrap wire on a small ferrite core.

Lower gate drive impedance and a wider duty-cycle range can be obtained with the circuit in Figure 24a. In this circuit, Q1 and Q2 (a single Micro-8 package) are used to buffer the input and drive the primary of the transformer. The complementary MOS output stage insures low output impedance and performs wave shaping. The output stage is fed by a dc restorer made by C2 and D1 that references the signal to the positive rail. D1 and D2 are also used to generate the gate drive voltage.

The input and output wave form with 1nF load capacitance are shown in Figure 24b. The turn-on and turn-off delays are 50ns. The rise and fall times are determined by the 10 Ohm resistor and the capacitive load. This circuit will operate reliably between 20 and 500 kHz, with on/off times from 0.5 to 15 microsecs.

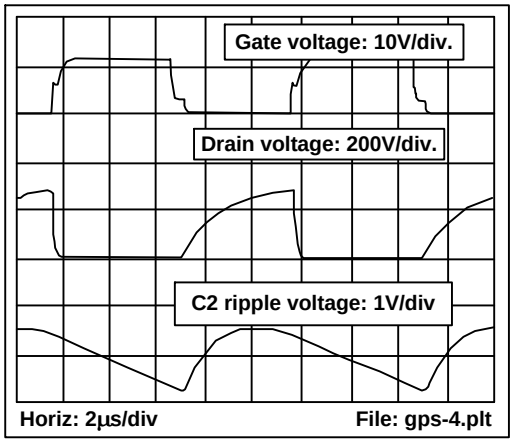

Figure 20. Waveforms of the circuit in Figure 23a. with C1=680pF, R3=1k, f=100kHz.

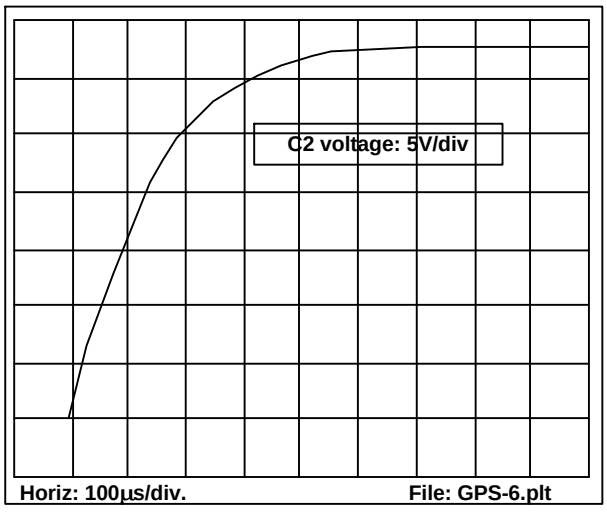

Figure 22. Start-up voltage at 100 kHz for the circuit in Figure 23a. with C1=680pF, R3=R3=1k

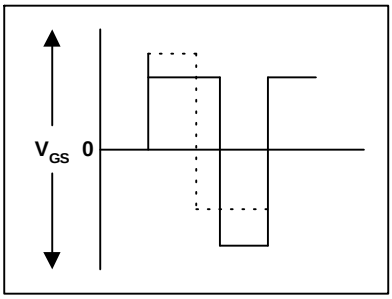

Figure 23. Volt-seconds across winding must balance

Due to the lack of an under voltage lock-out feature, the power-up and power down behavior of the circuit is important. Intentionally C1 and C2 are much bigger in value then C3 so that the voltage across C3 rises to an adequate level during the first incoming pulse. The power-up wave forms at 50kHz switching frequency and 50% duty cycle are shown in Figure 25. During the first pulse, the output voltage is 10V only, and drops back below 10V at the fifth pulse.

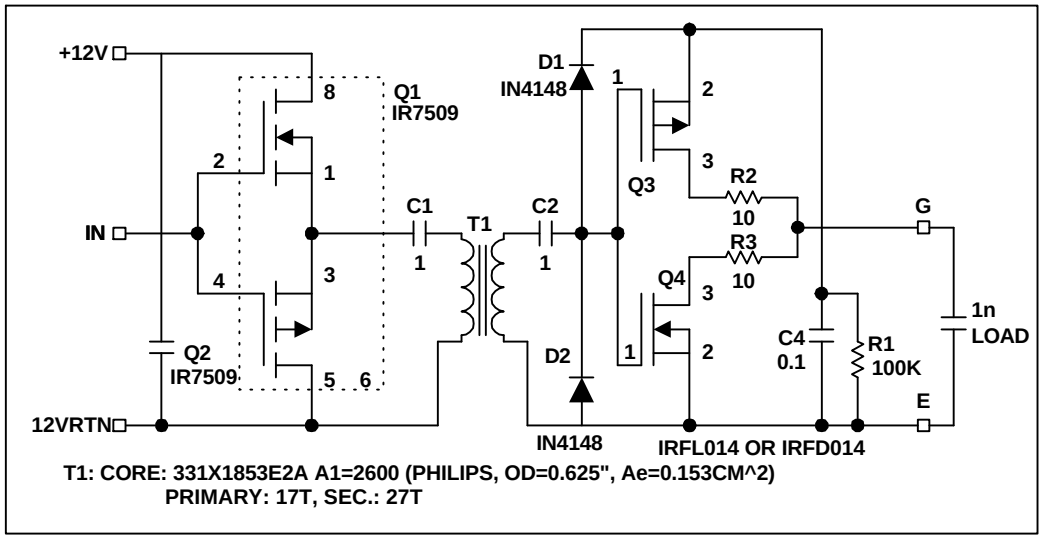

Figure 24a. Improving the performance of a gate drive transformer

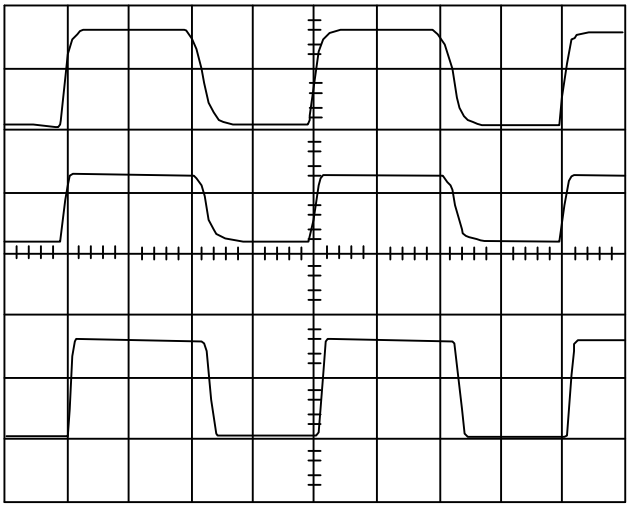

Figure 24b. Waveforms associated with the circuit of Figure 24a

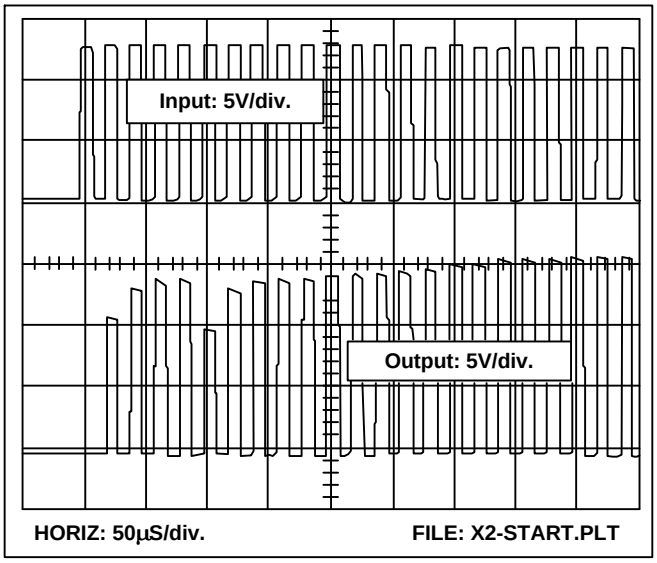

Figure 25. Waveforms during start-up for the circuit in Figure 24a.

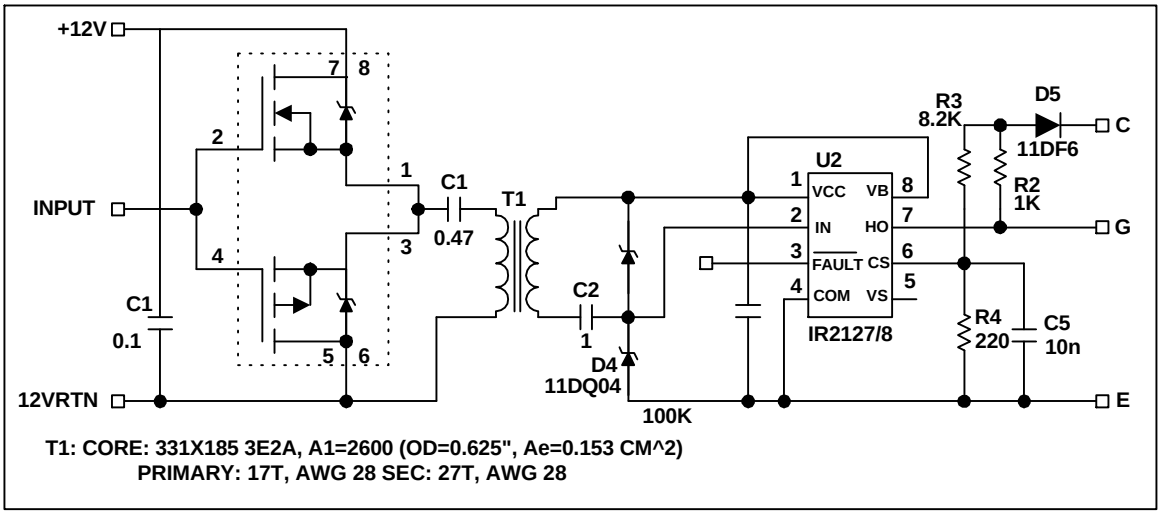

Figure 26a. Transformer-coupled MGD with UV lockout and short-circuit protection

The power down of the circuit is smooth and free from voltage spikes. When the pulse train is interrupted at the input, the C2 capacitor keeps the input of the CMOS inverter high and R1 discharges C3. By the time the input to the CMOS inverter drops below the threshold voltage of Q4, C3 is completely discharged the output remains low.

The addition of a MOS-Gate Driver IC improves the performance of the circuit in Figure 24a, at the expenses of prop delay. The circuit shown in Figure 26a has the following features:

- No secondary supply required
- Propagation delay ~500ns (CL= 10nF)
- Duty cycle range 5% to 85%
- Nominal operating frequency 50kHz (20kHz to 100kHz)
- Short circuit protection with Vce sensing. Threshold Vce = 7.5V
- Undervoltage lock-out at Vcc = 9.5V
- Over voltage lock out at Vcc = 20V

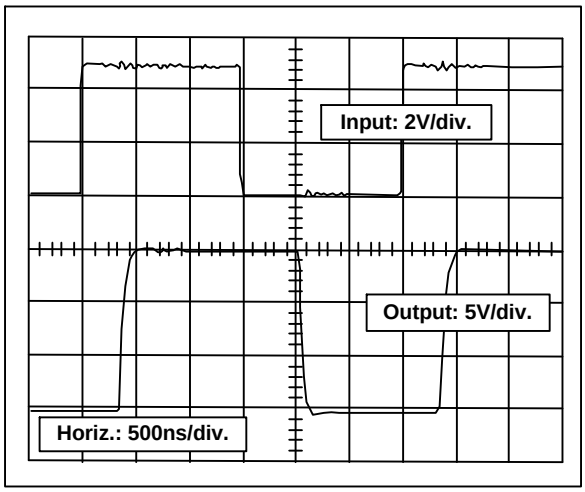

Figure 26b. Waveforms associated with the circuit of Figure 26a.

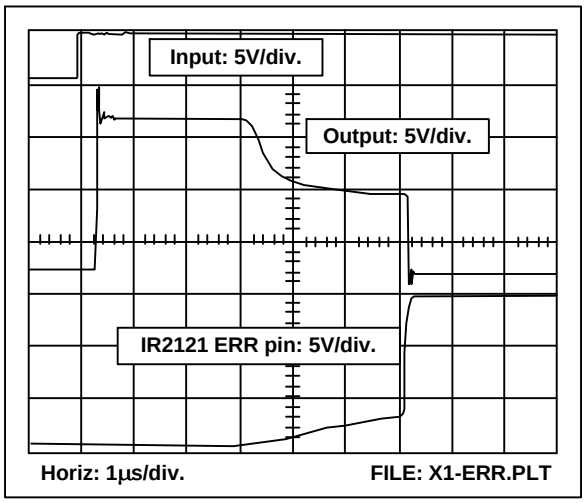

Figure 27. Shutdown due to high V_{CEsat}

The short circuit protection is implemented with a Vce sensing circuit in combination with the current sense input (CS) of IR2127/8. When the HO pin if U2 goes high R3 starts charging C5. Meanwhile the IGBT turns on, the collector voltage drops to the saturation level, D5 goes into conduction and C5 discharges. When the collector voltage is high, D5 is reverse biased and the voltage on C5 keeps raising. When C5 voltage exceeds 250mV the IR2127/8 shuts down the output. The fault to shut-down delay is approximately 2 microsecs.

For operation with a large duty cycle, several options are available. The circuits described in AN-950 use a saturating transformer to transfer the drive charge to the gate. The circuit shown in Figure 28a, on the other hand, achieves operation over a wide range of duty cycles by using the MGD as a latch. It has the following features:

- Frequency range from DC to 900kHz.
- Turn-on delay: 250ns.
- Turn-off delay 200ns
- Duty cycle range from 1% to 99% at 100kHz.
- Under voltage and over voltage lockout.
- Optional short circuit protection, as shown in Figure 26a

In the circuit of Figure 28a the transformer is small (8 turns), since it transmits only short pulses to the secondary side. The MGD on the secondary side of the transformer is latched by the feedback resistor R4. Figures 28b and 28c show the performance of this circuit at the two extremes of 900 kHz and 2.5 Hz

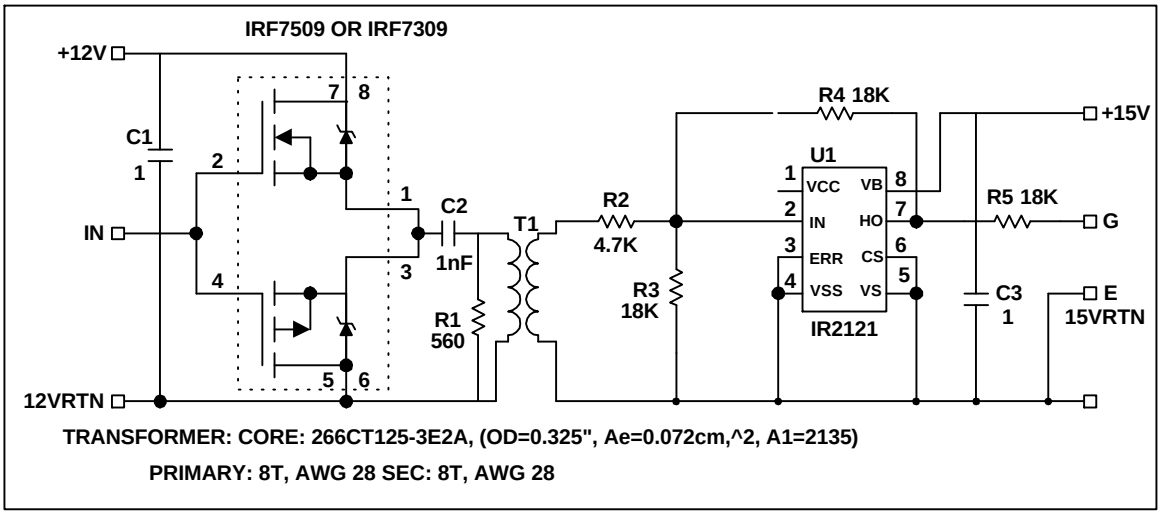

Figure 28a. Transformer-coupled MGD for operation from DC to 900 kHz

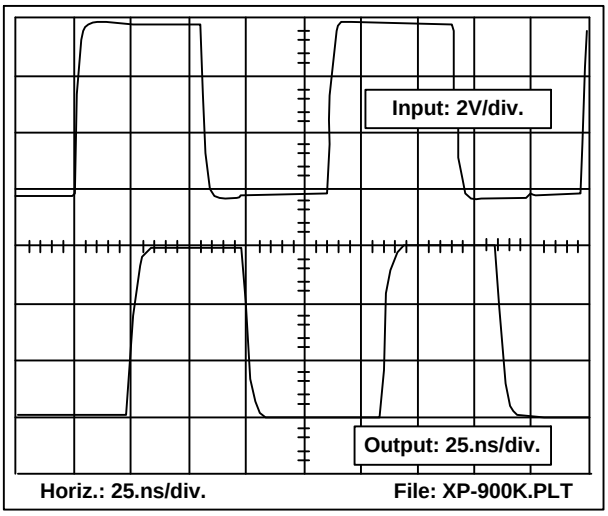

Figure 28b. Waveforms associated with the circuit of Figure 28a operated at 900 kHz

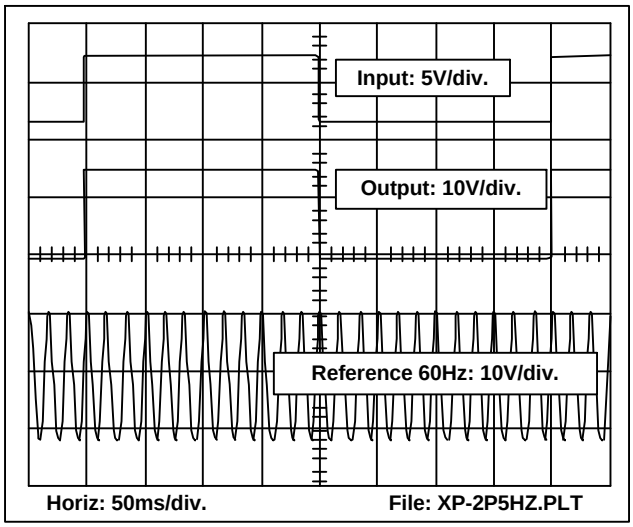

Figure 28c. Waveforms associated with the circuit of Figure 28a operated at 2.5 Hz

7.2 Chopping gate drives

Chopper circuits can maintain a gate drive signal for an indefinite period of time, have good noise immunity performance and, with some additional circuitry, the isolated supply can be avoided.

The basic operating principle is shown in Figure 29. To turn on the MOSFET, a burst of high frequency is transmitted to the secondary side. The MOSFET is turned off by interrupting the high frequency. The diode and the bipolar transistor form a crowbar that rapidly discharges the gate.

In addition to providing the gate drive signal, the high frequency transformer is frequently used to power auxiliary circuitry, like short-circuit protection, thus avoiding a dedicated supply.

8. DRIVE REQUIREMENTS AND SWITCHING CHARACTERISTICS OF LOGIC LEVEL HEXFET®S

Many applications require a power MOSFET to be driven directly from 5 V logic circuitry. The on-resistance of standard power MOSFETs is specified at 10 V gate drive, and are generally not suitable for direct interfacing to 5V logic unless an oversized MOSFET is employed.

Logic level HEXFET®s are specifically designed for operation from 5V logic and have guaranteed on-resistance at 5 or 4.5 V gate voltage. Some have guaranteed on-resistance at 2.7 V.

Some important considerations for driving logic level HEXFET®s are discussed in this section and typical switching performance of these is illustrated when driven by some common logic drive circuits.

8.1 Comparison to Standard HEXFET®s

Some devices are available as Logic-level HEXFET®s as well as standard HEXFET®s. The logic-level version uses a thinner gate oxide and different doping concentrations. This has the following effects on the input characteristics:

- Gate Threshold voltage is lower.
- Transconductance is higher.
- Input capacitance is higher.
- Gate-source breakdown voltage is lower.

While input characteristics are different, reverse transfer capacitance, on-resistance, drain-source breakdown voltage, avalanche energy rating, and output capacitance are all essentially the same. Table 3 summarizes the essential comparisons between standard and logic level HEXFET®s.

Characteristics and Ratings		Standard HEXFET® (IRF Series)	Comparable Logic Level HEXFET® (IRL Series)
Gate Threshold Voltage	$V_{GS(on)}$	2 - 4V	1 - 2V
On-Resistance	$R_{DS(on)}$	Logic level HEXFET® has same value of $R_{DS(on)}$ V_{GS} = 5V as standard HEXFET® at V_{GS} = 10V $R_{DS(on)}$ of logic level HEXFET® also speed at V_{GS} = 4V	
Transconductance	gfs	Typically 39% larger for logic level HEXFET®	
Input Capacitance	Crs	Typically 33% larger for logic level HEXFET®	
Output Capacitance	Crss	Essentially the same	
Reverse Transfer Capacitance	Crss	Essentially the same	
Gate Charge Gate-Source	Qgs	Essentially the same	
Gate-Drain	Qgd	Essentially the same	
Total	Qg	Essentially same as V_{GS} = 10V	Essentially same at V_{GS} = 5V
Drain Source Breakdown Voltage	BV_{DSS}	Same	
Continuous Drain Current	I_D	Same	
Single Pulse Avalanche Energy	E_{AS}	Same	
Max. Gate-Source Voltage	V_{GS}	± 20V	±10V

Table 3: Essential Comparisons of Standard and Logic Level HEXFET®s

The gate charge for full enhancement of the logic level HEXFET®is, however, about the same as for a standard HEXFET®because the higher input capacitance is counteracted by lower threshold voltage and higher transconductance. Since the logic level HEXFET®needs only one half the gate voltage, the drive energy is only about one half of that needed for the standard HEXFET®. Since the gate voltage is halved, the gate drive resistance needed to deliver the gate charge in a given time is also halved, relative to a standard HEXFET®. In other words, for the same switching speed as a standard HEXFET®power MOSFET, the drive circuit impedance for the logic level HEXFET®must be approximately halved.

The equivalence of switching times at one half the gate resistance for the logic level HEXFET®is illustrated by the typical switching times for the IRL540 and the IRF540 HEXFET®s shown in Table 4, using data sheet test conditions.

Gate Resistance	Gate Voltage	Drain Current	Typical Values (ns)			
R_G (Ω)	V_{GS} (V)	I_D (A)	$t_{D\ on}$	t_r	$t_{D\ on}$	t_r
9	10	28	15	72	40	50
4.5	5	28	15	72	44	56

Table 4: Typical Resistive Switching Times for IRL540 and IRF540

TTL families do not actually deliver 5V in their V_{OH} condition, even into an open circuit. The 5V level can, however, be reached by the addition of a pull-up resistor from the output pin to the 5V bus, as illustrated in Figure 30. Without the pull-up resistor, the $R_{DS(on)}$ value at V_{GS} = 5V may not be attained, and the value specified at V_{GS} = 4V should be used for worst case design.

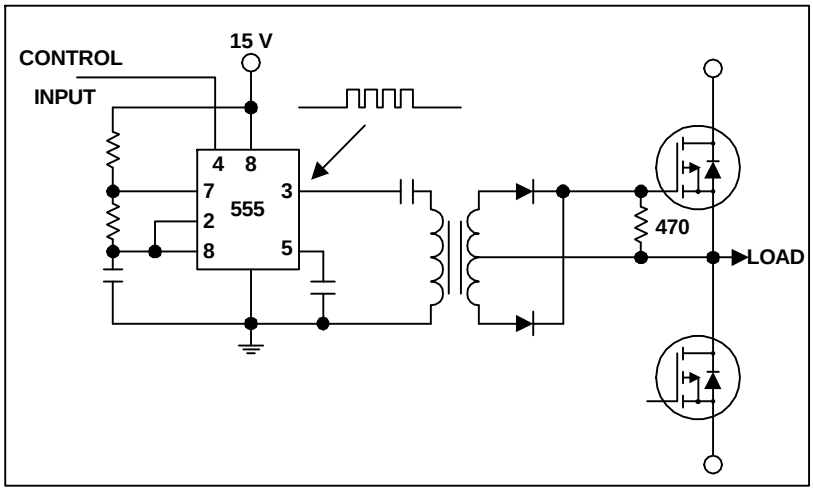

Figure 29.

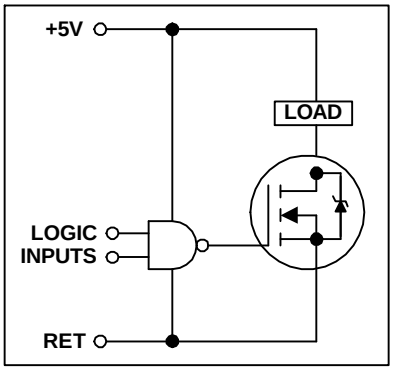

Figure 30. Pull-up resistor used to deliver 5V gate drive

8.2 Driving Logic Level HEXFET®s

The gate threshold voltage of MOSFETs decreases with temperature. At high temperature it can approach the $V_{OL(max)}$ specification of the logic driver. Care should be exercised to insure that $V_{TH(min)}$ at the highest operating temperature is greater than $V_{OL(max)}$ of the various logic families in order to guarantee complete turn off.

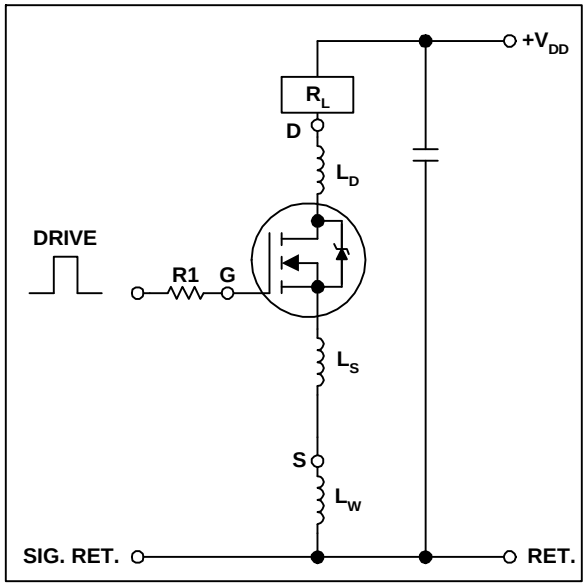

Figure 31a. High common mode inductance

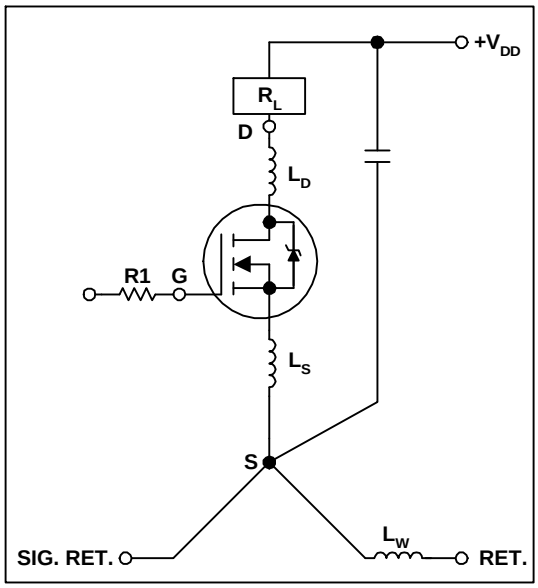

Figure 31b. Minimum common mode inductance

Common source inductance plays a significant role in switching performance. In the circuit of Figure 31a the switching performance is degraded due to the fact that V_{GS} is reduced by (L_S + L_W) di/dt, where di/dt is the rate of change of the drain current. By eliminating L_W from the drive circuit, V_{GS} can approach the applied drive voltage because only L_S (the internal source inductance) is common.

This can be done by separately connecting the power return and the drive signal return to the source pin of the switching HEXFET®, as shown in Figure 31b. Thus, the load current I_D does not flow through any of the external wiring of the drive circuit; consequently, only the internal source inductance L_S is common to both load and drive circuits.

In the case of logic level HEXFET®s, for which V_{GS} is 5V and not 10V, the loss of drive voltage due to common mode inductance has proportionately twice the effect as it would on a 10V drive signal, even though actual values of L_S and L_W are the same.

8.3 Resistive Switching Tests

In the following tests of switching performance, the physical layout of the test circuit was carefully executed so to minimize the common source inductance. The following precautions were also observed:

1. R_L was built by paralleling 0.5W resistors to achieve the desired load resistance (see Table 5).
2. To minimize inductance in the load circuit, a 10 μF low-ESR low-ESL capacitor was connected directly from $+V_{DD}$ to the source of the DUT.
3. To provide a low source impedance for the 5V gate pulse of the DUT, a 0.1 μF low-ESR low-ESL capacitor was connected directly between pin 14 and pin 7 of the driver IC.
4. To provide minimum common source impedance, the source of the DUT was the common return point of all ac and dc system grounds.
5. To reduce stray inductances and thus achieve maximum switching speeds, the physical size of the high current loop (R_L, DUT, 10 μF) was reduced to the smallest practical limits.

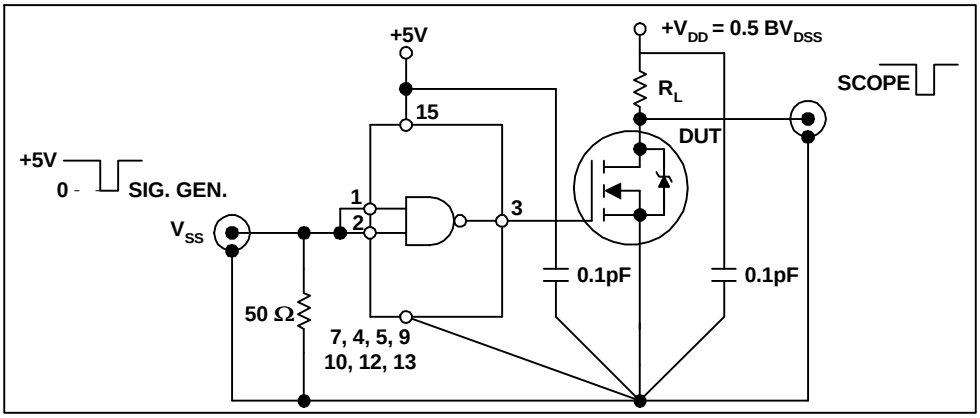

Figure 32. Switching test circuit. Logic level driver is one-quarter of a quad NAND gate.

Only the 5 volt families have been tested as logic level HEXFET®drives: bipolar and CMOS (and their derivatives), as indicated below.

9. SIMPLE AND INEXPENSIVE METHODS TO GENERATE ISOLATED GATE DRIVE SUPPLIES

.

In several applications, dc-to-dc converters are used to power the MOS Gate Driver. Although the gate drive requires little power, the noisy environment, the isolation voltage and creepage distance requirements and the high dv/dt between the primary and secondary size make the design of the DC-to-DC converter somewhat complicated. Its key parameters are listed below: OUTPUT VOLTAGE, CURRENT. The output voltage of the DC-to-DC converter is the sum of the positive and negative drive voltage to the gate. The load current required from the DC-to-DC converter is the sum of the current consumption of the drive circuit and the average drive current to the gate.

dv/dt CAPABILITY. When the DC-DC converter powers a high side switch, the secondary side of the converter is connected to the output of the power circuit. The rapid change of high voltage at the output of power circuit stresses the isolation of the transformer and injects noise to the primary side of the transformer. Switching noise at the primary side disturbs the operation of the converter and the control circuit for the power stage, causing false triggering and shoot-through. Therefore a transformer with high voltage isolation, appropriate creepage distances and low winding-to-winding capacitance is required in this application.

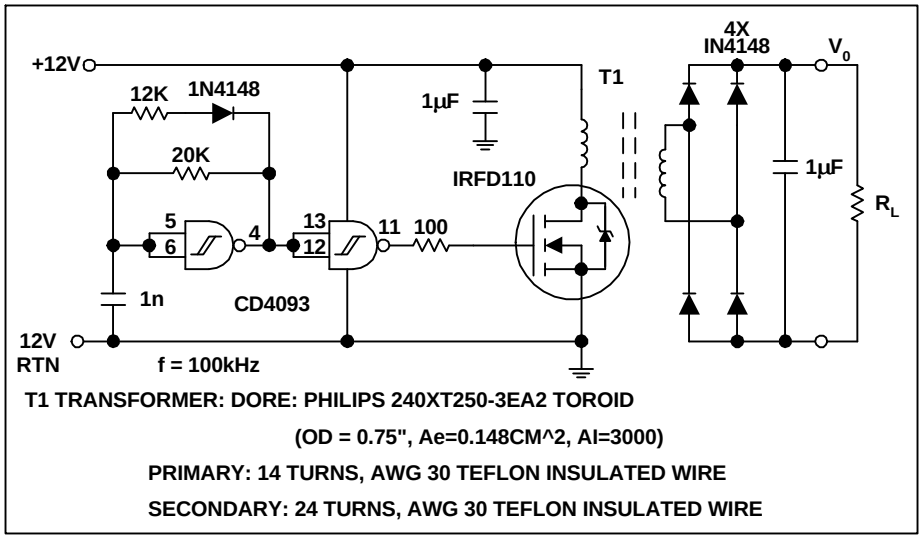

Figure 33a. 100 kHz Forward converter

SMALL SIZE. To reduce the interwinding capacitances the transformer must be made small. This implies operation at high frequency. Small size and compact layout help reducing the EMI and RFI generated by the converter. Figure 33a shows a forward converter made with two CD4093 gates to generate the clock and drive the MOSFET. Energy as transferred to the secondary when the MOSFET is on, in about 33% of the cycle. When the MOSFET is off, the secondary winding is used to demagnetize the transformer and transfer the magnetizing energy to the load, thus eliminating the need for a demagnetizing winding. The switching waveforms are shown in Figure 33b. The ringing in the drain voltage during the fly-back period is due to the loose coupling between the primary and the secondary windings. The load current vs. output voltage characteristic of the circuit is shown in Figure 34. When the output current falls below 5 mA, the circuit works as flyback converter because the demagnetizing current flows through the output. A minimum load of 5mA is required to limit the output voltage at 15V.

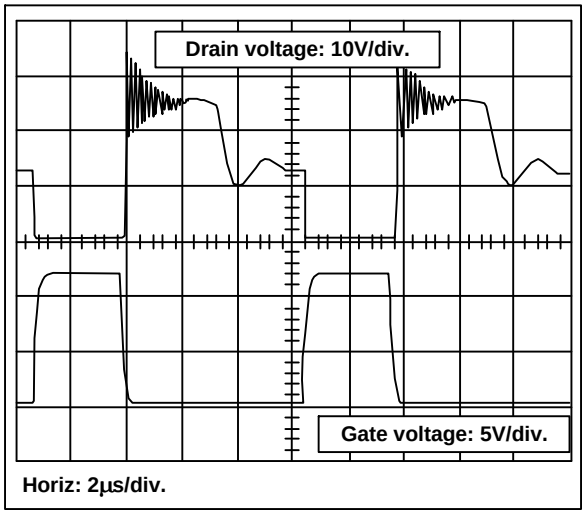

Figure 33b. Waveforms associated with the circuit in Figure 33a

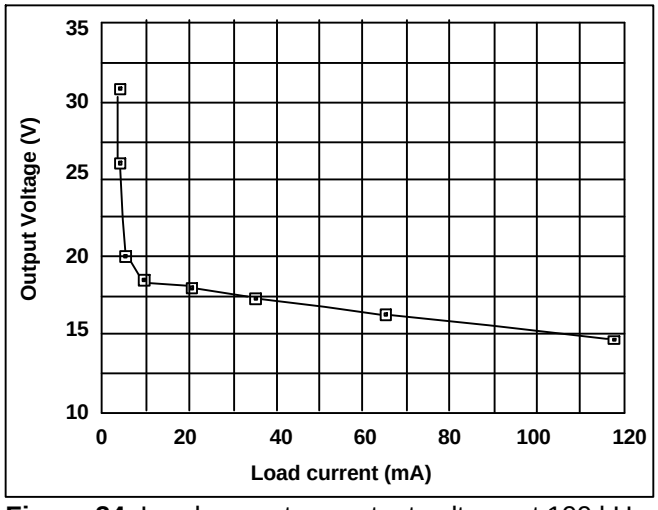

Figure 34. Load current vs. output voltage at 100 kHz, Rout = 27.7 Ohms

If the converter is loaded with a constant and predictable load, a zener can provide the necessary regulation. Otherwise a three-terminal regulator or a small zener-driven MOSFET may be necessary.

The circuit in Figure 35a is similar to the previous one, except that the higher switching frequency is higher (500 kHz) and the transformer is smaller. The remaining three gates in the package are connected in parallel to drive the MOSFET and reduce the switching losses. The switching waveforms are shown in Figure 35b. The output resistance (Rout) of this circuit is higher than the circuit shown in Figure 33a, mainly because the stray inductance of the smaller transformer is higher and the effects of the stray inductance are higher. Figure 37a shows a push-pull operated at 500 kHz. The single gate oscillator produces a 50% duty cycle output, while the remaining gates in the package are used to drive the push-pull output stage. The primary of the transformer sees half the voltage compared to the previous circuit, therefore the number of turns at the primary were reduced to half.

10. PHOTOVOLTAIC GENERATORS AS GATE DRIVERS

A photovoltaic generator is a solid state power supply powered by light, normally an LED. The combination of the LED and the photovoltaic generator in one package is called a Photovoltaic Isolator or PVI and is available in a 8-pin DIP package. As a voltage source, the PVI can function as a "dc transformer" by providing an isolated low current to a load. While an optoisolator requires a bias supply to transmit a signal across a galvanic barrier, the PVI actually transmits the energy across the barrier. More information on the PVI can be found in Application Note GBAN-PVI-1 which appears in the Microelectronic Relay Designer' s Manual. This data book also contains the data sheet for the photovoltaic isolator, the PVI1050. A circuit is also provided in the AN to significantly speed up turn off of the switch. As a gate driver the PVI has significant limitations: its short circuit current is in the order of 30 microA with a very high internal impedance. Its simplicity, however, makes it appealing in solid-state relay replacements, where switching times are not important and switching transients are not present.

A typical application is the ac switch described below. The IGBT and the power MOSFET are not suited to switching AC waveforms directly. The IGBT can only conduct current in one direction while the power MOSFET has an anti-parallel diode that will conduct during every negative half-cycle. Bidirectional blocking capability can be achieved by connecting two power MOSFETs source to source, or two IGBTs with anti-parallel diodes emitter to emitter, as shown in Figure 39.

In the case of the MOSFET, there is the possibility that, for low current levels, the current flows through both MOSFET channels, instead that one MOSFETs and diode, thereby achieving lower overall voltage drop. The MOSFET channel is a bidirectional switch, that is, it can conduct current in the reverse direction.

If the voltage across the MOSFET channel is less than the VF of the intrinsic diode (which typically has a higher VF than discrete diodes), then the majority of the current will flow through the MOSFET channel instead of the intrinsic diode. The gate drive for both the MOSFETs and IGBTs must be referenced to the common sources or emitters of the devices. Since this node will be swinging with the AC waveform, an isolated drive is necessary. The PVI can be used, as shown in Figure 40.

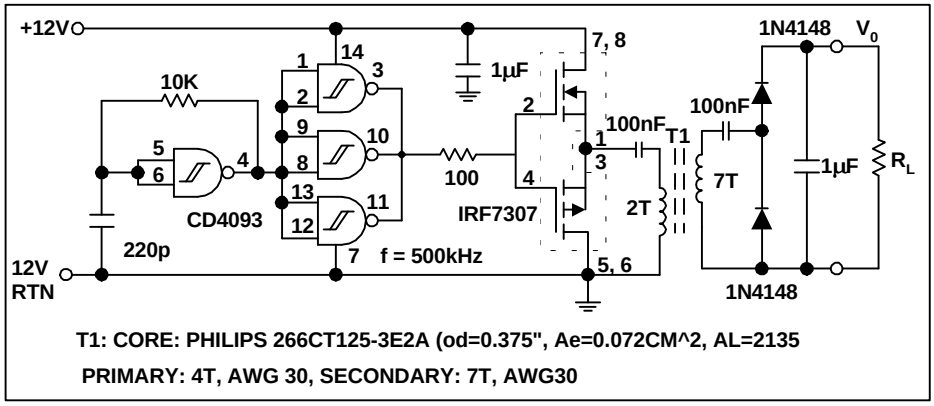

Figure 37a. 500 kHz Forward converter

11. RESONANT GATE DRIVE TECHNIQUES

As indicated in Section 14, gate drive losses in hard switching are equal to Qgs x Vgs x f. An IRF630 operated at 10 Mhz with a gate voltage of 12 V would have *gate drive losses* of 3.6 W, independent from the value of the gate drive resistor. Clearly, to achieve hard switching at this frequency, the resistance of the gate drive circuit is limited to whatever is associated with the internal impedance of the driver and with the gate structure of the device itself. Furthermore, the stray inductance of the gate drive circuit must be limited to tens of nH. The design and layout of such a circuit is not an easy task.

An alternative method to drive the gate in such an application is to design a resonant circuit that makes use of the gate capacitance and stray inductance as its reactive components, adding whatever inductance is necessary to achieve resonance at the desired frequency. This method can reduce the peak of the gate drive current and losses in half, while simplifying the design of the gate drive circuit itself. Since the gate charge is not dissipated at every switching transition, but stored in a reactive component, the gate drive losses are proportional to the resistance of the gate drive circuit, rather than being independent from it. More information on this gate drive method can be found in an article by El-Hamamsy: Design of High-Efficiency RF Class-D Power Amplifier and in references at the end of this article (IEEE Transactions on Power Electronics, May 1994, page 297).

Summary:

- *General guidelines*
- *Steady state sharing*
- *Dynamic sharing at turn-on*
- *Dynamic sharing at turn-off*
- *Related topics*

Whenever devices are operated in parallel, due consideration should be given to the sharing between devices to ensure that the individual units are operated within their limits. Items that must be considered to successfully parallel MOSFETs are: gate circuitry, layout considerations, current unbalance, and temperature unbalance between devices. Paralleling helps to reduce conduction losses and junction to case thermal resistance. However, switching losses remain the same, or may even increase. If they are the dominant losses, only a thermal resistance improvement will be achieved by paralleling. Paralleling to take advantage of lower price of smaller devices should not be attempted without due consideration of the technical risks. Experimental results should be obtained at the extremes of the manufacturing tolerances.

The three most important parameters from this point of view are: voltage, current and junction temperature. Voltage unbalances will be briefly examined in a qualitative way in the next section with other general considerations. The effects of current and temperature unbalances will be analyzed in the following sections.

1. General guidelines on paralleling

Generally speaking, voltage equality is ensured by the fact that the devices are in parallel. However, under transient conditions, voltage differentials can appear across devices, due to di/dt effects in unequalized stray inductances.

The stray inductances of a typical power circuit, like the one shown in Figure 1, have different effects, depending on where they are situated. The effects of the emitter and collector inductances that are common to the paralleled pair have been analyzed in INT-936 and will be ignored here.

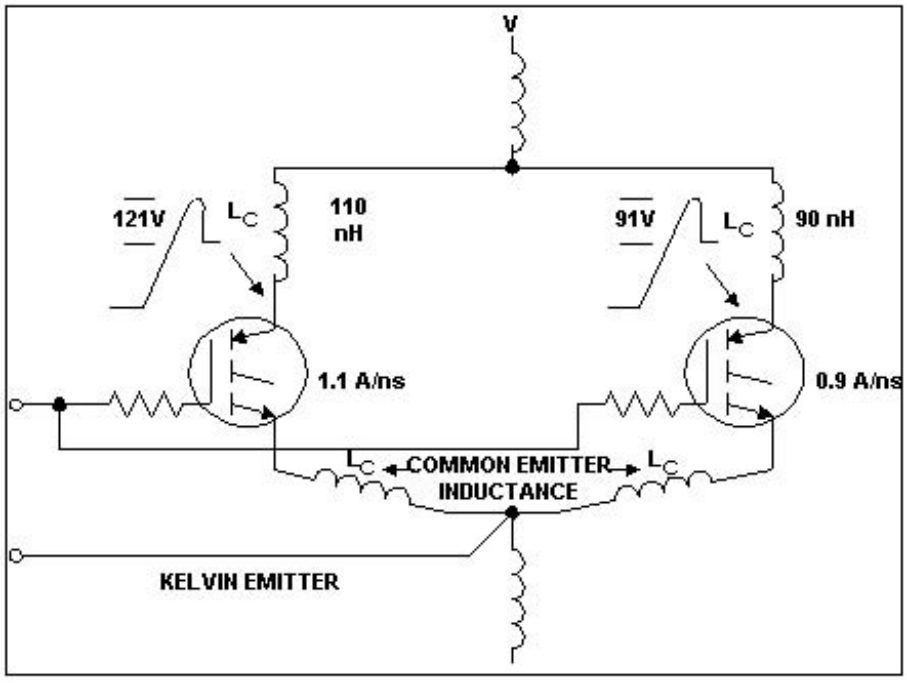

Figure 1. The effect of different di/dt and stray inductances on collector

An unbalance of 10% in the stray inductances that are in series with each collector, combined with a di/dt unbalance of 10% translates in an unbalance of 20% in the overshoot seen at turn-off (81 vs. 121V). To minimize these differentials both di/dt's and stray inductances have to be matched. However, if the overshoot does not violate the ratings of the MOSFET, the differential in the turn-off losses is negligible

The impact of the common emitter inductance on switching energy, on the other hand, is far from negligible, as explained in INT-937. Furthermore, the MOSFET with lower common source inductance turns off before the other, which is left to shoulder the entire load current during the turn-off transient. It follows that switchmode operation of paralleled IGBTs should not be undertaken unless the common emitter inductances are matched in value.

Figure 2 shows that when using paralleled devices, a low impedance path is generated that may be prone to parasitic self oscillations. This is analyzed in greater detail in Ref [1]. Individual gate resistors provide the necessary damping andgate decoupling to prevent oscillations.

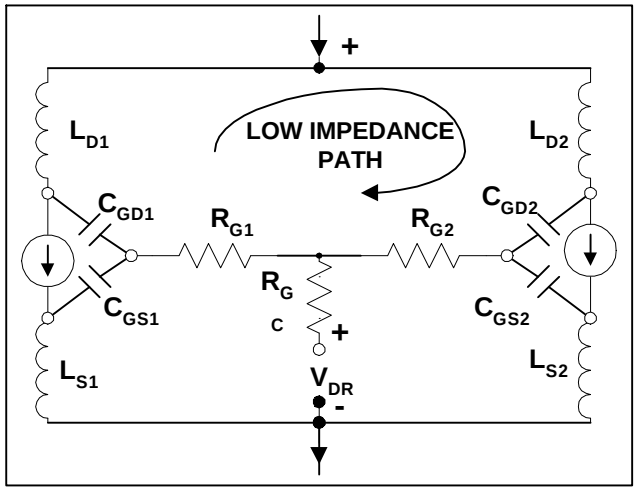

Figure 2. Low impedance Path for Parasitic Oscillation for Unbalanced Parallel Branches

In summary, the following general guidelines should be followed when paralleling MOSFETs:

* Use individual gate resistors to eliminate the risk of parasitic oscillation;

* Equalize common emitter inductance and reduce it to a value that does not greatly impact the total switching losses at the frequency of operation;

* Reduce stray inductance to values that give acceptable overshoots at the maximum operating current.

* Ensure the gate of the MOSFET is looking into a stiff (voltage) source with as little impedance as practical. This advice applies equally well to both paralleled and single device designs.

* Zener diodes in gate drive circuits may cause oscillations. Do not place them directly gate to emitter/source to control gate overvoltage, instead place them on the driver side of the gate isolation resistor(s), if required.

* Capacitors in gate drive circuits may also cause oscillations. Do not place them directly gate to emitter/source to control switching times, instead increase the gate isolation resistor. Capacitors slow down switching, thereby increasing the switching unbalance between devices.

Stray components are minimized by a tight layout and equalized by symmetrical position of components and routing of connections. INTDT 94-2 shows some preferred layout arrangements.

These guidelines ensure that the voltage and switching unbalances due to the layout are negligible with respect to those due to the MOSFETs themselves, analyzed in the next sections.

Two questions must be considered: (1) "steady-state" sharing of current, and (2) dynamic sharing of current under the transitional switching conditions.

2. Steady-State Sharing of Current

During the periods outside of the switching transitions, the current in a parallel group of HEXFET Power MOSFETs will distribute itself in the individual devices in inverse proportion to their ON resistance. The device with the lowest ON resistance will carry the highest current. This will, to an extent, be self-compensating, because the power loss in this device will be the highest. It will run hottest, and the increase in ON resistance due to heating will be more than that of the other devices, which will tend to equalize the current.

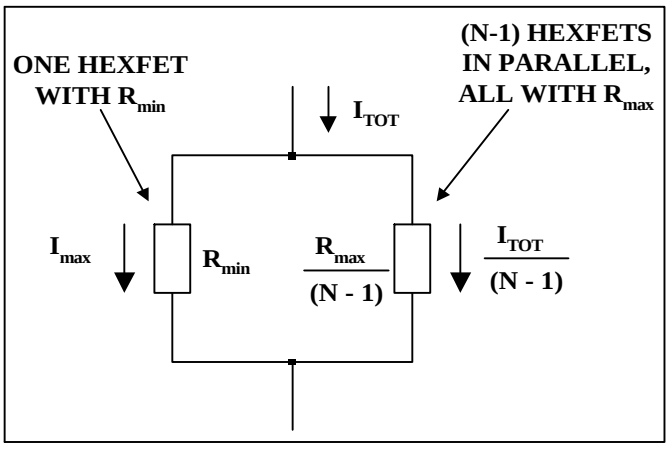

Figure 3. Simplified Equivalent Circuit for Estimating Worst Case Steady-State Current Unbalance

An analysis of the "worst case" device current in a group of "N" parallel connected devices can be based on the simplifying assumption that (N-1) devices have the highest limiting value of ON resistance, while just one lone device has the lowest limiting value of ON resistance. The analysis can then be concentrated on the current in this one device.

The equivalent electrical circuit shown in Figure 3 simplifies the analysis further by assuming the number of devices is sufficiently large that the current that flows through each of the high resistance devices is approximately $I_{TOT}/(N-1)$. On this assumption, the voltage drop across the lone low resistance device, and hence the current in it, can be calculated.

The ON resistance of each of the "high resistance" devices, at operating temperature, T, is given by:

$$\mathbf{R_{(max)T} = R_{(max)25}\left(1+\left[\left(T_A-25\right)+\frac{I^2{}_{TOT}}{(N-1)^2}R_{(max)T}\ R_{JA}\right]K\right)} \quad (1)$$

where $R_{(max)25}$ is the limiting maximum value of ON resistance at 25° C, R_{JA} is the total junction-to-ambient thermal resistance in deg. C/ W, and K is the per unit change of ON resistance per °C.

$$\therefore \quad \mathbf{R_{(max)T} = \frac{R_{(max)25}\left(1+\left[T_A-25\right]K\right)}{1-R_{(max)25}\frac{I^2{}_{TOT}}{(N-1)^2}R_{JA}K}} \quad (2)$$

The voltage drop, V, across the parallel group is: $\mathbf{V = \frac{I_{TOT}}{(N-1)} \bullet R_{(max)T}}$ (3)

The resistance of the one low resistance device at its operating temperature is:

$$\mathbf{R_{(min)T} = R_{(min)25}\left(1+\left[\left(T_A-25\right)+V\ I_{(max)}\ R_{JA}\right]K\right)} \quad (4)$$

where $R_{(min)\ 25}$ is the limiting minimum value of ON resistance at 25°C, and $I_{(max)}$ is the current in this device.

But,

$$R_{(min)T} = \frac{V}{I_{(max)}}$$

$$\therefore \quad I(max) = \frac{-b+\sqrt{(b^2+4aV)}}{2a} \quad (5)$$

where:
$b = R_{(min)\ 25}\ (1 + [T_A - 25]\ K)$
$a = R_{(min)\ 25}\ V\ R_{JA}\ K$

The following example shows the “worst case" degree of current sharing that can be expected, by applying the above relationships to the IRFP150 HEXFET Power MOSFET, and making the following assumptions:

$R_{(max)\ 25} = 0.045\Omega$
$R_{(min)\ 25} = 0.035\Omega$
$R_{JA} = 3$ deg. C/W

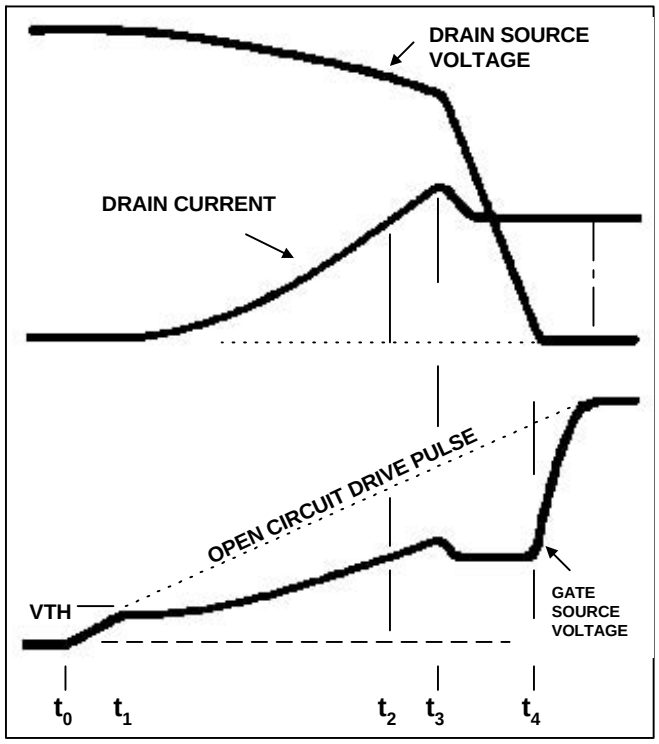
$$\mathbf{\frac{I_{TOT}}{(N-1)} = 20A} \quad (6)$$

K = 0.006 per degree C
$T_A = 35°C$

Using the relationships (2), (3), and (5) above, it can be calculated that the "worst case" maximum value of device current is 27A for the hypothetical situation where all devices but one have high limiting ON resistance, of 0.0452 and carry 20A each, whereas the remaining one has low limiting ON resistance of 0.03Ω.

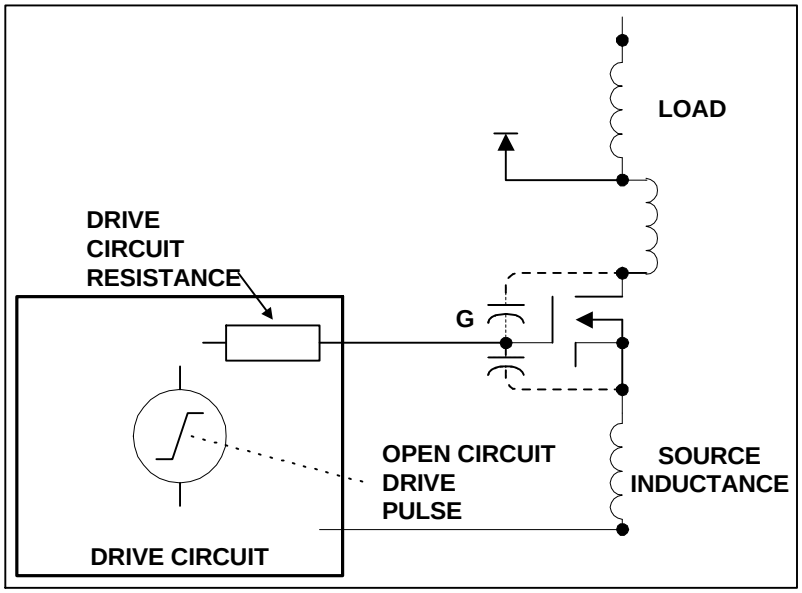
3. Dynamic Sharing of Current during turn-on

It is necessary to take positive steps to ensure that the current is distributed properly between a group of parallel connected devices during the switching transition. Since the HEXFET Power MOSFETs will not all have identical threshold and gain characteristics, some will tend to switch sooner than others, and attempt to take more than their share of the current. Adding to the problem is the fact that circuit inductance associated with each device may be different, and this will also contribute to unbalancing the current under switching conditions. Here we will provide a brief qualitative description of the different events that occur during a switching transition.



The problem will be introduced by considering the switching waveforms for a typical clamped inductive load. Figure 4 shows waveforms of drain current, drain-to-source voltage, and gate voltage during the turn-ON interval. For reasons of clarity we have shown the applied drive pulse increasing at a relatively slow rate.

At time, t_0, the drive pulse starts its rise. At t_1, it reaches the threshold voltage of the HEXFET Power MOSFET, and the drain current starts to increase. At this point, two things happen which make the gate-source voltage waveform deviate from its original “path." First, inductance in series with the source which is common to the gate circuit develops an induced voltage, as a result of the increasing source current. This voltage counteracts the applied gate drive voltage and slows down the rate-of-rise of voltage appearing directly across the gate and source terminals; this, in turn, slows down the rate-of-rise of the source current. This is a negative feedback effect; increasing current in the source produces a counteractive voltage at the gate, which tends to resist the change of current.



The second factor that influences the gate-source voltage is the so called "Miller" effect. During the period t_1 to t_2, some voltage is dropped across circuit inductance in series with the drain, and the drain-source voltage starts to fall. The decreasing drain-source voltage is reflected across the drain-gate capacitance, pulling a discharge current through it, and increasing the effective capacitance load on the drive circuit. This, in turn, increases the voltage drop across the impedance of the drive circuit and decreases the rate-of-rise of voltage appearing between the gate and source terminals. This also is a negative feedback effect; increasing current in the drain results in a fall of drain-to-source voltage, which, in turn, slows down the rise of gate-source voltage and tends to resist the increase of drain current. These effects are illustrated diagrammatically in Figure 5.

Figure 4. Waveforms at Turn-ON

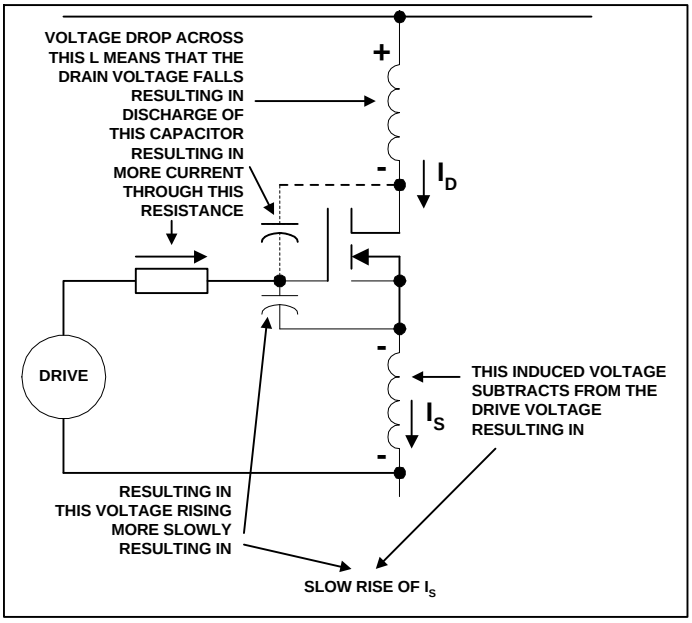


Figure 5. Diagrammatic Representation of Effects When Switching-ON

This state of affairs continues throughout the period t_1 to t_2, while the current in the HEXFET Power MOSFET rises to the level of the current, I_M, already flowing in the freewheeling rectifier, and it continues into the next period, t_2 to t_3, while the current increases further, due to the reverse recovery of the freewheeling rectifier.

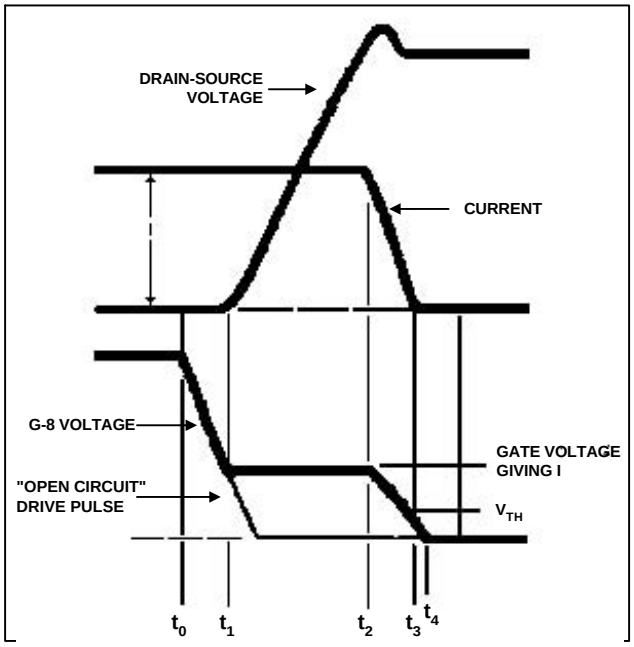
At time t_3, the freewheeling rectifier starts to support voltage, while the drain current and the drain voltage start to fall. The rate-of-fall of drain voltage is now governed by the Miller effect, and an equilibrium condition is reached, under which the drain voltage falls at just the rate necessary for the voltage between gate and source terminals to satisfy the level of drain current established by the load. This is why the gate-to-source voltage falls as the recovery current of the freewheeling rectifier falls, then stays constant at a level corresponding to the motor current, while the drain voltage is falling.

Finally, at time t_4, the HEXFET Power MOSFET is switched fully ON, and the gate-to-source voltage rises rapidly towards the applied "open circuit" value.

The above explanation, summarized in Figure 5, provides the clue to the difficulties that can be expected with parallel connected devices. The first potential difficulty is that if we apply a common drive signal to all gates in a parallel group, then the first device to turn ON—the one with the lowest threshold voltage—will tend to slow the rise of voltage on the gates of the others, and further delay the turn-ON of these devices. This will be due to the Miller effect. The inductive feedback effect, on the other hand, only influences the gate voltage of its own device (assuming that each source has its own separate inductance).
The second potential difficulty is that if the individual source inductances are unequal, then this will result in dynamic unbalance of current, even if the devices themselves are perfectly matched. Obviously, the solution to this is to ensure that inductances associated with the individual devices are as nearly equal as possible. This can be done by proper attention to the circuit layout.

As examined in detail in Ref. [1], there are several other circuit and device parameters that will contribute to dynamic unbalance. The conclusions presented in the above mentioned paper indicate, however, that the problem is not severe, as long as attention is paid to the following points, in order to ensure satisfactory sharing of current between parallel HEXFET Power MOSFETs at turn-ON:

- Threshold voltages should be within determined limits.
- Stray inductances throughout the circuit should be equalized by careful layout.
- Gates should be decoupled with individual resistors, but not more than strictly required, as it will be explained later.



4. Dynamic sharing during turn-Off

Similar considerations apply to the dynamic sharing of current during the turn-OFF interval. Figure 6 shows theoretical waveforms for the circuit of Figure 4 and 5 during the turn-OFF interval. At t_0, the gate drive starts to fall. At t_1, the gate voltage reaches a level that just sustains the drain current, I. The drain-to-source voltage now starts to rise. The Miller effect governs the rate-of-rise of drain voltage and holds the gate-to-source voltage at a level corresponding to the constant drain current. At t_3, the rise of drain voltage is complete, and the gate voltage starts to fall at a rate determined by the gate-source circuit impedance, while the drain current falls to zero.

Figure 6. Waveforms at TURN-OFF

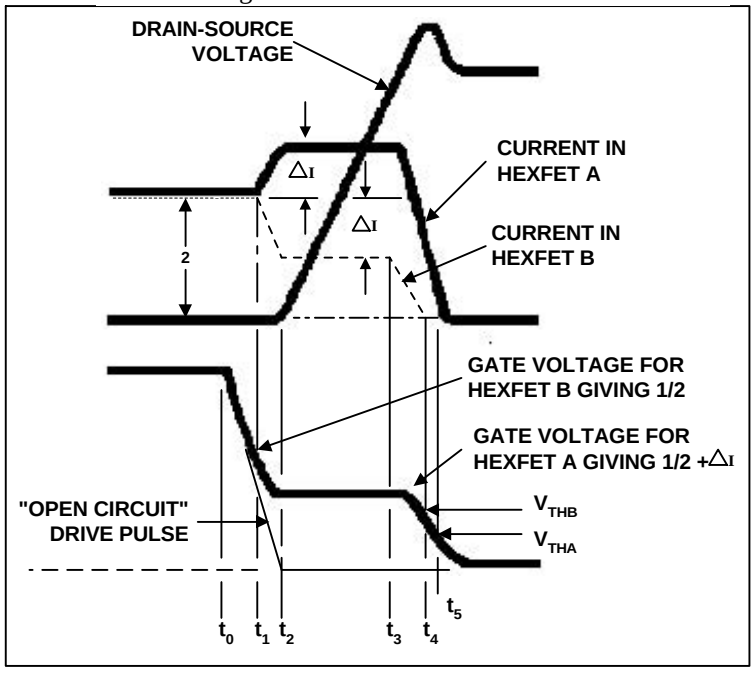


Figure 7 shows theoretical waveforms for two parallel connected HEXFET Power MOSFETs with their gates connected directly together. For purposes of discussion, the source inductance is assumed to be zero. At t_1, the gate voltage reaches the point at which HEXFET Power MOSFET B can no longer sustain its drain current.

The load current now redistributes; current in HEXFET Power MOSFET B decreases, while that in HEXFET Power MOSFET A increases. At t_2, HEXFET Power MOSFET B can no longer sustain its current; both HEXFET Power MOSFETs now operate in their 'linear" region, and the drain voltage starts to rise. The gate-to-source voltage is kept practically constant by the Miller effect, while the currents in the two HEXFET Power MOSFETs remain at their separate levels. Clearly, the unbalance of current in this example is significant.

While a turn-off unbalance is potentially a more serious problem, the analysis in Ref. [1] shows that this is not so in practice as long as the devices are turned off with a "hard" (very low impedance) gate drive. This by itself will almost guarantee limited dynamic unbalance at turn-off.

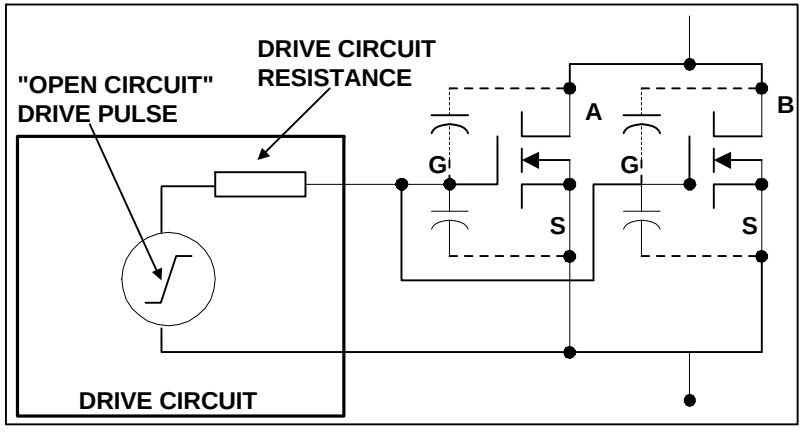

Figure 7. Waveforms at Turn-OFF - Two HEXFET Power MOSFETs with Common Gates and Common Sources

In summary, to achieve good sharing at turn-off the same precautions should be used as for turn-on, with the addition of a "hard" drive.

1. Input behavior of a MOS-gated transistor

Designers unfamiliar with MOSFET or IGBT input characteristics begin drive circuit design by determining component values based on the gate-to-source, or input, capacitance listed on the data sheet. RC value based on the gate-to-source capacitance normally lead to a gate drive that is hopelessly inadequate.

Although the gate-to-source capacitance is an important value, the gate-to-drain capacitance is actually more significant—and more difficult to deal with—because it is a non-linear capacitance affected as a function of voltage; the gate-to-source capacitance is also affected as a voltage function, but to a much lesser extent. This gate-to-drain capacitance function is similar to that found in vacuum tube amplifiers.

The gate-to-drain capacitance effect is akin to the “Miller” effect, a phenomenon by which a feedback path between the input and output of an electronic device is provided by the interelectrode capacitance. This affects the total input admittance of the device which results in the total dynamic input capacitance generally being greater than the sum of the static electrode capacitances. The phenomenon of the effects of the plate impedance and voltage gain on the input admittance was first studied in vacuum tube triode amplifier circuits by John M. Miller. Essentially, at high frequencies where the grid-to-plate (gate-to-drain) capacitance is not negligible, the circuit is not open but involves a capacitance that is a function of the voltage gain. Solving for the "Miller" effect is not exactly a straightforward process, even with vacuum tubes where much is known, but is even more difficult in MOSFETs. In actuality, the gate-to-drain capacitance though smaller in static value than the gate-to-source capacitance, goes through a voltage excursion that is often more than 20 times that of the gate-to-source capacity. Therefore, the gate-to-drain or “Miller” capacitance typically requires more actual charge than the input capacitance.

To account for both gate-to-source and gate-to-drain capacitance in a way readily usable by designers, International Rectifier supplies a “gate charge” specifications for its IGBTs and HEXFET POWER MOSFETs. that can be used to calculate drive circuit requirements. Gate charge is defined as the charge that must be supplied to the gate, either to swing the gate by a given amount, or to achieve full switching.

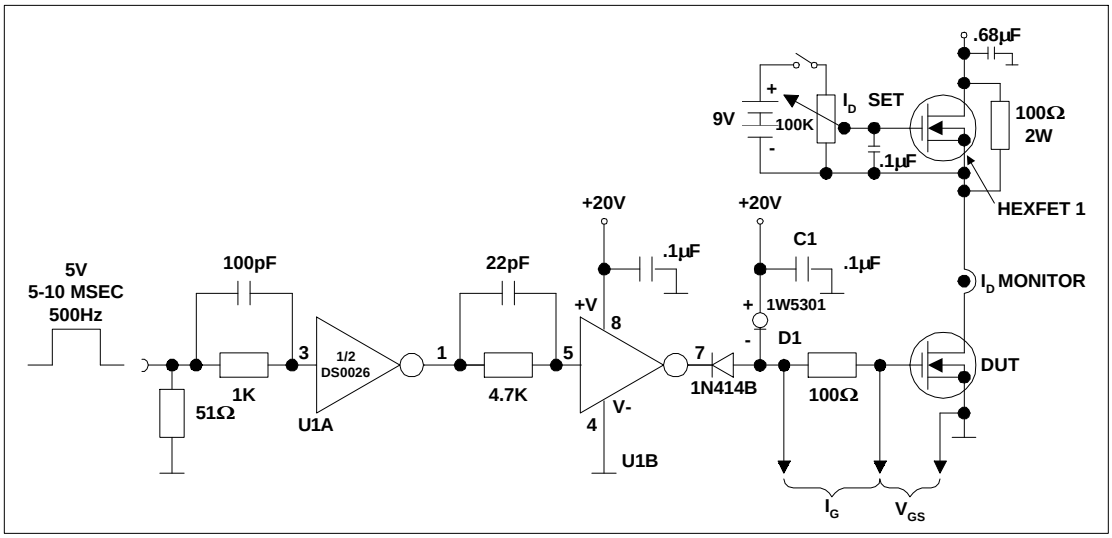

Figure 1. HEXFET POWER MOSFET Gate Charge Circuit.

2. Test Circuit

A typical test circuit that can be used to measure the gate charge is shown in Figure 1. In this circuit, an approximately constant current is supplied to the gate of the device-under-test from the 0.1 microfarad capacitor C1, through the regulator diode D1. A constant current in the drain circuit is set by setting the voltage on the gate of HEXFET POWER MOSFET 1, so the net measurement of the charge consumed by the gate is relative to a given current and voltage in the source-to-drain path.

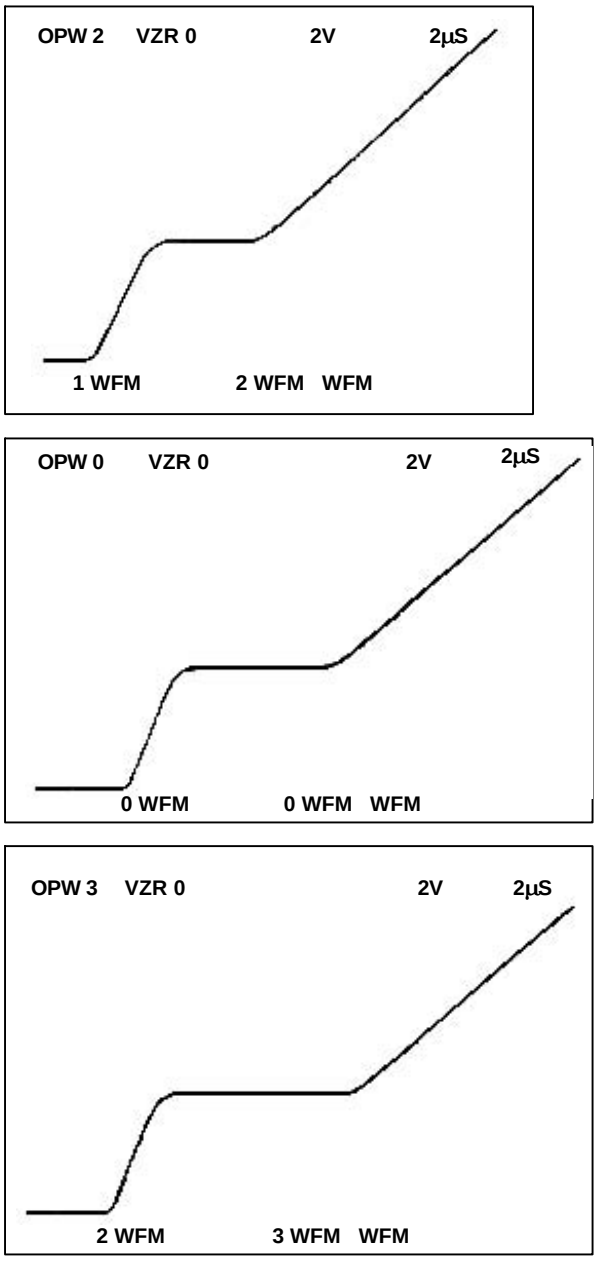

Figure 2. Gate Charge Waveform for Different Values of Drain Voltage (IRF130: l_G = 1.5 mA, I_D =1A, V_{DD} = 10, 40 and 80 volts).

The importance of the gate charge data to the designer is illustrated as follows. Taking the charge are required to switch a previous example, about 15 nanocoulombs of gate if 1.5 amps is supplied to the gate, the device will be drain voltage of 80 volts and a drain current of 12 amps. Since the 15 nC gate charge is the product of the gate input current and the switching time, switched in 10 nS. It follows that if 15 mA is supplied to the gate, then switching occurs in 1 us, and so on. These simple calculations immediately tell the designer the trade-offs between the amount of current available from the drive circuit and the achievable switching time. With gate charge known, the designer can develop a drive circuit appropriate to the switching time required.

Consider a typical practical example of a 100 kHz switcher, in which it is required to achieve a switching time of 100 nanoseconds.

An oscillogram of the gate-to-source voltage during testing, shown in Figure 2, relates the gate voltage to time. Since a constant current is supplied to the gate, the horizontal time scale is directly proportional to the charge supplied to the gate. With a suitable scaling factor, therefore, this oscillogram is a plot of gate voltage versus charge. The point on the oscillogram of the second voltage rise indicates where the device is fully switched on. During the first voltage rise, the gate-to-source capacitance is charging, and during the flat portion, the gate-to-drain capacitance is charging. This oscillogram therefore clearly differentiates between the charge required for the gate-source and gate-to-drain ("Miller") capacitances. At the second voltage rise, both capacitances are charged to the extent needed to switch the given voltage and current. A more detailed explanation of the interpretation of this data is given later. The graph in Figure 3 represents gate voltage versus gate charge in nanocoulombs for an IRF130. Although the second voltage rise indicates the point at which the switching operation is completed, normal design safety margins will dictate that the level of drive voltage applied to the gate is greater than that which is just required to switch the given drain current and voltage. The total charge consumed by the gate will therefore in practice be higher than the minimum required-but not necessarily significantly so. For example, the gate charge required to switch 12 amps at 80 volts is 15 nanocoulombs (point A), and the corresponding gate voltage is about 7 volts.

If the applied drive voltage has an amplitude of 10 volts (i.e. a 3 volt margin), then the total gate charge actually consumed would be about 20 nanocoulombs, (point B). As shown on the graph, whether switching 10 volts or 80 volts in the drain circuit, there is a much less than proportional difference in the charge required. This is because the "Miller" capacitance is a nonlinear function of voltage, and decreases with increasing voltage.

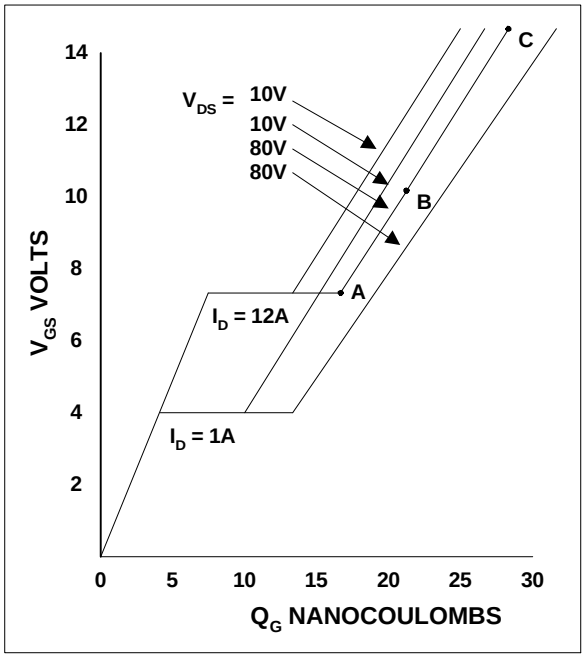

Figure 3. Gate Voltage Versus Gate Charge for the IRF130.

The required gate drive current is derived by simply dividing the gate charge, 15 X 10^{-9}, by the required switching time, 100 X 10^{-9}, giving 150 mA. From this calculation, the designer can further arrive at the drive circuit impedance. If the drive circuit applies 14 volts to the gate, for instance, then a drive impedance of about 50 ohms would be required. Note that throughout the "flat" part of the switching period (Figure 3), the gate voltage is constant at about 7 volts. The difference between the applied 14 volts and 7 volts is what is available to drive the required current through the drive circuit resistance.

The gate charge data also lets the designer quickly determine average gate drive power. The average gate drive power, P_{DRIVE}, is $Q_G V_G f$. Taking the above 100 kHz switcher as an example, and assuming a gate drive voltage V_G of 14 volts, the appropriate value of gate charge Q_G is 27 nanocoulombs (point C on Figure 3). The average drive power is therefore 27 X 10^{-9} X 14 X 10^5 = 0.038 Watts. Even though the 150 mA drive current which flows during the switching interval may appear to be relatively high. the average power is minuscule (0.004%) in relation to the power being switched in the drain current. This is because the drive current flows for such a short period that the average power is negligible. Thus actual drive power for MOSFETs is minute compared to bipolar requirements, which must sustain switching current during the entire ON condition. Average drive power, of course, increases at higher frequencies, but even at 5 MHz it would be only 1.9W.

3. The Gate Charge Curve

The oscillograms of the gate-to-source voltage in Figure 2 neatly delineate between the charge required for the gate-to-source capacitance, and the charge required for the gate-to-drain, or "Miller" capacitance. The accompanying simplified test circuit and waveform diagram (Figures 4 and 5 respectively) give the explanation. Before time t_0, the switch S is closed; the device under test (DUT) supports the full circuit voltage, V_{DD}, and the gate voltage and drain current are zero. S is opened at time t_0; the gate-to-source capacitance starts to charge, and the gate-to-source voltage increases. No current flows in the drain until the gate reaches the threshold voltage. During period T_1 to t_2, the gate-to-source capacitance continues to charge, the gate voltage continues to rise and the drain current rises proportionally. So long as the actual drain current is still building up towards the available drain current, I_D, the freewheeling rectifier stays in conduction, the voltage across it remains low, and the voltage across the DUT continues to be virtually the full circuit voltage, V_{DD}. The top end of the drain-to-gate capacitance C_{AD} therefore remains at a fixed potential, whilst the potential of the lower end moves with that of the gate. The charging current taken by C_{AD} during this period is small, and for practical purposes it can be neglected, since C_{AD} is numerically small by comparison with G_{CS}.

At time t_2, the drain current reaches I_D, and the freewheeling rectifier shuts off; the potential of the drain now is no longer tied to the supply voltage, V_{DD}. The drain current now stays constant at the value I_D enforced by the circuit, whilst the drain voltage starts to fall. Since the gate voltage is inextricably related to the drain current by the intrinsic transfer characteristic of the DUT (so long as operation remains in the "active" region), the gate voltage now stays constant because the "enforced" drain current is constant. For the time being therefore, no further charge is consumed by the gate-to-source capacitance, because the gate voltage remains constant. Thus the drive current now diverts, in its entirety, into the "Miller" capacitance C_{AD}, and the drive circuit charge now contributes exclusively to discharging the "Miller" capacitance.

The drain voltage excursion during the period t_2 to t_3 is relatively large, and hence the total drive charge is typically higher for the "Miller" capacitance C_{AD} than for the gate-to-source capacitance G_{CS}. At t_3 the drain voltage falls to a value equal to I_D x $R_{DS(ON)}$, and the DUT now comes out of the "active" region of operation. (In bipolar transistor terms, it has reached "saturation."

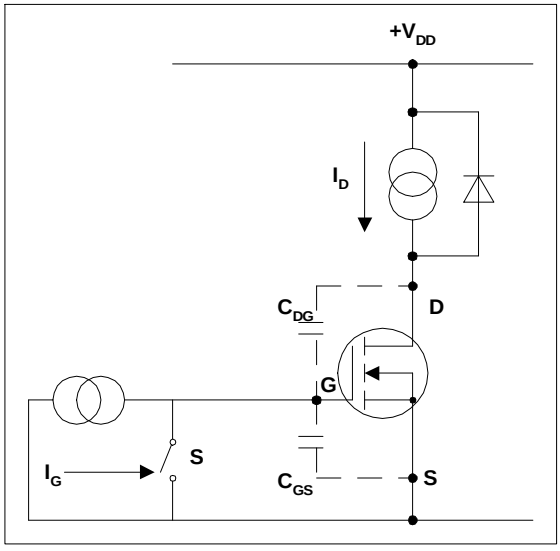

Figure 4. Basic Gate Charge Test Circuit

The gate voltage is now no longer constrained by the transfer characteristic of the device to relate to the drain current, and is free to increase. This it does, until time t_4, when the gate voltage becomes equal to the voltage "behind" the gate circuit current source. The time scale on the oscillogram of the gate-to-source voltage is directly proportional to the charge delivered by the drive circuit, because charge is equal to the product of current and time, and the current remains constant throughout the whole sequence. Thus the length of the period t_0 to t_1 represents the charge Q_{GS} consumed by the gate-to-source capacitance, whilst the length of the period t_2 to t_3 represents the charge Q_{GD} consumed by the gate-to-drain or "Miller" capacitance. The total charge at time t_3 is the charge required to switch the given voltage V_{DD} and current I_D. The additional charge consumed after time t_3 does not represent "switching" charge; it is simply the excess charge which will be delivered by the drive circuit because the amplitude of the applied gate drive voltage normally will be higher (as a matter of good design practice) than the bare minimum required to accomplish switching.

4. Beware When Comparing Different Products

Manufacturers sometimes make technical claims for their products that appear to be plausible, but which in actuality do not stand up to scrutiny. A case in point concerns the input capacitance of a power MOSFET. Statements such as "the input capacitance of device Y is less than that of device X, ergo Y is a faster switch than X", are frequently bandied about, but are just as frequently erroneous. Apart from the obvious speciousness of many such statements — "apples" are frequently not compared with "apples", and obviously larger chips have more self capacitance than smaller ones—the more basic fundamentals are generally overlooked. As this application note shows, of "bottom line" importance is the total gate charge required for switching. The lower the charge, the lower is the gate drive current needed to achieve a given switching time.

A general comparison between hypothetical MOSFETs brands "X" and "Y" is illustrated in the Figure. Device X has a higher input capacitance; hence the initial slope of its gate charge characteristic is less than that of device Y. Q_{GS} of device X is, however, about the same as that of device Y, because it has a higher transconductance and therefore requires less voltage on its gate for the given amount of drain current (V_{GX} is less than V_{GY}) The "Miller" charge consumed by device X is considerably less than that consumed by device Y. The overall result is that the total charge required to switch device X, Q_X, is considerably *less* than that required to switch device Y, Q_Y. Had the comparison between devices X and Y been made on the more superficial basis of input capacitances, it would have been concluded— erroneously— that Y is "better" than X. Another consideration is the energy required for switching. Again, device X scores handsomely over device Y in this example. The energy is the product of the gate charge and the gate voltage, and is represented by the area of the rectangle whose corner lies at the "switching point". (Point 1 for device X, and point 2 for device Y.) It is obvious that X requires significantly less gate energy than Y. To summarize: beware of superficial comparisons. Check the full facts before deciding which MOSFET really has the edge in switching performance.

The class AB amplifier described in this application note uses a complementary pair of HEXFET Power MOSFET devices as the output stage. This feature offers performance improvements over the equivalent bipolar output stage and allows a reduction in the complexity of the driver circuit, the output devices being driven by a single class A driver. At the time the work was done, logic level HEXFET Power MOSFETs were not available and standard devices were used. The use of low-threshold devices would simplify the bias circuit and reduce the quiescent power dissipation The design described will deliver 60W rms into a 4 ohm load when working from +30V supplies. The bandwidth is in, excess of l00kHz, but may be tailored to the user requirements by making component value changes.

1. CIRCUIT DESCRIPTION

The amplifier circuit diagram is shown in Figure 1, and the components listing in Table 1. Split power supply rails ($\pm V_{DD}$) are used, giving improved rejection of power supply ripple and allowing the load, R_{load}, to be direct coupled. The output devices Q_5, Q_6 , operate in source follower configuration. This offers a twofold advantage; a) the possibility of oscillation in the power output stage is reduced as the voltage gain is less than unity and b) signal feedback through the heatsink on which the devices are assembled is eliminated as the drain terminal, which is electrically connected to the tab on the TO220 package, is at dc voltage.

Symmetrical output is achieved by providing "bootstrapped" drive to the gate of the n-channel device, Q_5, from the output. The use of the bootstrap circuit, C_4, R_8, R_9 also allows the driver transistor, Q_4, to operate at near constant current which improves the linearity of the driver stage. The diode D_1 acts as a clamp for the bootstrap circuit, restricting the positive voltage at the gate of Q_5 to $+V_{DD}$. This allows symmetry to be maintained under overload conditions.

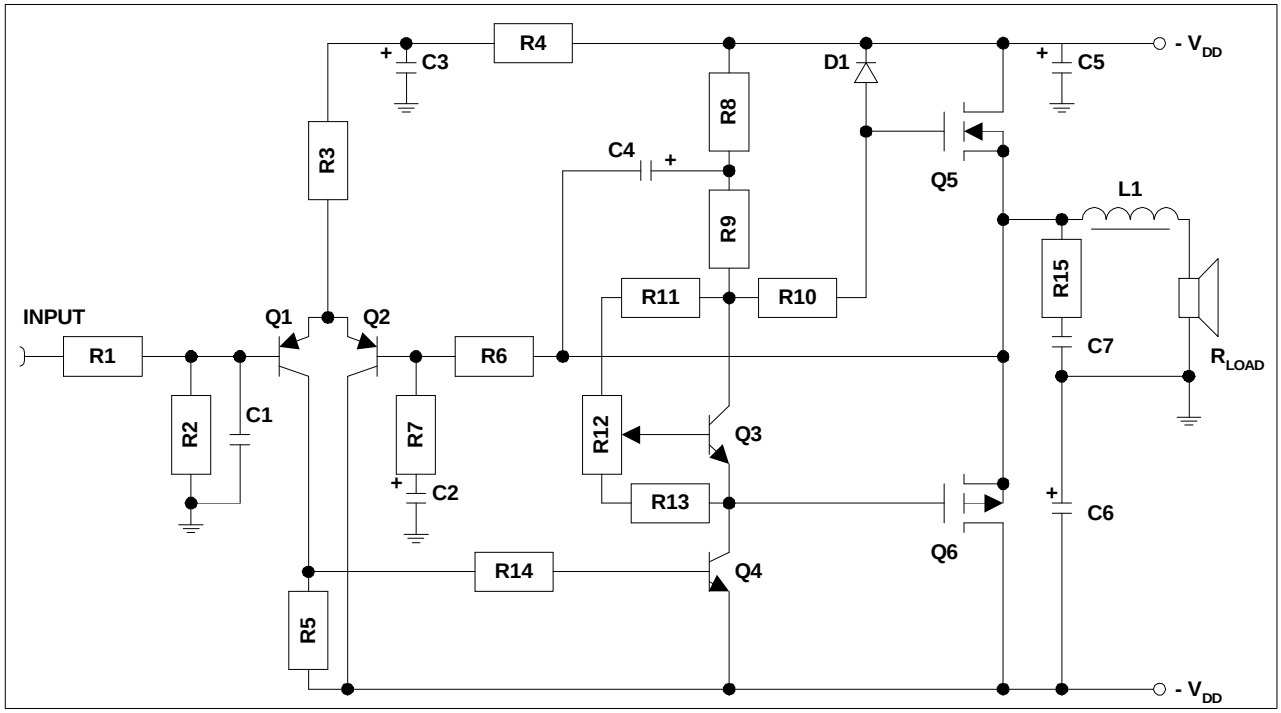

Figure 1. Class AB Amplifier Circuit Diagram

Transistor Q_3 and resistors R_{11}, R_{12}, R_{13} provide gate-source offset voltage for the output devices. R_{12} is variable, allowing adjustment of the output quiescent current for variation in HEXFET Power MOSFET threshold voltage. A degree of temperature compensation is built into the circuit as both the bipolar transistor, Q_3, emitter base voltage and the combined threshold voltages of the HEXFET Power MOSFETs, Q_5, Q_6 have a temperature coefficient of -0.3%/°C.

Table 1. Components List

The class A driver transistor, Q_4, operates at a bias current determined by resistors R_8, R_9, nominally 5mA. Q_4 is driven by a PNP differential input pair, Q_1, Q_2. The bias current in the input stage is set to 2mA by resistor R_3. Negative feedback from the output of the amplifier is fed to the base of Q_2 by resistor R_6. Components R_7, C_2 set the closed loop gain of the amplifier (R_6 /R_7) and provide low frequency gain boosting. The additional components R_{15}, C_7 connected between the output node and ground suppress the high frequency response of the output stage, allowing the h.f. performance of the amplifier to be determined by the input circuit. Components R_1, R_2, C_1 at the input of the amplifier define the input impedance (47Kohm) and suppress noise.

The amplifier input stage requires additional power supply ripple suppression which is provided by components R_4, C_3.

Additional circuit components have been added to ensure high frequency stability of the complete amplifier. Placement of the components and component values will depend to some extent on the printed circuit board layout. The following rules should be followed when designing the printed circuit board:

(a) A 'common ground' principle should be

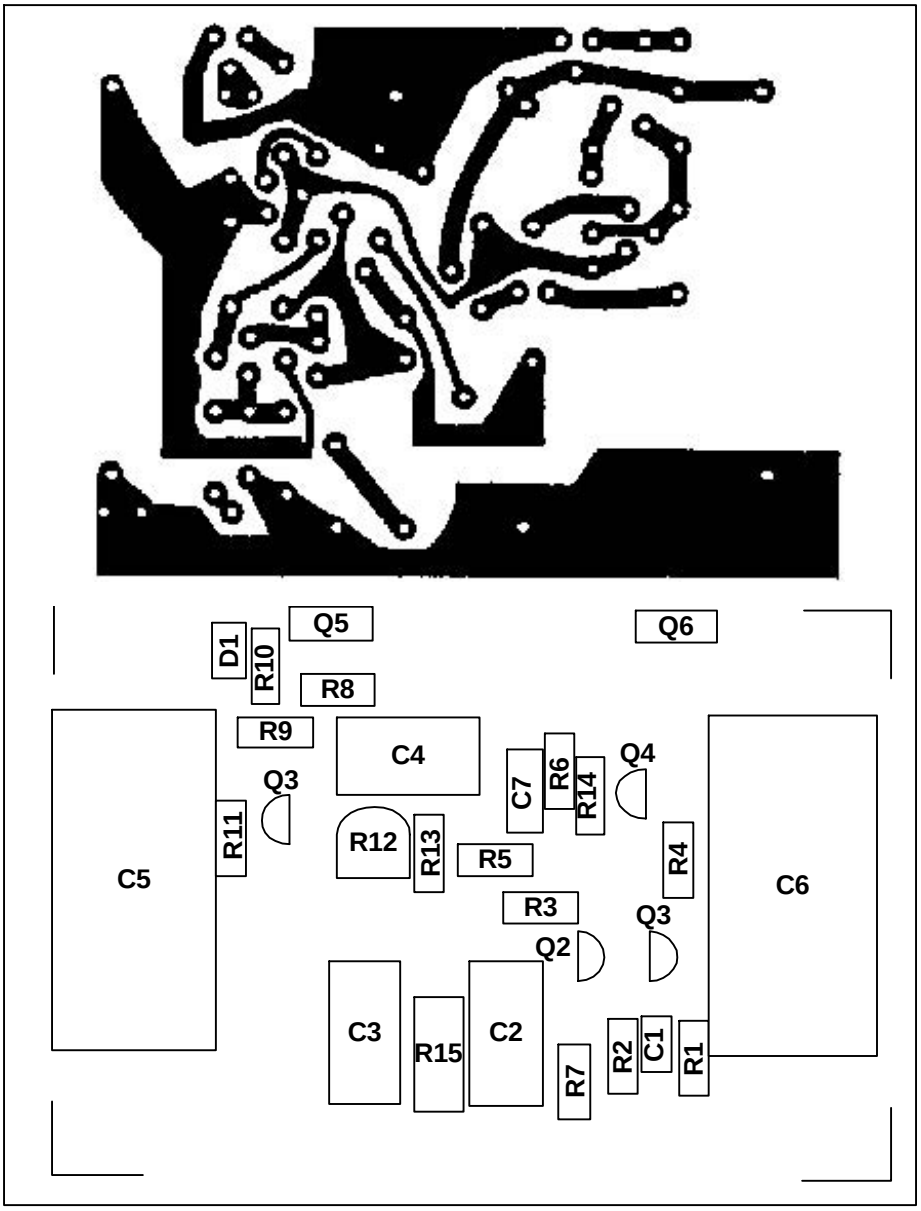

Figure 2. Amplifier Printed Circuit Board Layout

adopted, i.e., power supply decoupling capacitors, load and input stage biasing components should all be taken to ground in close proximity, eliminating the effects of common node ground current. Similarly, a "common output node" should be used, the load, feedback resistor and h.f. suppression components being taken from a common point on the pcb.

(b) The length of connecting lead to the gate terminals of HEXFET Power MOSFETs Q_5, Q_6 should be an absolute minimum to avoid oscillation of the power output stage. A series gate resistor, R_{10}, may be used to suppress oscillation, but too high a resistor value will limit the slew rate. Oscillation of the amplifier caused by capacitive coupling to the base of the driver transistor, Q_4, is suppressed by the addition of a series resistor, R_{14}.

(c) Phase shift in the amplifier when driving a reactive load can lead to high frequency instability. With a capacitive load, the addition of a small, air-cored choke (3µH with an 8 ohm, 2µF load) will restore stability. The final value of the choke is defined by experiment.

Figure 2 shows a printed circuit layout which can be used for the circuit shown in Figure 1. The preceding design rules have been followed.

2. AMPLIFIER PERFORMANCE

(a) *Output Power:* To achieve 60W rms into a 4 ohm load, the current in the load is 3.9A rms or 5.5A pk. This information is derived from equations (1) and (2):

$$P_O = I^2_{rms} R_{load} = \frac{V^2_{rms}}{R_{load}} \qquad (1)$$

$$I_{rms} = \frac{I_{pk}}{\sqrt{2}} \qquad (2)$$

$$V_{rms} = \frac{V_{pk}}{\sqrt{2}} \qquad (3)$$

Also from equation (1), the voltage developed across the load at 60W output is 15.5V rms or 22V pk. To sustain a source current of 5.5A, the n-channel HEXFET Power MOSFET, IRF530, requires a gate-source voltage of 5V. One can conclude that the gate bias voltage to achieve peak power in the positive sense is $V_{pk} + V_p = 27V$. A similar calculation for the negative peak, using the P channel HEXFET Power MOSFET IRF9530, shows that a negative gate bias supply of -28V is required.

Consequently, a ±30V supply will be adequate for a 60W output, provided that the supply voltage does not fall below ±28V when loaded, i.e., the power supply impedance should be better than 1 ohm. The relationship between the power delivered to the load and the power absorbed from the supply is shown in Figure 3, assuming a sinusoidal waveform and a ±30V supply. The curve representing the power delivered to the load can be easily plotted with the help of equation (1) for different values of load current.

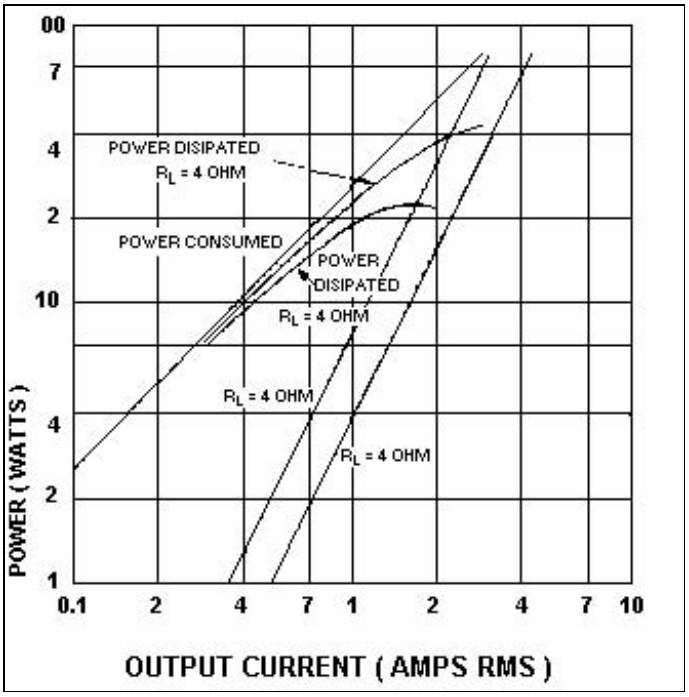

Figure 3. Power Curves for the Amplifier with 4 and 8 Ohm Loads and ± 30V Power Suuplies

The power absorbed from the supply has been plotted with the help of the following relationship:

$$P_S = \left(V_{avg}\right)\left(I_{avg}\right)$$
$$= \left(2V_{DC}\right)\left(\frac{\sqrt{2}}{\pi} I_{rms}\right) \qquad (4)$$

The difference between the two is the power dissipated in the HEXFET Power MOSFETs and as it can be seen from Figure 3, it has a peak of approximately 46W. Assuming a maximum ambient temperature of 55°C, the total thermal resistance between the junction of the two HEXFET Power MOSFETs and the ambient will have to be less than 2°C/W. Considering that the IRF530 and IRF9530 have a thermal resistance between junction and case of 1.7°C/W each, the maximum case temperature will have to be less than 110°C and the thermal resistance of the heatsink will have to be less than 1.15°C/W to ambient.

(b) *Frequency Response*: Open shown in Figure 4. The open loop gain, measured with gate and source connections to the HEXFET Power MOSFETs broken, is 30db, -3db points occurring at 15 Hz and 60kHz. Closed loop curves are shown for amplifier gains of 100 (R_7 = 470 ohm) and 20 (R_7 = 2.2K ohm). In both instances the curves remain flat to within +1db between 15 Hz and 100kHz with an 8 ohm load. The slew rate of the amplifier, measured with a 2V pk-pk square wave input is 13V/µs positive going and 16V/µs negative going. The discrepancy could be balanced out by addition of a series gate resistor for Q_6.

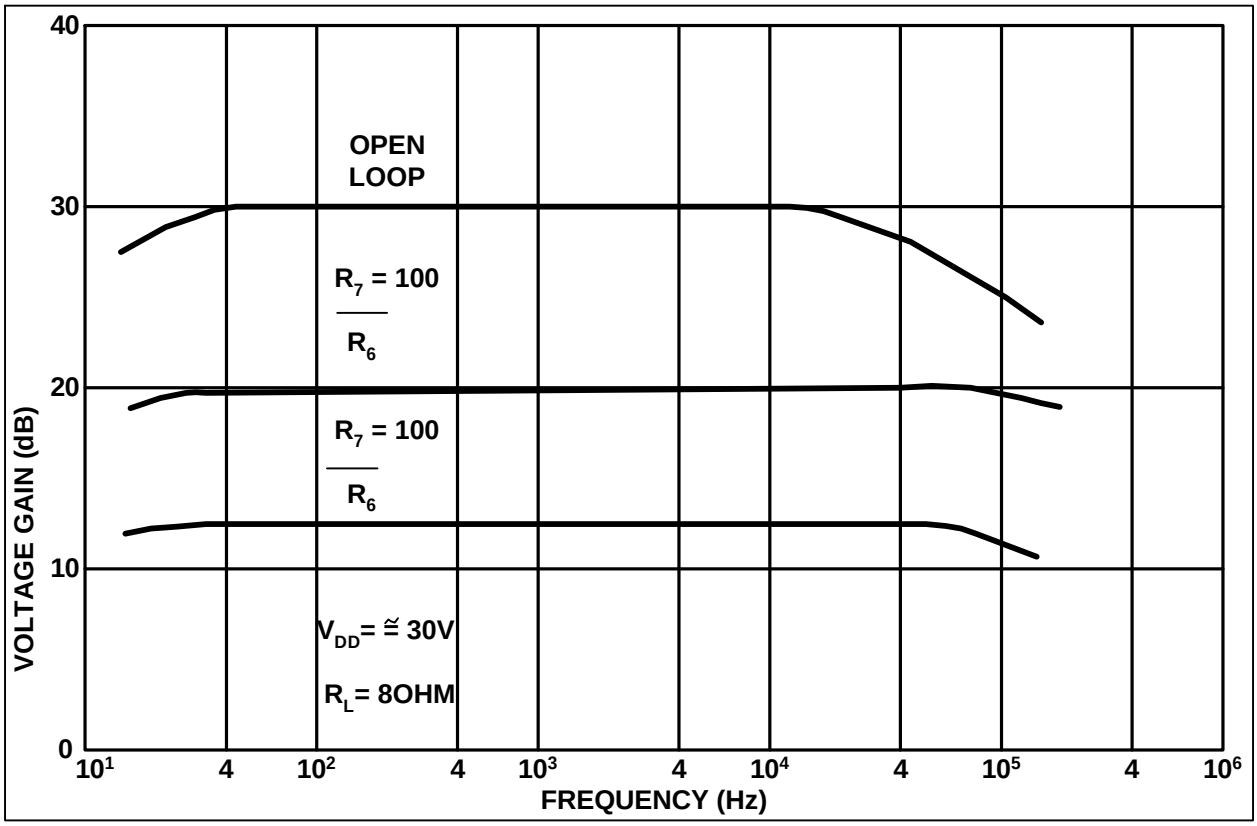

Figure 4. Amplifier Open and Closed Loop Frequency Response Curves

(c) *Total Harmonic Distortion*: The fidelity of the amplifier is shown in the distortion curves, Figure 5, and is limited by the loop gain. Reduction of the closed loop gain from 100 to 20 produces a significant improvement in distortion figure. The output stage quiescent current was adjusted to 100mA and can influence the distortion measurement significantly if allowed to fall below 50mA.

(d) Quiescent Operating: The dependence of the quiescent current in the output stage and of the offset voltage on power supply voltage are illustrated in Table 2. The quiescent current is set by first adjusting the potentiometer, R_{12}, for minimum offset voltage-turned fully anticlockwise if the pcb layout in Figure 2 is used - and applying the power supply voltage, the positive

supply passing through an ammeter with 1A f.s.d. R_{12} is then adjusted until the meter reading is 100mA with ±30V supplies. The meter should be removed from circuit before applying an input signal to the amplifier.

3. POWER SUPPLY REGULATION REQUIREMENTS

A simple line derived power suitable for the class AB amplifier is illustrated in Figure 6. The ±30V supplies are taken from the centertapped secondary of the line transformer. The 2200µF decoupling capacitors, (Figure 1) which should be mounted as close as possible to the amplifier output stage, reduce the supply frequency ripple to 5.5V pk-pk at full load.

4. SET-UP PROCEDURE AND TROUBLESHOOTING

It is unlikely that any experienced experimenter will have difficulty in achieving satisfactory results when building an amplifier to this design. The printed circuit board shown in Figure 2 is intended to assist in this respect. The major problems anticipated are those associated with the faulty assembly of components and damage to the HEXFET Power MOSFETs through handling or circuit oscillation.

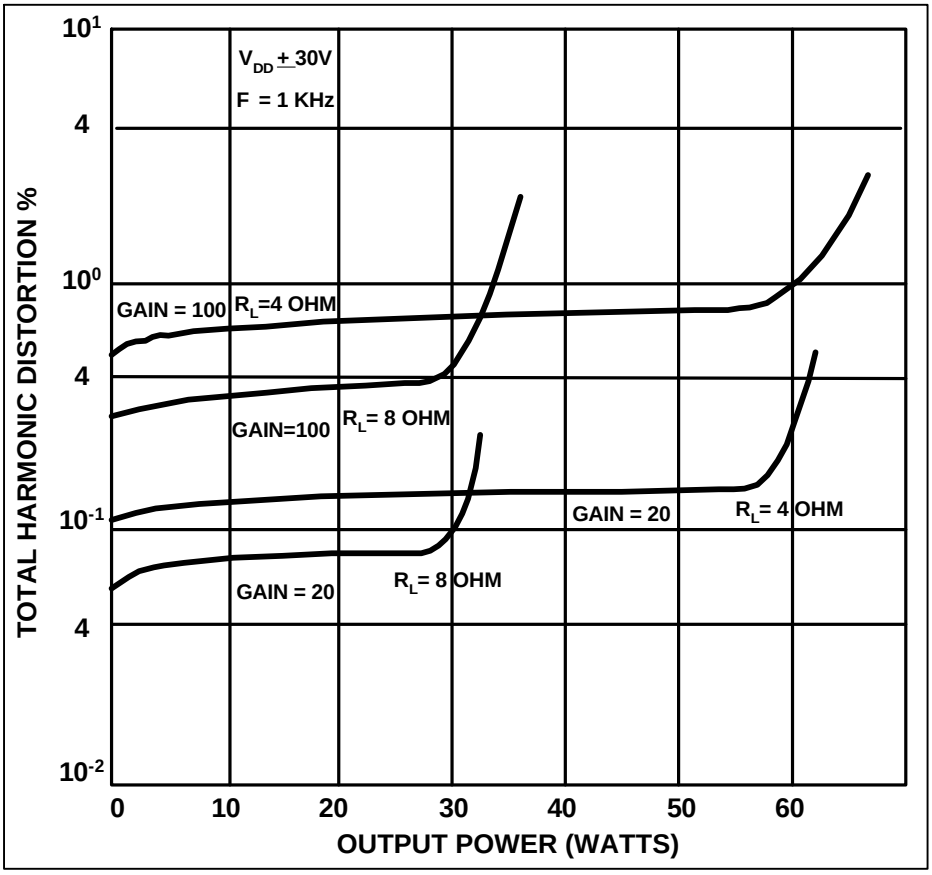

Figure 5. Amplifier Total Harmonic Distortion Curves

The following troubleshooting checklist is offered as a guide to the experimenter:

1. When assembling the printed circuit board, mount the passive components first, ensuring the correct polarity of electrolytic capacitors. Then solder in the transistors Q_1 - Q_4 checking for correct pin identification. Finally, mount the HEXFET Power MOSFETs, avoiding static discharge by shorting the pins together to ground and using a grounded soldering iron. Check the assembled board for correct component placement. A component side overlay as shown in Figure 2 is useful for this purpose. Check the copper side of the board for solder bridges between tracks, and remove them. Check for dry solder joints visually and electrically using a resistance meter and rework, if necessary.

2. Power can now be applied to the amplifier and the output stage quiescent current set to between 50 and 100mA. The potentiometer, R_{12} is first adjusted for minimum offset (fully anticlockwise on the pcb layout in Figure 2). An ammeter is connected in series with the positive supply and selected to read 1A f.s.d R_{12} is adjusted until the ammeter reads between 50mA and 100mA.

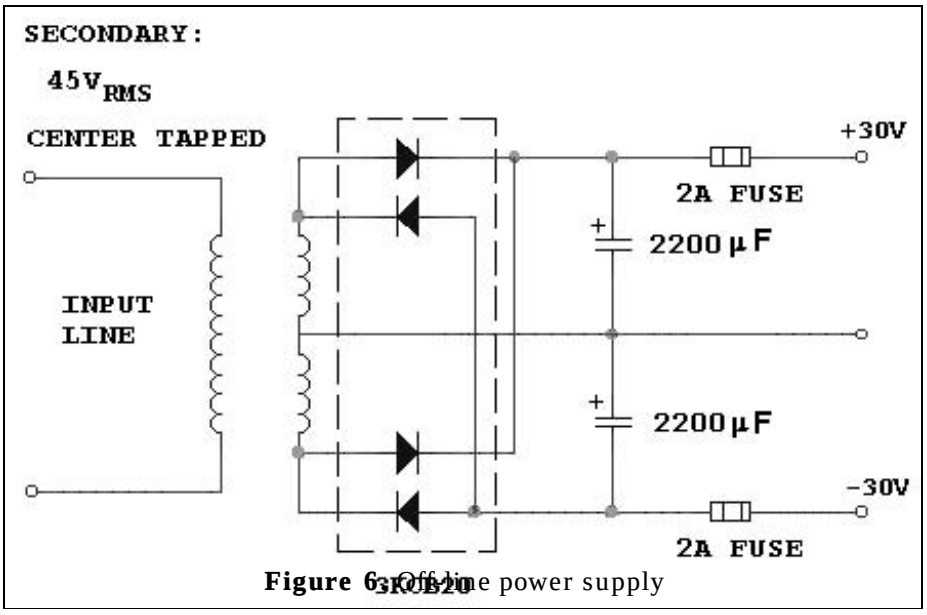

Figure 6. Off-line power supply

Quiescent current setting can be performed without the load connected.
If, however, a loudspeaker load is connected in circuit, it can be protected by a fuse from dc overload. With the quiescent current set, the output offset voltage can be confirmed to be less than 100mV. Excessive and erratic variation in quiescent current as R_{12} is adjusted are indicative of circuit oscillation or faulty wiring. The solutions described in "Circuit Description" (series gate resistors, minimized gate wiring and common earthing) should be adopted. Also, supply decoupling capacitors should be mounted in close proximity to the amplifier output stage and load ground point. Quiescent current setting should be performed with the HEXFET Power MOSFETs mounted on their heatsink to avoid overdissipation.

3. With the quiescent current set, the ammeter should be removed from the positive supply and a signal can be applied to the amplifier input. Signal requirements for full rated output are:

gain = 100:
R_L = 4 Ω, V_{in} = 150mV rms
R_L = 8 Ω, V_{in} = 160mV rms

gain = 20:
R_L = 4 Ω, V_{in} = 770mV rms
R_L = 8 Ω, V_{in} = 800mV rms

Variation in Output Offset Voltage and Output Quiescent Current with Supply Voltage

Supply Voltage + V_{DD} V	Output Offset V_{OS} mV	Output Quiescent Current Iq mA
35	-40	135
30	-20	100
25	+4	75
20	+30	54

Table 2. Variation in Output offset voltage and Output quiescent current with supply voltage

"Clipping" of the output waveform when operating at rated power indicates poor supply regulation and can be remedied by reducing the input signal amplitude and derating the amplifier. Alternatively, a lower impedance supply should be used. The frequency response of the amplifier can be checked over the frequency range 15 Hz - 100kHz with the aid of an audio test set or signal generator and oscilloscope. Distortion of the output waveform at high frequency is indicative of a reactive load and adjustment of the output choke will be required to restore the waveform. The high frequency response may be tailored with a compensation capacitor in parallel with R_6. The low frequency response is controlled by components R_7, C_2.

4. Hum pickup will be more likely to occur in a high gain circuit. Pickup at the high impedance input is minimized by use of a shielded cable, grounded at the signal source. Supply frequency ripple injected through the supply to the input stage of the amplifier can be detected across capacitor, C_3. This is attenuated by the common mode rejection ratio of Q_1, Q_2 before being amplified. However, if this is the source of hum, adjustment to the values of C_3, R_5 can be made to suppress the signal amplitude.

5. In the event of the output stage being destroyed, either through short circuit load or h.f. oscillation, both HEXFET Power MOSFETs should be replaced. It is unlikely, however, that other circuit components will have been affected. The setup procedure should, of course, be repeated with the new devices in circuit.

5. PERFORMANCE SUMMARY

Using a complementary pair of HEXFET Power MOSFETs, IRF530 and IRF9530 and with a ±30V supply, the following performance can be achieved:

Maximum rms output power:

60W into 4Ω
32W into 8Ω

Bandwidth:

15 Hz to 100kHz ±1db

Total harmonic distortion (1kHz):

0.15% at 60W into 4Ω
0.08% at 32W into 8Ω

Voltage gain:

Adjustable, X100 to X20

Input impedance: 47KΩ

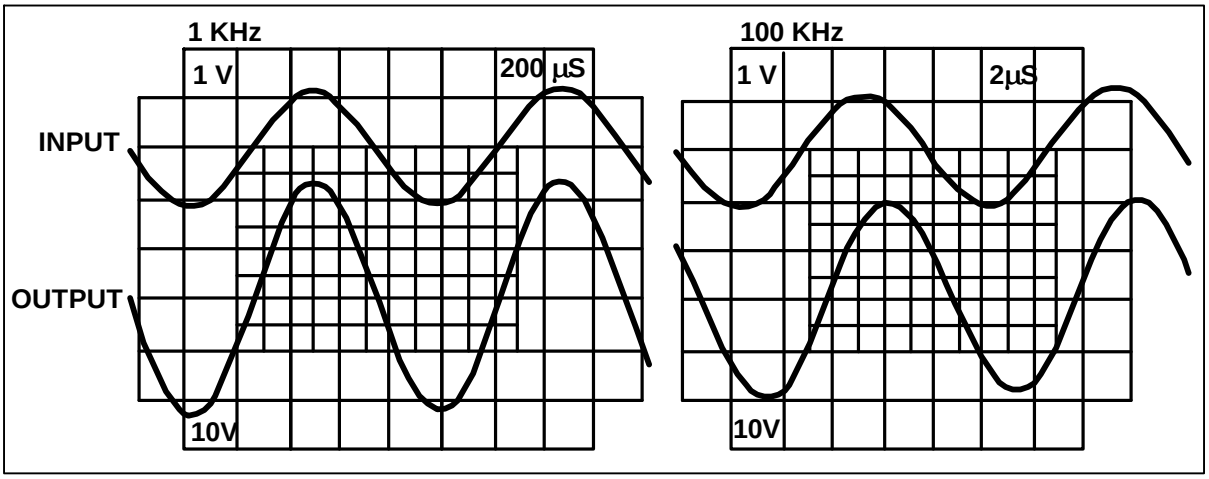

Figure 7a: Sinewave Frequency Response

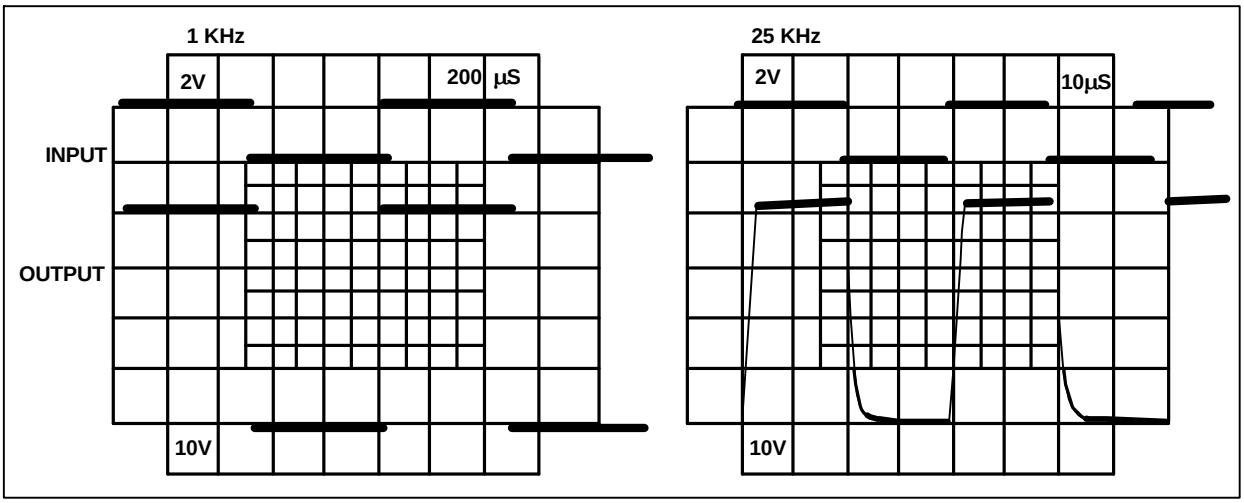

Figure 7b: Square Wave Response

Figure 7a & 7b: Amplifier Waveforms illustrating Frequency Response

Figure 7 illustrates the amplifier response to 1kHz and 100kHz sinewave input signals and also the square wave response at 1kHz and 25kHz.

Thermal Stability of MOSFETs

Prepared by: Alan Ball
ON Semiconductor
Application Engineering Manager

ON Semiconductor®

http://onsemi.com

A variety of applications use hot−swap controllers, often to increase the reliability of a system. However, a failure in the hot−swap circuit would defeat that purpose. When you use MOSFETs in their active region to control current, such as you would for a controller that operates in a constant−current mode of operation, they have an inherent failure mechanism. In this mode, the MOSFET can get hot spots and fail, long before the device exceeds its Safe Operating Area (SOA) ratings.

Engineers have long understood that MOSFETs are positive temperature coefficient devices. Therefore, as the temperature of the device increases, the resistance increases. In other words, higher temperatures result in lower currents. This fact is important if you want to operate MOSFETs in parallel. With a good thermal path between devices, the positive temperature coefficient reduces the current in the hottest device and forces more of it to flow in the cooler device, thereby avoiding thermal runaway.

Engineers often think of a MOSFET as a single power transistor, but it is a collection of thousands of tiny power FET cells connected in parallel. In terms of sharing current, the same application of the positive temperature coefficient applies. In this case, the thermal path between the cells is better than that of separate packaged devices, because the cells are all on the same die.

As the current density of a small group of cells increases, those cells heat up, increasing the resistivity of those cells and forcing current to flow in neighboring cells, which minimizes the thermal gradient and avoids hot spots. This process is an essential physical tenet that allows the parallel array of cells to function reliably.

If the MOSFET exhibits a negative thermal coefficient, today's parallel cell structure would cause serious reliability issues. In fact, in some modes of operation, the thermal coefficient goes negative. You can easily understand this phenomenon by looking at the transconductance curves for a FET device (refer to Reference 1).

A typical set of transconductance curves clearly demonstrates this effect as shown by Figure 1. Below are curves from three typical devices used in hot swap applications.

AND8199/D

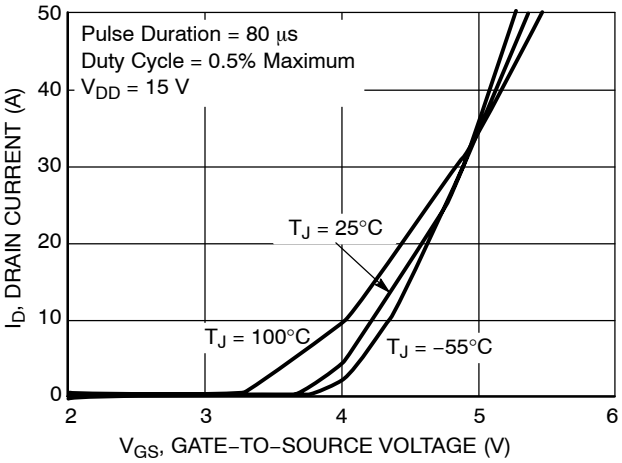

Figure 3. Fairchild HUF75631SK8

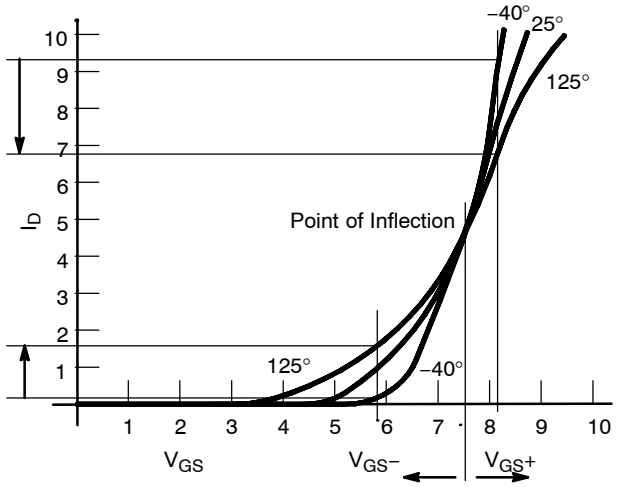

Figure 4. Typical Transconductance Curve

All three devices shown have one thing in common: a point of inflection at which the temperature coefficient is zero. At greater gate−to−source voltages, the coefficient is positive, and, at lower gate−to−source voltages it is negative.

Figure 4 illustrates the change from negative to positive. At a gate−to−source voltage greater than that of the inflection point (V_{GS}+), a positive temperature coefficient exists. At this gate voltage, the drain conducts more than 9.0 A of current. However, at 125°C the drain current reduces to less than 7.0 A. The arrow at the left of Figure 4, which shows the current decreasing due to an increase in temperature, indicates this drop.

At a gate−to−source voltage below the inflection point (V_{GS}−) a negative temperature coefficient exists. At −40°C, the drain current is close to zero. However, at 125°C, the drain current is more than 1.0 A. A second arrow at the left of Figure 4 indicates this relationship, and the current rises due to an increase in temperature.

The implication is that when you are controlling the FET with a gate−to−source voltage below the inflection point, thermal runaway can occur. When one cell or a small group of cells becomes hotter than the surrounding cells, they tend to conduct more current. This situation, in turn, creates more heat, which allows more current to flow. These cells can pull a large amount of current and, if not limited in time, can cause the device to fail.

This situation is similar to the well−known phenomenon of secondary breakdown that occurs in bipolar transistors except that a bipolar junction transistor is a single device, and you can take steps to avoid its destruction. A power MOSFET contains thousands of parallel devices that are internal to the die, and you cannot individually protect them. If hot spots occur, the SOA characteristics of the heavily conducting cells differ greatly from those of the marginally conducting cells.

The thermal−runaway situation occurs when you use large devices at low current−limit settings. Even though it would appear to be desirable to use a very large MOSFET for an application such as a hot swap and limit it to a low current, it may be an inappropriate approach. Use of a very−low−on−resistance device offers low losses for steady−state operation but may cause the device to fail during a short circuit or an overload.

One way to overcome this problem is to directly sense the die temperature of the MOSFET by integrating the MOSFET with the controller using a monolithic approach. ON Semiconductor takes this approach with its new line of hot−swap ICs. In this case, the temperature can be sensed directly on the FET die. The location of the sense element on the die is critical for ensured protection of the device. If a hot spot occurs too far from the sense location, the device may be unable to protect itself.

Discrete hot−swap controllers employ a number of protection schemes. Thermal instability is an issue only if the controller can go into a constant−current mode of operation. Some protection circuits simply shut off the MOSFET switch if a number of conditions indicate a dangerous area of operation. Controllers that use a constant−current method of protection can use timers or other schemes along with the current−limit circuit to reduce the risk of failure.

Because system efficiency is an important parameter, it is tempting to use the largest MOSFET possible to reduce losses. It is important to keep in mind, however, that this approach may require you to make a trade−off with the system reliability if you are not mindful of the possible thermal instability. You can reliably use a large power device at a low current limit level if you handle it properly.

New 500V Linear MOSFETs for a 120 kW Active Load

Authors: Richard Frey, Denis Grafham - APT, Tom Mackewicz - TDI-Dynaload.

Summary

Power MOSFETs are generally designed as switches. Total power dissipated is the sum of "on"-state losses (Id^2 x Rds(on)) plus losses generated during the very short switching intervals. Desirable characteristics include the lowest possible ON resistance, high breakdown voltage, very high gain (g_{fs} or G_m), minimum switching losses, and a low gate threshold voltage $V_{GS(th)}$.

In those applications requiring operation in the linear region, these characteristics are not ideal. Firstly, G_m is too high and, secondly, $V_{GS(th)}$ has a negative temperature coefficient ($\Delta V_{th}/\Delta T_J$), which makes it impossible to maintain constant drain current without negative feedback. Finally, and most dangerous of all, large switchmode MOSFETs exhibit a phenomenon known as "hot spotting" or current tunnelling.

In an ideal device, current density across the die is uniform and the resulting junction temperature profile is also uniform. In practice, however, minor imperfections such as small voids in the die attachment solder or non-homogeneous junction doping etc, cause non-uniform current distribution and variations in the junction temperature profile. Hot spotting is then triggered by the negative temperature coefficient of gate threshold voltage acting in a localized manner. As one part of the die heats up more than another, the local junction $V_{GS(th)}$ falls and G_m then causes that area to turn on harder, drawing even more current. Since G_m increases with current, the runaway process accelerates rapidly until failure occurs.

The development of the 500V APL501JN linear power MOSFET and its 1kV APL1001JN sibling was stimulated by the expressed desire of linear MOSFET customers to have greater usable power dissipation. Understanding the nature of hotspotting led to innovative re-engineering to lower the V_{GS} versus I_C temperature coefficient crossover point. In these new devices, the source structure has been modified to produce an asymmetric channel, that is one where some parts of the interdigitated single channel are longer than others. The effect of this is to reduce current density in the channel region which in turn lowers the tempco crossover point. The onset of forward biased thermal runaway is retarded, enabling up to 50% more usable power dissipation in the linear mode.

One such application that has benefited from this new technology is the TDI Dynaload range of water-cooled dynamic loads. Here, individual 12kW modules are paralleled together to produce integrated and very compact power systems capable of dissipating up to 120,000 Watts, for such end uses as power supply testing.

Introduction

It is not appreciated in the all-pervasive switchmode world that power MOSFETs cannot and do not meet their published Forward Biased Safe Operating Area (FBSOA) ratings, because the average designer working in this discipline does not care. Such is not the case, however, among those engineers constrained to use these devices in the “linear mode”, where significant and concurrent values of drain voltage and current produce very high internal power dissipation.

FBSOA Testing

There is no easy way to test for FBSOA, because it is by nature a destructive test. Furthermore, there are significant variations in capability from unit to unit within a production lot and even more between die lots. Statistical analysis of the results will yield both typical and limit values for the part. For commercial production, a screening test is used which tests to a minimum level.

The SOA test fixture uses a water-cooled heat sink to keep the case close to 25C. A test value of drain voltage is selected, typically 50 to 80 percent of the rated drain voltage. The drain current is sensed by a sense-resistor in series with the source. An op amp, with its non inverting input tied to a reference voltage, establishes the device drain current as a function of the sense-resistor voltage.. The test procedure is to gradually increase the drain current in steps until the DUT fails. Each of the steps is held for a minute to ensure that the junction temperature reaches equilibrium. The power dissipation at which failure occurs is recorded for each device, and this defines the DC Safe Operating Area.

If the current is pulsed and the pulse width kept less than the thermal time constant of the device, the failure point can be several times the rated power dissipation of the device. This demonstrates that the failure mechanism is hot spotting. Under pulsed conditions, the junction temperature is more uniform so that the "hot spot" does not have time to develop.

Forward biased safe operating area for a semiconductor device (FBSOA or just SOA for linear devices) is a triangular area bounded on the left side by a positive sloped line defined by the Rds(on) of the device, and on the right side by a negative slope line determined by the power dissipation of the device. A typical SOA curve is shown in Figure 1.

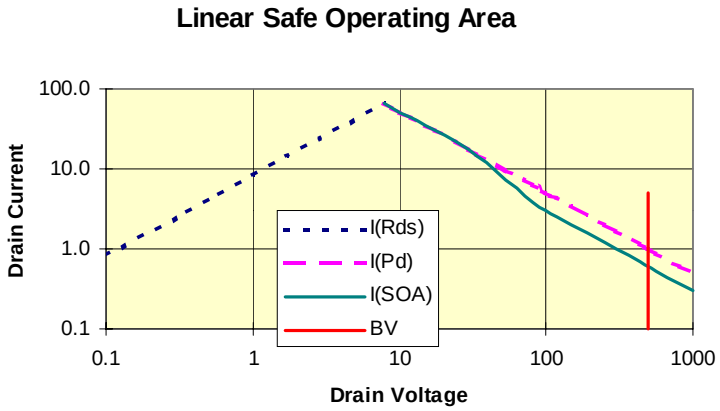

Figure 1 Typical FBSOA Curve

This figure appears on virtually every power device data sheet and, athough the $R_{\Theta JC}$ and $R_{DS(on)}$ parameters on which it is based are carefully measured and controlled by the manufacturer, the figure itself is derived by calculation and is seldom if ever rigorously validated.

In the case of switchmode devices, FBSOA is of little importance. The device is operated between two points on the figure, one on the Rds line at some current and one off the chart at some voltage and zero current. Power dissipation in a switched application is the sum of the on loss, $I_D^2 \times R_{DS(on)}$,and the dynamic switching losses which occur while making the transition between the two operating points. The characteristics which concern a switchmode designer are the $R_{DS(on)}$ characteristic and the parameters which determine the dynamic losses. Linear operation is different. The device is operated in a non-saturated mode, away from the $R_{DS(on)}$ line and somewhere within the SOA. In this mode, it behaves as a variable resistance, which is is exactly its role as a programmable active load.

Circuit for an active load

Linear operation of a MOSFET cannot be reliably accomplished without negative feedback. Whether as a "programmable resistor" in an active load or as the control element in a linear series regulator, the device must always be used inside a control loop. Within such a loop, thermal variations of V_{th} and G_m can be accommodated.

As a design example, consider the active device requirements for a programmable load to be used for testing a regulated power supply. The power supply has a maximum output of 3.5A at 300V. The active load will therefore need a device with a BV_{DSS} of at least 300V and must be capable of dissipating the entire output of the supply plus a safety factor to permit testing of the over current protection feature.

Devices suitable for the voltage requirement are fairly common, but a single device with more than 500W of usable power dissipation is not. The question is then to decide how many devices must be paralleled.

The APL501J device has a rated FBSOA of 300W and a rated power dissipation P_D of 520W, but as already explained this latter is not really usable in linear operation. The critical parameter defining allowable power capacity is $R_{\Theta JC}$. For an APL501J, $R_{\Theta JC}$ is 0.24K/W and $R_{\theta CS}$ 0.6K/W, so if the desired operating T_J is 130°C and the sink is water cooled at 30°C, the allowable (switchmode) power dissipation is (130-30)/0.3 = 330W. However, since this exceeds the 300W FBSOA rating of the device, the 300W max FBSOA limit must prevail. Applying a 20% safety factor reduces this to 240W.

If the power supply being tested is capable of delivering 3.5A at 300V, the MOSFET load-bank must absorb 1050W. 1050W/240W = 4.4, so five devices in parallel are required, assuming that five devices can be configured to share the load equally.

Paralleling devices

No matter how carefully devices are matched for one given characteristic, G_m for example, differences in other parameters and variations in mechanical assembly will generally conspire to unbalance paralleled devices. Some form of feedback control is mandatory to assure current sharing, and the easiest way to do this is to install source resistors to monitor the drain current of each MOSFET. Resistor tolerances then determine the relative matching between the MOSFETs. The resulting resistor voltages are applied to the inverting inputs of operational amplifiers driving the gates, the non-inverting inputs being tied to a current-dependent reference voltage.

The value of the source resistor depends on the dynamic range of adjustment required, the noise content in the output, the minimum load resistance and the stability requirements of the system. A resistor outputting 1 to 2 volts maximum is ideal. The temperature coefficient of the resistors will determine the temperature stability of the system. Since the feedback is unique to each device, any number of MOSFETs may be paralleled without risk. The same current-dependent reference voltage can be applied to all the opamps. A typical arrangement is shown in Figure 2.

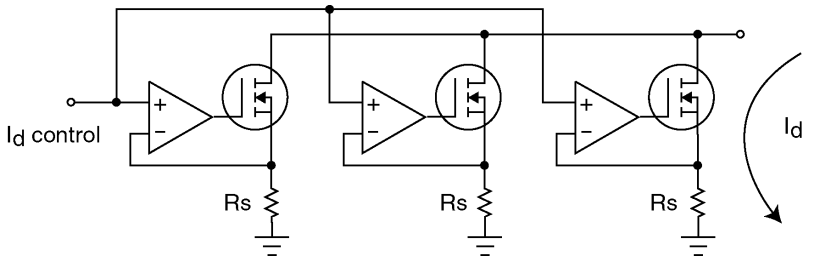

Figure 2- Paralleling several MOSFETS

Device changes to improve SOA

The development of the 500V APL501JN along with its 1kV APT1001JN stable-mate was stimulated by the expressed desire of potential users to have substantially increased allowable power dissipation in the linear mode. As already postulated, the fundamental mechanism behind MOSFET FBSOA failures is localized thermal runaway caused by “hot spotting”. It results from the interaction between non-uniform heating over the surface of the die and the negative temperature coefficient of gate threshold voltage as illustrated in Figure 3.

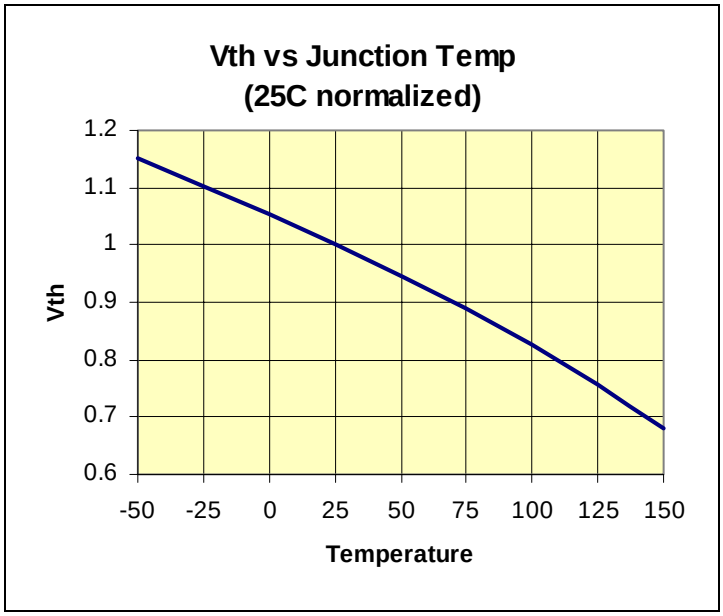

Figure 3

The phenomenon can be viewed as a classic example of an unstable feedback loop. From a device standpoint, only three variables can be manipulated to improve the stability of the system: $R_{\Theta JC}$, G_m, and the tempco of V_{th}.

- In the case of the APL501 and APL1001, $R_{\Theta JC}$ is a function of die size and the package, so is more or less fixed. In any event, since a bigger die would yield a lower $R_{\Theta JC}$ and a higher G_m, the net loop gain would remain unchanged.
- Within limits, the very high G_m of a switchmode device can be reduced considerably before difficulties start to appear in linear applications. Common MOSFET design rules indicate that G_m is generally inversely proportional to $R_{DS(on)}$ and proportional to channel width and die area.
- The primary means for improving SOA of the new design was to reduce its crossover or turnover current. Crossover current of the original switchmode part was 30A, this being where the transfer characteristic curves cross in Figure 4, or the current at which the slope is zero in Figure 5. By modifying the gate-source geometry using a fabrication process dubbed "asymmetric channel", the crossover current was reduced by half, with commensurate improvements in linear-mode FBSOA and usable power dissipation.

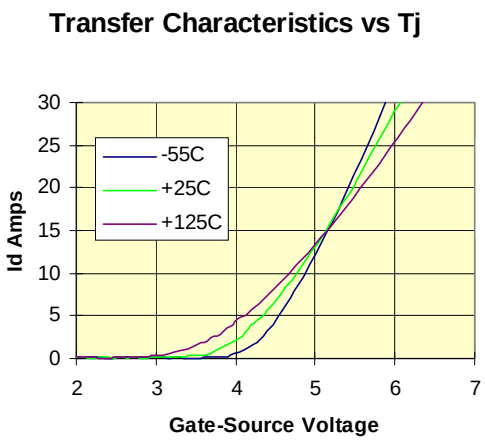

Figure 4

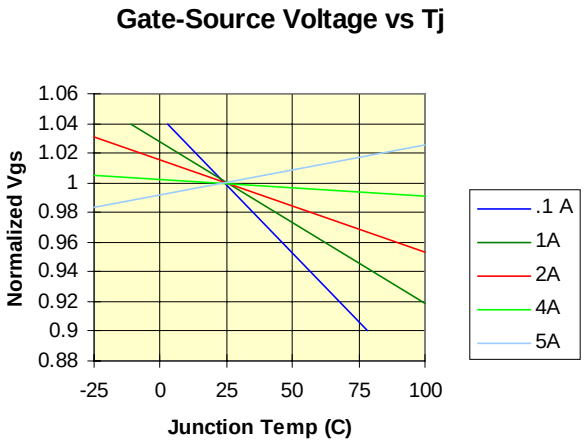

Figure 5

As can be seen from Table 1, crossover performance differs markedly among nominally similar devices - all having chip areas of about 128,000 sq mils. Note that the later high performance switchmode designs- characterized by higher speed, lower gate charge, tighter gate/source pitch, lower on-state resistance etc, all display progressively worse FBSOA performance as measured by crossover current. As a result, the new optimized linear design was based on the older MOS IV process, rather than on the more recent MOS V or MOS VI developments.

Device	Crossover Current	Device Process
APL501J	15A	New Linear Process
APT5010JN	30A	MOS IV®
APT5010JVR	62A	MOS V®
APT5010LLC	100A	MOS VI®

Table 1 Performance versus Process

A schematic cross section of the APL501J chip is depicted in Fig 6. Unlike the vast majority of competitive power MOSFETs that feature multi-cellular chip structures, APT devices are manufactured with a single-cell interdigitated gate and source structure. A proprietary process change results in the formation of a shorter channel length along one side of the structure. The net effect is the creation of two distributed parallel MOSFETs with different transfer characteristics. The portion of the die with the shorter channel length has a slightly lower gate threshold voltage (V_{th}) and a lower zero temperature coefficient point than the portion with the longer channel. At low drain currents, the low V_{th} portion of the die dominates the current flow. Since this portion of the die is operating closer to the zero temperature coefficient point, hot spotting and subsequent thermal runaway is less likely to occur. At higher currents, the current sharing between the two portions of channel becomes more uniform and operation approaches that of a device with a normal symmetrical channel structure. In this situation, the usable FBSOA is 50% higher than that of the original APT PowerMOS IV® switchmode device.

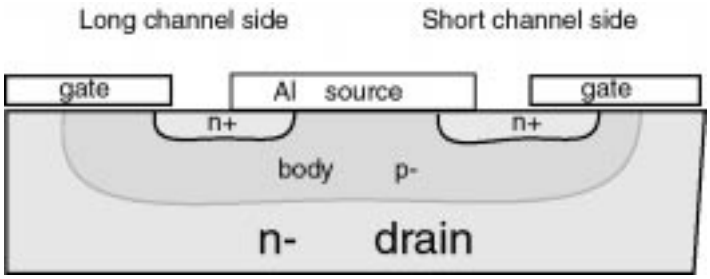

Figure 6 – Asymmetric Source

Conclusions

Incorporated into TDI-Dynaload's WCL series of 12kW water-cooled electronic load modules, which may be stacked together to dissipate up to 120kW at 400V or 10,000A per system, APT's new APL501J linear MOSFETs operate safely and consistently at power levels in excess of 300W at 400V. In comparison, SOT227 packaged

switchmode devices from other manufacturers are limited to about 100W at 400V. This vast improvement in FBSOA has allowed TDI to develop the highest power density electronic loads available today. Although the APL501J does exhibit the power roll off with applied drain voltage characteristic of all switchmode devices, this can be put to good advantage in the new device, in that the SOA curve shows a dramatic increase in power capability at lower voltages. At voltages below 100V, Dynaload has demonstrated that the APL501J is capable of dissipating up to 500W without failure.

SOLID STATE OPTRONICS

Application Note 050
Failure Mode of SCR-Output Relays vs. MOSFET-Output Relays at High Temperature

Introduction

High temperature is a common environmental stress in many solid state relay applications. Application engineers must have a solid understanding of how a relay can be expected to fail if the temperature exceeds the rating of the package. This paper aims to compare the theoretical and experimental failure modes of SCR-output relays vs. MOSFET-output relays at high temperature.

Let us first define failure for an SSR as a condition in which we lose control of the output. For example, if we want to turn the output off and are unable to do so, that will be considered a failure. Similarly, if we try to turn the output on and we are stuck in an open condition, that is a failure.

Solid state relays are typically rated for an operating temperature in the neighborhood of 85º C. This nominal figure depends on the maximum junction temperature of the output structure. We consider high temperature to be any temperature above 85º C.

This report is broken up into two parts: 1) theoretical discussion of SCR and MOSFET at high temperature; 2) experimental results supporting theory.

Theoretical Discussion

SCRs at High Temperature

An SCR is simply a p-n-p-n structure with a gate terminal (Fig.1). We can break the structure down as back-to-back transistors, one p-n-p, the other n-p-n. With that simplification, we can see that temperature analysis of the bipolar transistor extends logically to the SCR structure.

It is a well known empirical fact that leakage current approximately doubles with every 10° C increase in temperature.[1] In a bipolar transistor, this increase in leakage is accentuated by the "transistor action" of the device. This can be explained by using an n-p-n transistor as an example. As we increase the temperature, more and more electrons are able to jump the barrier from the emitter to the base. This further biases the base region with respect to the emitter and collector, causing an increase in collector current. In fact, a transistor can be turned on simply by applying high temperature - sufficient leakage current can be generated to trigger the transistor action.

This discussion extends to the SCR, which is nothing more than two bipolar transistors driving each other. Any effect felt by the bipolar transistor is only magnified when discussing the SCR. The effect is not additive, it is multiplicative.

There is another temperature-related phenomenon we must point out: as we increase temperature, diode voltage decreases at an approximate rate of 2 mV/°C.[2] Therefore, a transistor in the on state will have a tendency to not only stay on at high temperature, but to conduct even more fully; i.e., the barrier between p- and n-type regions is reduced even more.

The result of these two phenomena is that the bipolar transistor has a negative temperature coefficient; the higher the temperature, the higher the collector current at a given base drive.

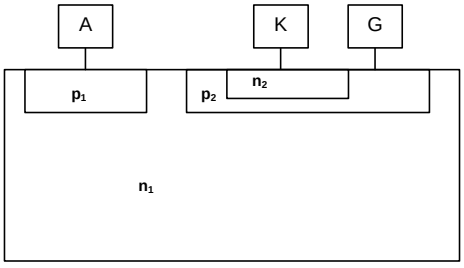

Fig. 1: SCR structure

Let's now extend the discussion to the SCR, specifically in Solid State Optronics device S742. The S742 uses two SCRs in the output; thus, it can only be utilized in AC applications. This is because the only way to prevent these particular SCRs from conducting once they are turned on is to reverse the voltage across their terminals. This is dictated by the output of the application. In a DC application, once the SCR is turned on, there is no way of turning it off. Under DC, the SCR never experiences the reverse voltage condition across its terminals necessary to prevent conduction.

An SCR in the off state will tend to turn on and stay on (latch) at high temperatures. Of course, in the S742 one SCR will always be non-conducting because of the reverse voltage on the output. But the other will tend to turn on even without an input signal because of the above considerations.

MOSFETs at High Temperature

Under no gate bias, a MOSFET can be thought of as a pair of back-to-back p-n diodes (Fig. 2), from source-to-bulk and bulk-to-drain. Again, we point to the empirical fact that leakage current approximately doubles with every 10° C increase in temperature. However, as we increase temperature, we can think of the leakage current from each diode cancelling each other out, resulting in no net change in current.

The dominant temperature-related mechanism for the MOSFET is the reduction in carrier mobility. This reduction exists because of the increase of scattering a carrier experiences due to the increased excitation

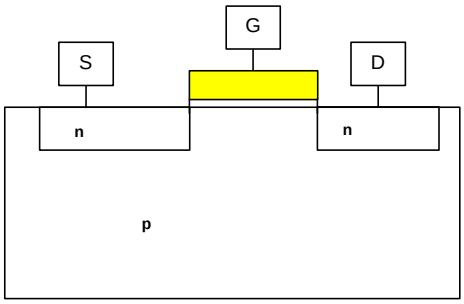

Fig. 2: MOSFET structure

of lattice sites in silicon at high temperature. The mobility of carriers in the channel of a MOSFET behaves according to the following empirical expression[3]:

$\mu(T) = \mu(300\ K)/(T/300)^a$- where T is measured in kelvins and *a* is 1.0-1.5

This relation shows that mobility may decrease as much as 40% for a 100° C temperature increase. Decreased mobility leads directly to an increase in on-resistance. Thus, we can say that the MOSFET's on-resistance has a positive temperature coefficient.

On the other hand, V_T, the threshold voltage of a MOSFET, typically decreases by approximately 1.5 mV/°C.[4] The reason for this effect is that at high temperature, we can expect an increase in thermally generated carriers (leakage). With more n-type carriers available in the conducting channel, we need less of a gate voltage to achieve the same amount of conduction.

This effect would tend to counter the decrease in mobility, however, the effect is relatively weak. V_T decreases by approximately 0.15 V for a 100° C increase in temperature - this is relatively insignificant. We would expect the reduction in mobility to be the dominant mechanism at high temperature.

The reduction in V_T is further offset by the reduction in the voltage of the gate driver circuit. In SSO's MOSFET-output devices, the driver consists of 14 series diodes. These diodes generate sufficient voltage to drive the gate of the output MOSFET, allowing conduction. As mentioned above in the SCR discussion, diode voltage drops at higher temperature. This in turn reduces the drive voltage to the gate of the MOSFET. Empirical results have shown that the drive voltage is reduced by approximately the same amount as the reduction in V_T, thereby virtually cancelling the effect.

Now, let's look at the potential failure modes. A MOSFET in the off state will not turn on when exposed only to high temperature. This is because high temperature alone will not be able to create the inversion layer beneath the gate necessary for conduction. A gate voltage is required to do this. Furthermore, a MOSFET in the on state will tend to conduct less and ultimately shut off at high temperatures due to the reduction in carrier mobility.

Experimental Results

In order to provide support for the theoretical conclusions, we ran a set of experiments with an SSO SCR-output device (SSO P/N S742) and an SSO MOSFET-output device (SSO P/N AD8C111) at high temperature. Please see attached documented procedure for details. In short, the test procedure consisted of 4 parts:

1) Take 20 S742s and put in oven cycling ON/OFF (10 HZ input square wave, 100 mA load); raise temperature until device fails and note failure mode.

2) Take 20 S742s and put in oven OFF (blocking 250 V_{RMS}); raise temperature until device fails and note failure mode.

3) Take 20 AD8C111s and put in oven cycling ON/OFF (10 HZ input square wave, 100 mA load); raise temperature until device fails and note failure mode.

4) Take 20 AD8C111s and put in oven OFF (blocking 275 V_{RMS}); raise temperature until device fails and note failure mode.

The following is a summary of the results of these experiments (please see attached documentation for further detail):

1) 18 of the 20 relays failed short; 1 failed open. The final relay didn't fail up to 145º C, at which point the oven's fuse mechanism prevented a further increase in temperature.

2) 18 of the 20 relays failed short. The other 2 relays didn't fail up to 175º C, at which point the oven's fuse mechanism prevented a further increase in temperature.

3) All 20 relays failed open - 11 of the 20 were "partially" conducting; the other 9 were completely OFF. (This result clearly shows the reduction in carrier mobility).

4) 13 of the 20 relays failed open. The other 7 didn't fail up to 150º C, at which point the oven's fuse mechanism prevented a further increase in temperature.

Conclusion

These results support theoretical expectations; namely, SCR-output devices can be expected to fail short at high temperature, while MOSFET-output devices can be expected to fail open.

Introduction

Sometimes, you just can't get rid of that %$#*& hum, no matter what you do. Especially with long interconnects (such as to a powered sub-woofer), earth loops can be a real pain. For this reason, just about all professional equipment uses balanced lines, which, if properly executed, will eliminate the hum completely.

With this simple project, you can have balanced lines too, simply adapting the unbalanced inputs and outputs of your hi-fi gear to become balanced, and then back to unbalanced at the other end. You can even be extra cunning, and power the remote converter from the cables carrying the signal. Professionally, this is called "Phantom Feed", and is used to power microphones and other low current equipment. The version I have shown is actually a differential feed. Whilst not as good as a true 48V phantom powering circuit, it does work, and makes an interesting experiment (if nothing else).

Description

Before we start, a brief description of the standard (unbalanced) and balanced line is in order. An unbalanced line is the type you have on the hi-fi, typically using an RCA connector, and feeding the signal through a coaxial cable. The inner cable carries the signal, and the outer shield is a screen, to prevent RF interference and general airborne noise from being picked up on the signal lead.

This is fine, except for one small detail - the shield must also carry the signal! This is the return path, and is required in all electrical connections - otherwise there is no current flow and the system will probably just hum softly (or loudly) with none of the wanted signal.

The problem with electricity (like water and most people) is that it always takes the path of least resistance, so when two pieces of equipment are connected, most likely there will be signal plus hum, because of the dreaded earth loop. This is formed when both items are connected to the mains earth, and also have their earth (zero Volt) points joined via the shields of the signal leads.

In some cases it is possible to disconnect the earth at one end of the cable - some people have also disconnected the mains (safety) earth. Both achieve the same result, but disconnecting the mains earth is extremely dangerous. Unfortunately, the result is not always as one would hope. RF interference can become much worse, and other noises become apparent that were absent before.

In contrast, a balanced connection uses two wires for the signal (much like the telephone circuit), with the signal equal in amplitude in each wire, but opposite in phase. Only the out of phase signal is detected by the remote balanced receiver, and any in phase (common mode) signal is rejected. RF interference and other noise will be picked up equally by both wires in the cable and so will be in phase. It will therefore be rejected by the receiver. In this way, it is possible to have long interconnects, with the shield connected at one end only. This cuts the earth loop, and the balanced connection ensures that only the wanted signal is passed through to the amplifier(s).

It is very important that the two signal leads are twisted together, and the tighter the twist, the better. The shield prevents RF and other interfering signals from causing too much trouble, and the final signal should be free from hum and noise. The shield serves the same function in an unbalanced circuit, but is less effective due to the fact that it usually serves as the signal return path, and any signal that does get through becomes part of the signal.

The idea of this project is to give you some options, and to assist in creating a solution - it should not be seen as a complete solution in itself. There are many variables - far too many to be able to say with complete confidence that this WILL prevent all hum and other interference. It might, but it is likely that some experimentation will be needed to get the results you want.

Note that for both transmitter and receiver, it is essential that 1% (or better) tolerance resistors are used. If the trimming option is implemented, then you could use 5% resistors, and you will be able to adjust the circuit to get maximum common mode rejection - however I recommend that you use the 1% metal film resistors. For the small extra cost you get much higher stability, and lower noise.

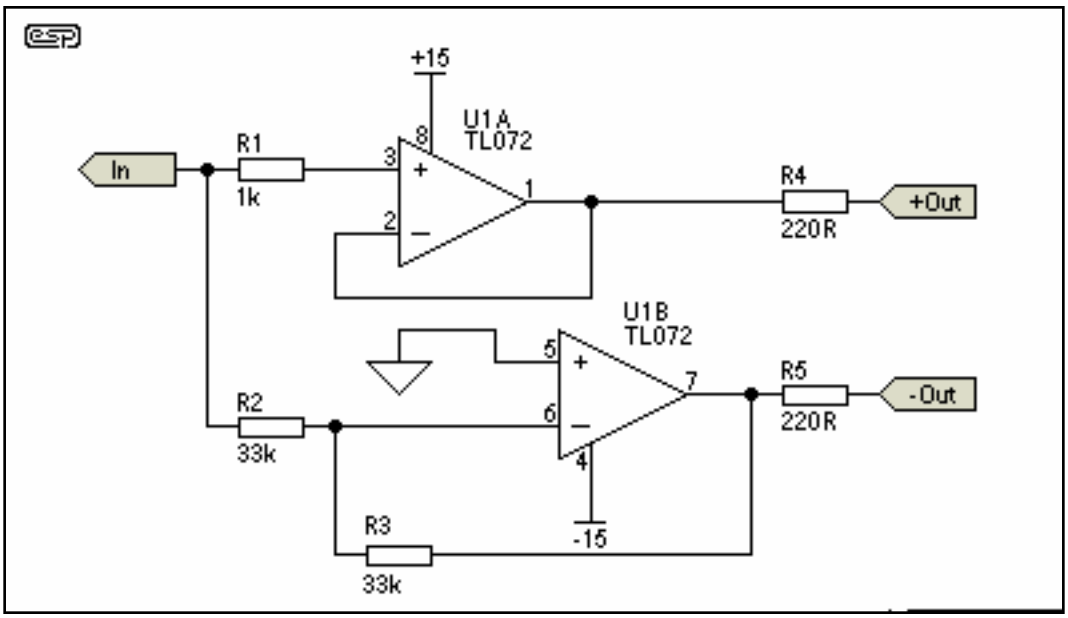

Figure 1 - Balanced Line Transmitter

The transmitter uses one opamp to buffer the signal, and the other to buffer and invert it. This creates a balanced signal, where as the signal swings positive on one lead, it swings exactly the same amount negative on the other. The 220 Ohm resistors at the output ensure stability with any lead, and are also used to attenuate the signal slightly. The signal swing from the transmitter (across both wires) is double the voltage of the input signal.

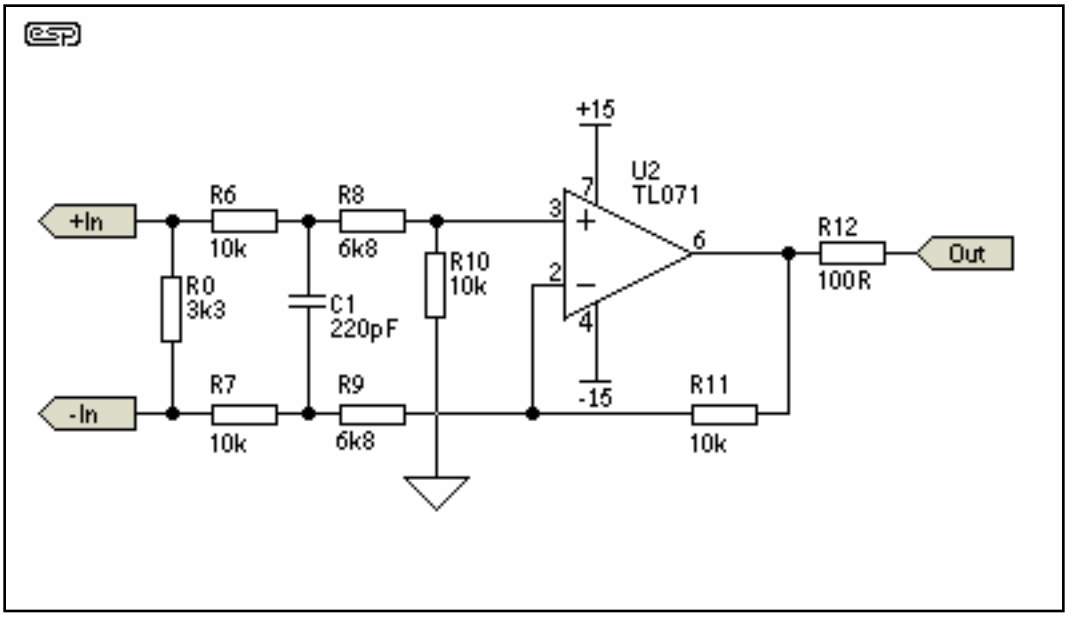

Figure 2 - Balanced Line Receiver

The receiver has an optional 3.3k resistor across the inputs (RO) to help balance the input against minor variations in cable impedance between the individual lines. The 220pF capacitor is for HF rolloff, and will attenuate any RF that might get picked up by the lead. Any common mode signal - where both leads provide a signal of the same polarity to the receiver circuit; typically noise - is rejected, leaving only the wanted signal.

The rest of the circuit is a conventional balanced input stage. This particular configuration is somewhat notorious for having unequal input impedances referred to earth. The 3.3k resistor helps this (a little, anyway), and the 220pF capacitor also assists at higher frequencies. A more complex circuit could have been used, but that would require 3 opamps, and for the intended task would offer few real advantages.

With the capacitor value chosen, there is about 0.1dB attenuation at 20kHz - if you don't like this idea, reduce the value to 100pF, however since 0.1dB is quite inaudible, there seems little point.

With the values shown, there is a very slight overall gain of just over 0.3dB. This is unlikely to be a problem. The circuit is designed to send the maximum level possible across the balanced cable, and most of the attenuation is performed at the receiver. This will reduce any noise picked up by a further 6dB for the transmitter / receiver pair.

It is also possible to ensure that the common mode rejection is as good as it can possibly get, by making R10 variable. I suggest that you use an 8.2k fixed resistor, with a 5k multi-turn trimpot in series. To balance the circuit, you may use an oscillator and millivoltmeter, or just a small battery and a multimeter.

Join the two inputs together, and connect the battery or audio oscillator between the two joined inputs and earth. Adjust the trimpot until there is 0V at the output - the common mode signal is now gone completely. Typically, this circuit will give a common mode rejection of about 40dB if not trimmed as described, but trimming will let you improve on this considerably.

Although this transmitter and receiver pair will probably allow the use of unshielded interconnects, I don't recommend this. Use a good quality shielded twin microphone cable. The earthing of the shield should normally be done at the receiver end, but in some cases you might find that the noise rejection is better if the transmitter end is earthed. Experimentation will be needed.

Phantom Power (For the Experimenter)

It is possible to run this unit with the signal leads also carrying the power for the receiver. We could use conventional phantom feed (using a 48V supply), but it is easier to use a differential feed, with the +ve and -ve supply voltages on the signal leads. The basic scheme is shown in Figure 3. This may be found to reduce common mode rejection, and it is essential that the power is completely noise free, or it will become part of the signal! If this method is to be tried, use the trimming option, so the supply feed resistors can be catered for. Alignment with a battery will no longer be possible, and a signal generator will have to be used - with coupling capacitors to each signal line.

The resistor RO must be removed in this configuration. I would strongly recommend that an output coupling capacitor is used from the Out terminal of the receiver, since it is likely that there will be some DC offset due to capacitor leakage currents.

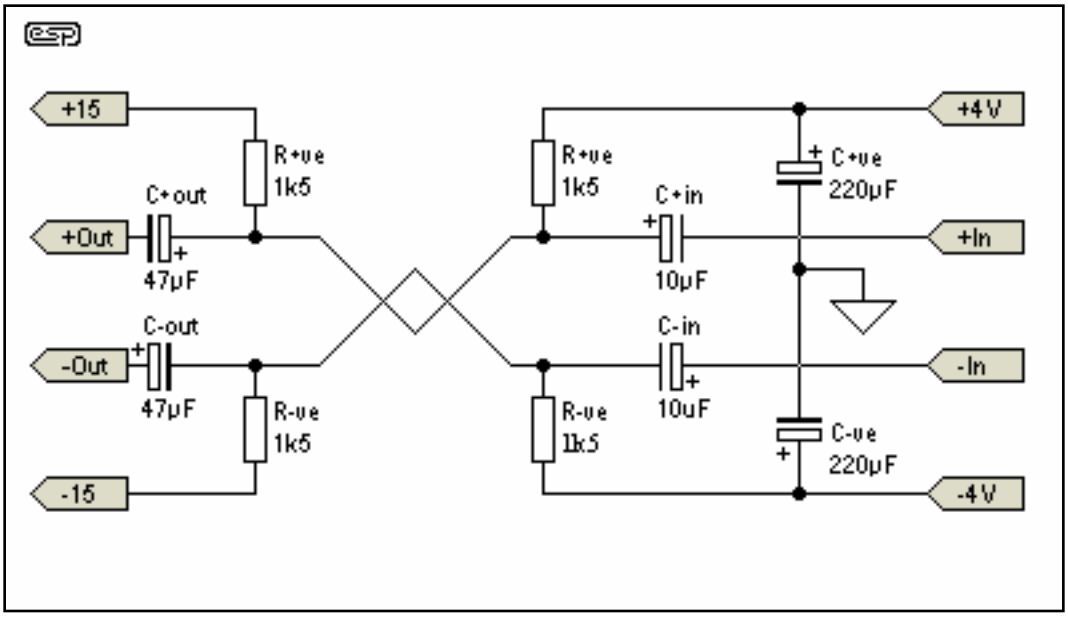

Figure 3 - Differential "Phantom" Powering

The voltage to the receiver opamp is reduced by this technique, and the maximum signal level will be reduced too. Only by experimenting will you be able to determine the exact power losses and maximum signal level attainable. The tests I did indicate that you should not expect more than about 1V RMS, but you might get more depending on the opamp used for the receiver. The power feed resistors also load the transmitter, and reduce its output capability somewhat. You might want to experiment with a low-power opamp (such as an LF351) as the receiver, as this will allow a higher supply voltage and more signal before distortion.

I would expect that the most likely use for this arrangement would be for a remote sub-woofer, where it may be very inconvenient to have to create an additional power supply. I can't say that I am completely happy with this arrangement, but it does work. A 48V phantom supply would be better, but it is not likely that too many constructors will want to go to this trouble.

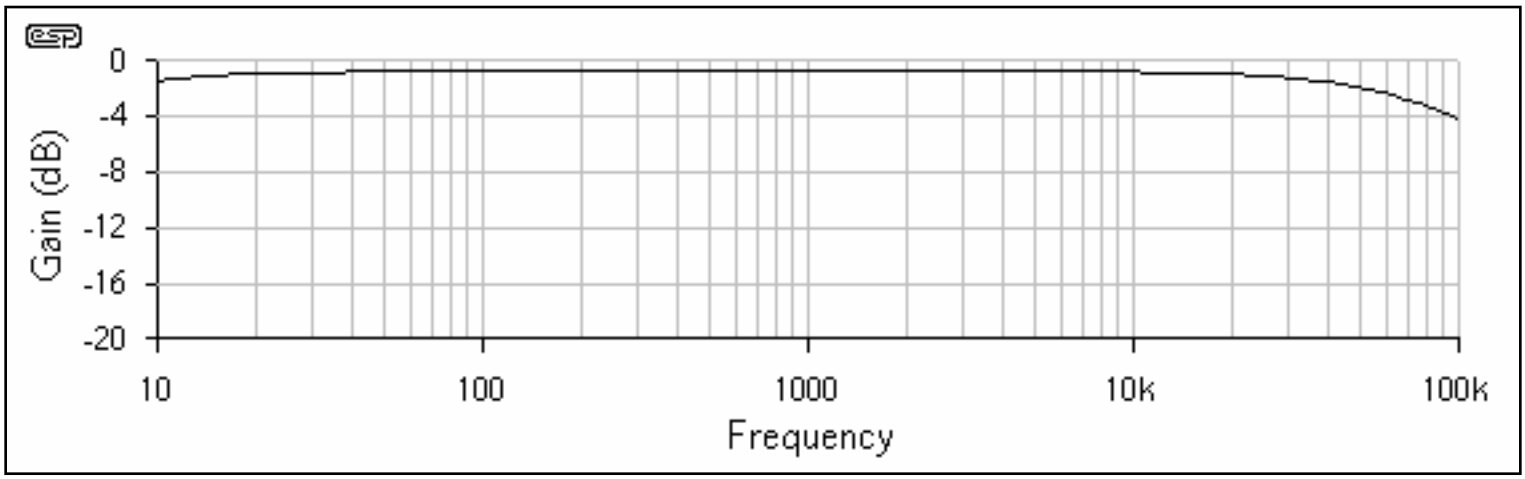

Figure 4 - Overall Frequency Response of Differential Feed and Both Circuits

The shield will now have to be connected at each end, but one end can be earthed using a 10 Ohm resistor, which should be bypassed with a 100nF capacitor. Again, experimentation is needed to determine which end should have the "hard" earth. Make sure that the connectors are polarised so that power cannot be connected the wrong way around. Diodes may be added if desired to provide proper protection. These should be in parallel with the receiver filter caps (C+ve and C-ve), because a series connection will reduce the voltage further (there is not a lot to start with, so a further reduction would be a disaster).

Use of a multi-cored cable and suitable connectors will allow you to run the power supply on separate wires in the cable, and the additional cost of the cable and connectors is likely to be offset by the simpler circuit and better performance. This may not always be possible, hence the differential phantom feed.

Balanced Transmitter and Receiver II

Rod Elliott (ESP) / Uwe Beis *

Updated 01 April 2002

PCBs are available for this project. Click the image for details.

Introduction

This is essentially an update to the original article on the subject, and includes some ideas to stimulate further thought on the subject. This is especially true of the last section (Hey! That's Cheating) - everyone wants balanced outputs free, well you can have them free (well, near enough anyway).

The balanced transmitter and receiver described in Project 51 work very well, but both are less than optimum under difficult conditions. Uwe has written an article (published on The Audio Pages) describing an active balanced transmitter that has performance almost equivalent to a transformer. There are ICs available that (almost) manage the same thing, and the principle uses feedback to equalise the levels from each transmitter opamp.

While Uwe has gone to a great deal of trouble to get his circuit to match a transformer as well as possible, this is not an easy circuit to get working well, and it requires 0.1% tolerance resistors and wide bandwidth opamps.

Enter ESP and the "simplification methodology" that I tend to use wherever I can. The result is a transmitter (in particular) that is extremely good, and matches the performance of a transformer to a quite acceptable degree. It's not perfect, but it is very stable, and requires no adjustments or close tolerance parts (1% resistors will provide a maximum error of 1/100, or 40dB common mode rejection and balance).

Use of closer tolerance resistors - and good or premium opamps - will give a circuit with excellent performance, and it will come very close to that of a transformer balanced circuit with none of the associated cost. Response is flat to at least 50kHz, with a low frequency limit of DC (as shown). Capacitors can be used to limit the low frequency limit if desired.

Mk II Receiver

The receiver is shown in Figure 1, and as shown does not have any RF protection. This configuration is somewhat better behaved than that shown in the original article, and presents exactly the same impedance to each of the balanced lines in the cable. This is also the case with the original version shown, but *only* if the source is balanced.

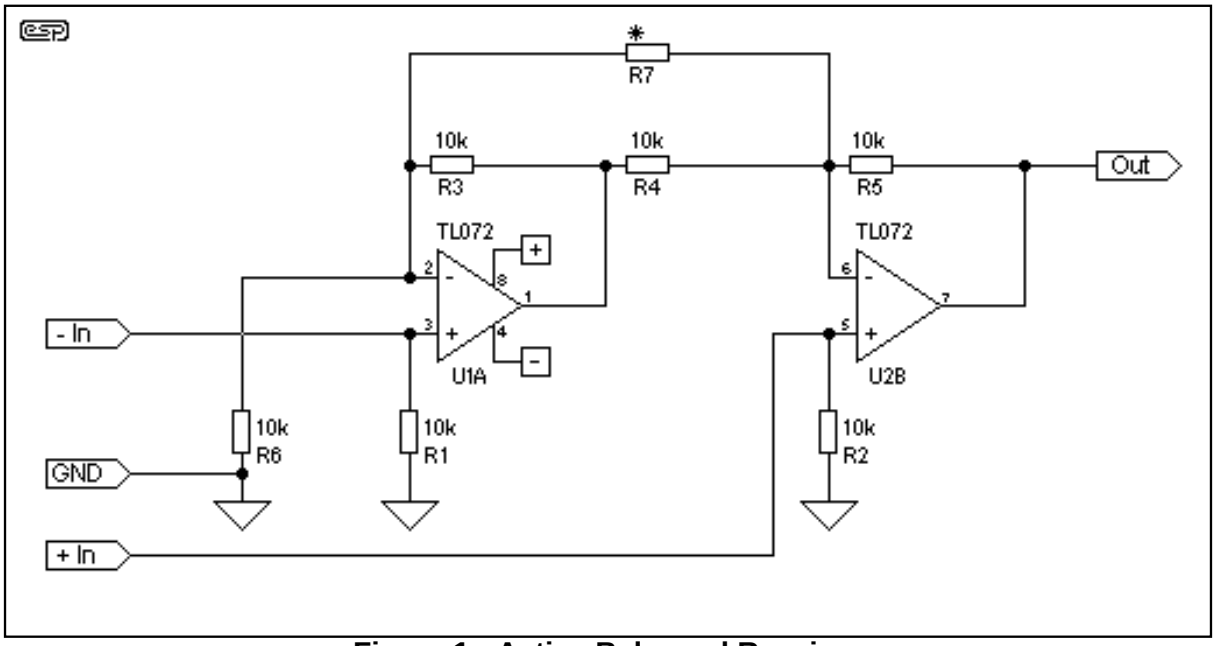

Figure 1 - Active Balanced Receiver

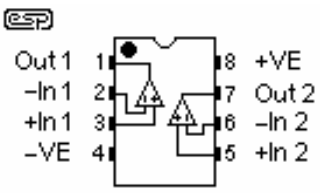
The resistor marked * (R7) may be left out, and the circuit will have a gain of 2. Installing this resistor will increase gain, but will have no effect on the input impedances or balance performance. The minimum gain for this circuit is 1.5 (if R6 and R7 are omitted), and this increases to 2 with R6 installed. The gain setting resistor R7 still works if R6 is omitted, with a value of 10k providing a gain of 3.5, and 1k giving a gain of 21 (26dB).



The standard pinouts for a dual opamp are shown (top view of device). It is suggested that a bypass capacitor (typically a 100nF ceramic or polyester) be connected between pins 4 and 8, as close to each opamp package as possible. Even with "slow" opamps, it is always a good idea to use a bypass cap to prevent possible instability at high frequencies.

The exact same scheme as shown in the original project could be used for the inputs on this version. One possible connection is shown in Figure 2. This is virtually identical to the configuration shown in Project 51, and will provide a very high noise rejection.

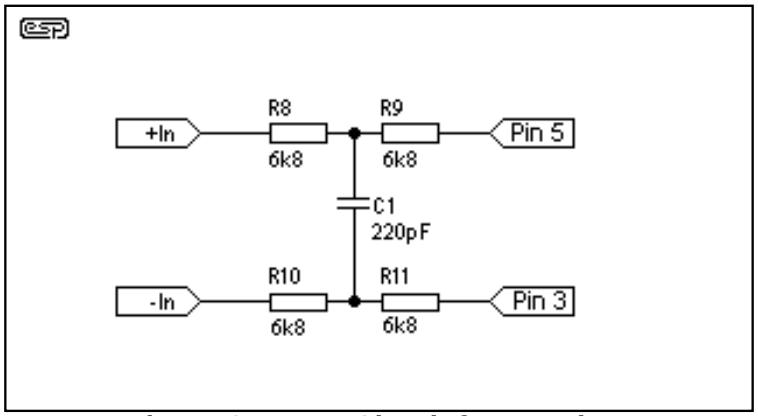


Figure 2 - Input Circuit for Receiver

The 10k resistors (R1 and R2) to ground are still needed, and this arrangement will reduce the gain by a little over 7db. Use lower value resistors for less attenuation, but remember that as the attenuation is reduced, so is noise immunity. 1k resistors would be the lowest value I'd recommend, and will cause minimum attenuation (about 1.6dB). C1 may be increased if desired, but if too high may cause rolloff of the signal source.

Mk II Transmitter

This transmitter is quite a bit more complex than the Project 51 version, but this is the price one pays for higher performance. The input is unbalanced, and has an input impedance of 11k. This must be driven from a low impedance source (such as an opamp's output) or performance will be degraded.

With the values shown, the circuit has a gain of 6dB when measured from the input, and between +Out and -Out. R13 and R14 are not absolutely essential in this version, but are recommended. They enforce a balance on the circuit, and prevent the possibility of "latch-up" where the outputs get stuck to a supply rail. This is extremely unlikely with the values shown, but the precaution is worth the very minor effort.

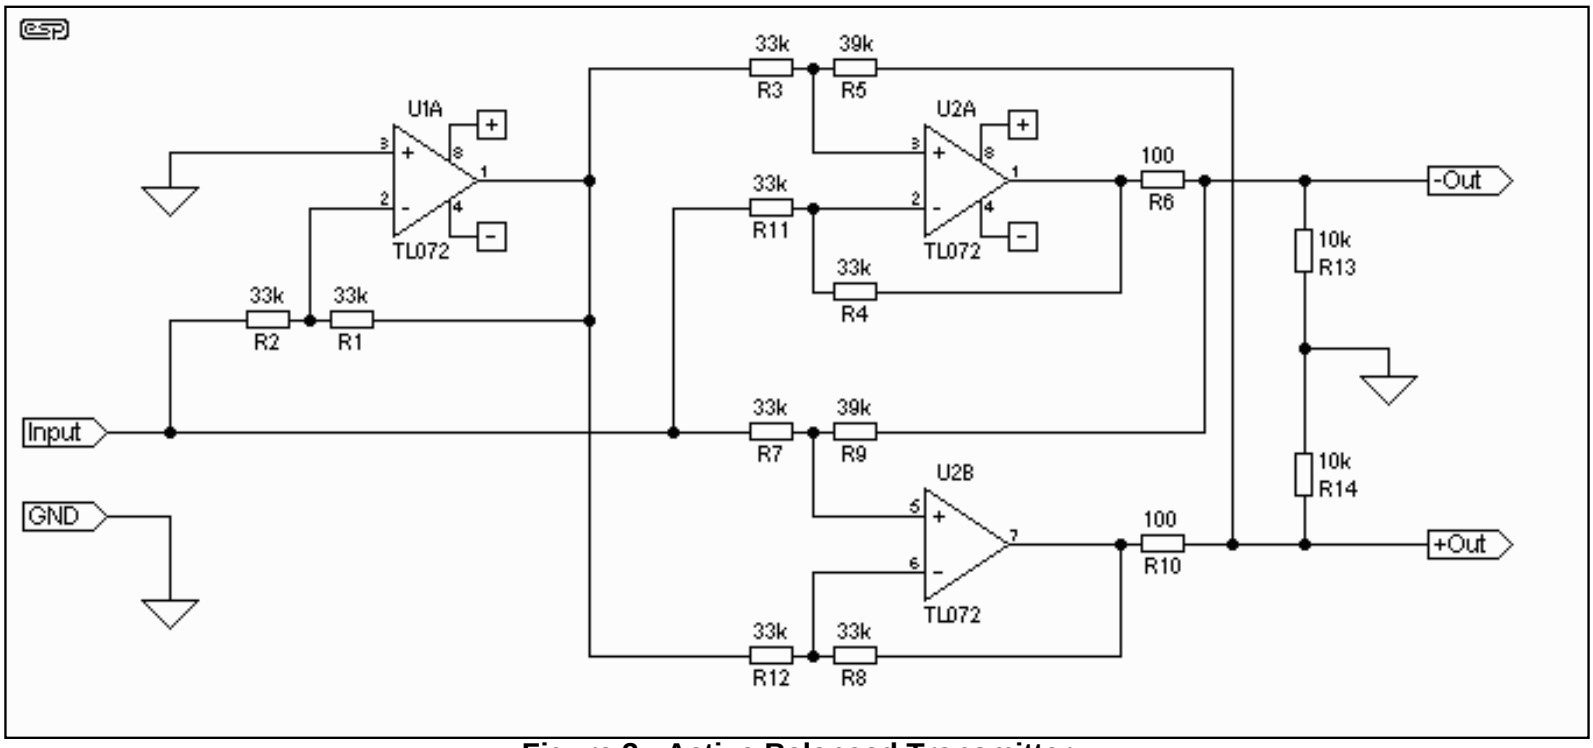

Figure 3 - Active Balanced Transmitter

If either output is shorted to ground by connection to an unbalanced input, the output voltage is only 0.4dB less than when operating in fully balanced mode. When one output is shorted, the feedback path to the other opamp is removed, so it provides (almost) the full swing that would normally be available between both opamps. This is the way a transformer (without centre tap) works, so the behaviour of this design is much closer to that of a transformer than the "standard" balanced output circuit.

1 Apr 2002 - I tested the circuit shown using 1458 dual opamps and 5% resistors. If the circuit is reliable and shows no bad habits with very basic opamps (basically dual 741s) and ordinary carbon resistors then I know that it will work when you use better components. Indeed, my test version is both stable and surprisingly accurate, despite the lowly parts used to test the circuit's operation. Because the crossed feedback paths are reduced from the optimum (by virtue of making R5 and R9 1.2 times the "correct" value), the overall stability and frequency response is much less dependent on the component values and opamp quality. I was able to verify that even using 741 type opamps, frequency response is less than 1dB down at 75kHz.

Somewhat surprisingly, output impedance is 100 ohms, and not the 200 ohms one would expect - there are 100 ohm resistors in series with each output after all. The crossed feedback paths make the difference here, and both simulation and measurement confirm that this is the case.

Construction Hints

Both the transmitter and receiver circuits require at least 1% tolerance resistors, or common mode rejection will be unacceptable. Even with 1% tolerance, the worst case rejection is only 40dB, and if you can use your multimeter to match the resistors to closer tolerance this will improve the performance.

Although the transmitter and receiver are shown with (mainly) 33k and 10k resistors respectively, these may be changed if desired. Any value between 10k and 100k could be used, but remember that higher value resistors create more thermal noise. R5 and R9 in the transmitter are approximately 1.2 times the other resistors - the next E12 value up. For example, if you elected to use 22k resistors throughout, then R5 and R9 would be 27k. Also remember that for the transmitter's input, the impedance is 1/3 of the resistor value used - 10k resistors would therefore give an input impedance of about 3k.

Both circuits require a balanced +/-12V or +/-15V supply (Project 05 or similar power supply), and it must be free of noise. Make sure that 100nF ceramic caps are placed between the supplies as close as possible to the supply pins of the opamps. This is especially important if you use high speed opamps.

Hey! That's Cheating

Finally, for those who want a balanced output that is really simple, try the circuit shown in Figure 4. Now look at it again - it's not balanced at all ... or is it?

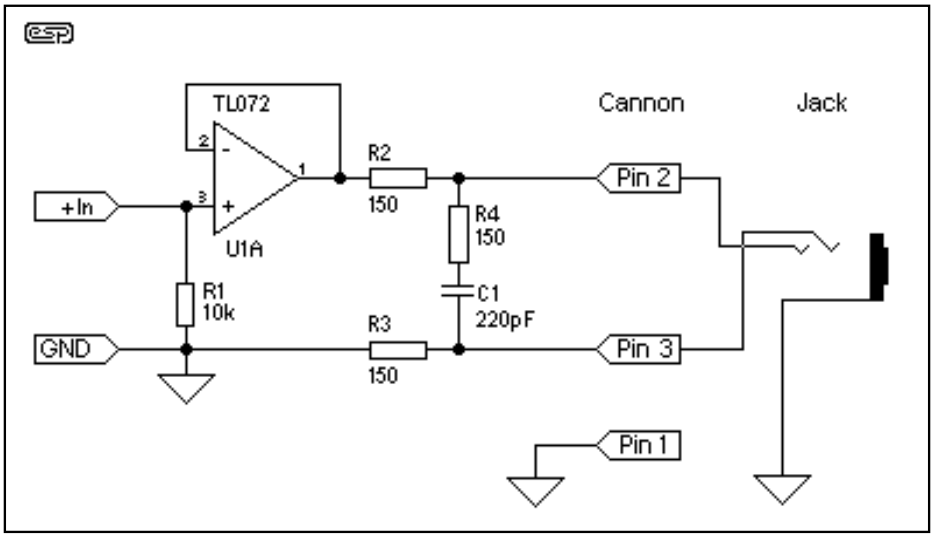

Figure 4 - Simplest Possible Balanced Output

Now, before you get all horrified, let's have a proper look at what is happening. The main trick with a balanced circuit is that the receiver should "see" the same impedance on each input. It doesn't actually care that much if there is signal on either or both wires (indeed, that is merely an *expectation* on our part), but even if the wanted signal is only on one wire, any induced noise will still be common mode, and will still be in phase across both wires. The noise gets cancelled either way, and the signal gets amplified, which is just what we want.

Yes, it's cheating - but it works. Apparently, this trick is used on some of the popular stage mixers, as well as some very well regarded phantom feed microphones (although as far as I know they don't use the Zobel network - this is optional BTW). There is less signal than one would expect (most balanced transmitter circuits have an effective gain of 6dB), but this is generally not an issue. In the case of a

microphone, the signal is the same as it would normally be anyway, and with a line output, 6dB of additional gain is usually not a problem to achieve. The amplifier as shown in Figure 4 only needs 2 x 10k resistors in the feedback path to achieve this (10k from output to -ve input (i.e. -in, *not* -ve supply pin), and 10k from -ve input to ground).

In most cases, this will work *just as well* as a true balanced output circuit. From the perspective of the balanced input circuit (the receiver), this arrangement provides exactly the same signal as if the circuit were fully balanced. Although 150 ohm resistors are shown for the balancing network, these can be changed if desired. Normally, I would expect that the values shown will be fine for almost all applications (effective output impedance is 300 ohms).

Somewhat predictably, the signal is only on one lead, so the cables had better be wired correctly if it is feeding an unbalanced input (but this is something that should be regarded as essential for all stage and studio work anyway).

Caveats - the output impedance of the opamp should be flat to a suitable high frequency, and this will not often be the case. Although I have shown a TL072 (or half thereof), I suggest that a better opamp should be used. A very high speed opamp (Such as the Texas Instruments THS6012 - See The Need For Speed) will help enormously here, but at considerable cost and inconvenience - unfortunately. In general, the output opamp should be as good as you can afford. A cheap opamp will give a cheap result. The optional zobel network will help ensure that the line appears properly balanced at all frequencies including RF, but cannot guarantee perfect results with any opamp. Resistor tolerances are just as important here as with any of the more complex versions - 1% is the minimum acceptable tolerance.

Inspiration

This new project article was inspired by Uwe Beis, and his article on the (almost) perfect balanced transmitter is published on these pages. Although the material here is somewhat "off topic" from his approach, the inspiration to experiment and try the various techniques came from his submission. I recommend that you read the full article, as it explains the operation of the balanced transmitter shown in Figure 3 very well, and will give you an idea of the dedication of some people (Uwe in this case) to the advancement of their understanding of analogue electronics.

Elliott Sound Products **Project 66**

Low Noise Balanced Microphone Preamp

By Phil Allison
(Edited by Rod Elliott - ESP)

PCBs are available for this project. Click image for details.

Introduction

This simple design has very low noise, close to the theoretical minimum, high hum rejection and variable gain with a single rotary pot. It is similar to that used in many professional grade mixing desks and can form the basis of a no compromise recording mixer for live work.

The design consists of differential compound pairs of transistors with a common mode (floating) gain control connecting the emitters of the pair. The compound pairs of 2N4403 and BC549s are far more linear than any single transistor. The circuit is differential in and out and therefore requires a balanced to unbalanced buffer to give suitable output for the next signal stages of a channel in a mixing desk. This is provided by a high performance op-amp differential gain stage, which can be a TL071 or similar IC of your choice. The stage has a gain of six or 15 dB and that sets the maximum input level at about 1.5 volts rms before clipping. This equals an SPL of over 150dB with a typical microphone!

Full gain is 1000 times or 60dB. Distortion is low to unmeasurable because it is below the noise level at high gains. The CMRR (Common Mode Rejection Ratio) is well over 60 dB and better than any available mic cable as far as hum rejection is concerned. The bandwidth extends beyond 100kHz, and no RF suppression is shown as it has proved unnecessary in practice. The input impedance or load on the mic is set by the two 3.3k ohm resistors. This will suit almost any mic with a nominal impedance of 150 to 600 ohms.

Description

The input stage is configured for least noise and this has meant a non IC approach. There are some special ICs that can be used for mic pre-amps, they contain a circuit like this one except fabricated on one chip. Examples include the SSM2017 (now obsolete) or the replacement INA217.

Components should all be readily available except for the 10 k ohm pot for the gain control. This needs to be a reverse log taper - or else use a multi-position switch with 6 dB gain steps covering the 60 dB range of the circuit. Make sure it is make before break.

Editor's Note - Alternatively, a standard log pot can be used, but wired "backwards". This will work fine if it is labelled "Attenuation" instead of "Gain". As the pot is advanced clockwise, the gain is reduced (attenuation is increased). Maximum gain will therefore be applied when the pot is fully anti-clockwise.

The +/-15 Volt power supply is important too, it must be regulated and low noise. If the usual voltage regulator ICs are used I recommend fitting a post filter consisting of a 10 ohm resistor and a 470 uF capacitor to remove any noise generated in the ICs (as shown in Figure 1). Some 7815 ICs could be sold as noise generators, the adjustable voltage ones (LM317, LM337) are very much quieter. A single regulator board may be used to power multiple preamps, with each preamp having its own post filter circuits. Because of the extensive filtering applied, the P05 (Rev-A) power supply is recommended for this preamp.

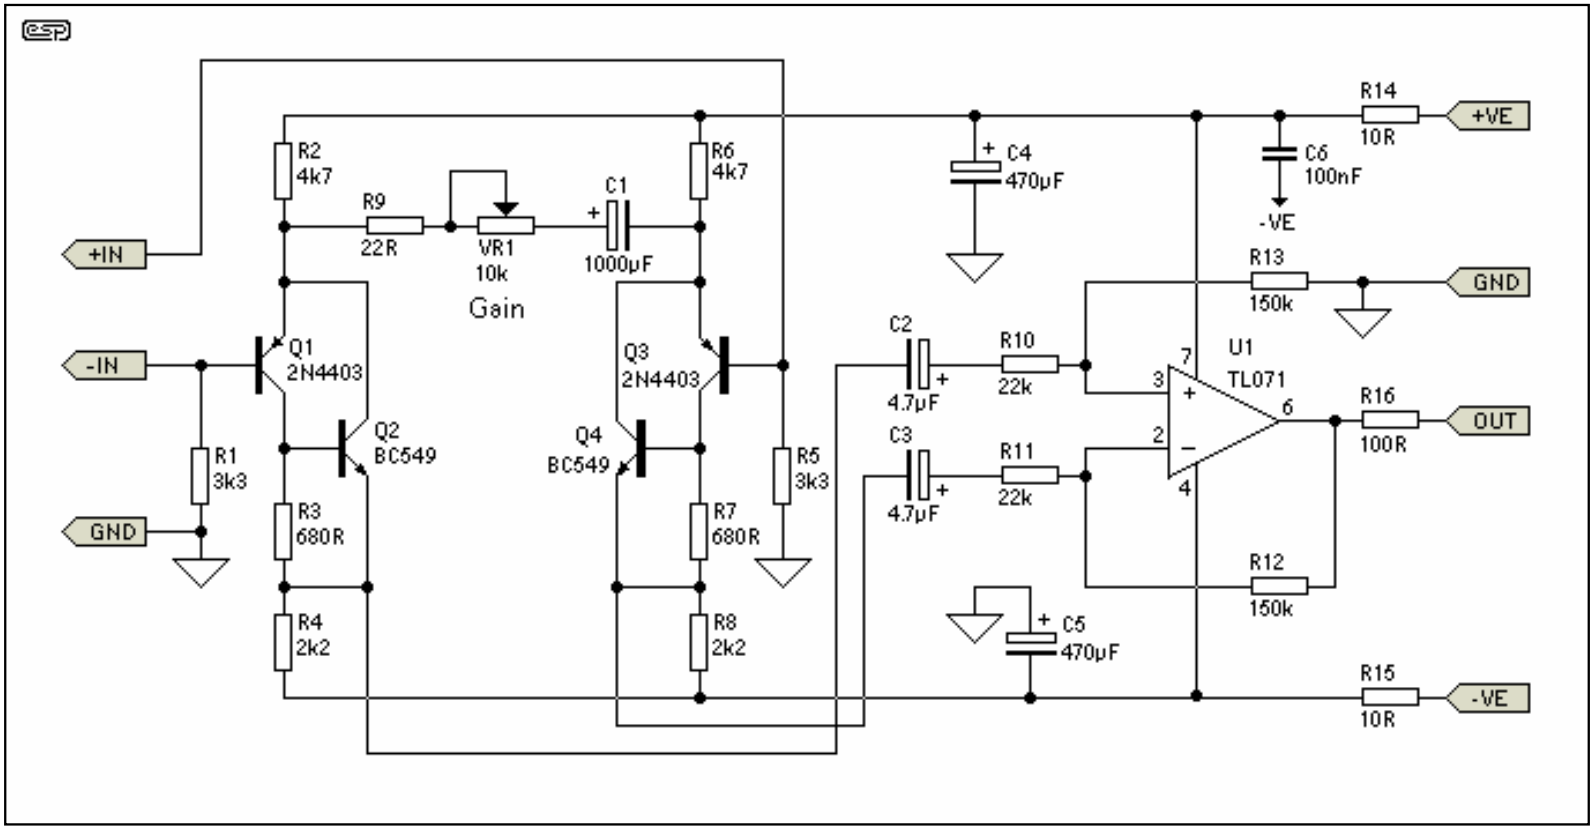

Figure 1 - Complete Microphone Preamp

Good quality components should be used with metal film resistors in the collectors and emitters of the input pairs for least noise. Where a resistor has significant DC voltage imposed on it in high gain circuits always use low noise types. Metal film resistors are about the best only bettered by wire wound which is a bit impractical. Avoid cermet, metal glaze, and very old carbon composition types. Also avoid bead tantalum capacitors, as they go leaky and crackle. They are just about the most fragile electronic components made. The 100nF capacitor (C6) should be mounted as close as possible to the opamp supply pins - a ceramic cap is recommended for best bypass performance at high frequencies.

The 1000uF capacitor can be a normal electrolytic of 10 or 16 volts rating. There is usually no problem

with zero DC bias on modern electros. All other electros should be 25V rating as a minimum.

Upon checking the published specs for the SSM2017 in regards to noise, my workshop version of the preamp measures at least as good with a 200 ohm source resistance (typical of most dynamic microphones).

> EIN = 0.27 uV rms in 20 kHz bandwidth with 200 ohm source.
> = 1.9 nV per root Hz (equal to spec for SSM 2017)
> Noise Figure = 0.9 dB rel 200 ohms.

Editor's Comment

I would suggest that 1% metal film resistors should be used throughout this circuit - the additional cost is negligible, and this will also ensure that the balanced buffer stage (U1) is properly balanced. Even a small error in the input and feedback components will degrade the common mode rejection.

Like Phil, I also recommend against the use of tantalum capacitors, and regular readers will notice that I have not suggested them for any project (although there was *one* suggestion that you could use them if you wanted to). The only capacitor fault I have ever had to track down with an *intermittent* short circuit was a tantalum bead type - it was neither fun, nor easy to find :-(

As with all circuits presented on these pages, feel free to experiment. The 2N4403 transistors may prove difficult for some readers to obtain, and BC559s can be substituted with some possible increase in noise. I would expect that any increase will be acceptable for most applications. Performance should otherwise be much the same as described.

The preamp is ideal for portable use, and can be operated from a pair of 9V batteries.

Note: PCBs are available for this preamp. There are a couple of very minor changes to the circuit, and the board is a dual preamplifier - two completely independent microphone preamps on one PCB. Included with the construction data (available when you purchase the PCB) is a switched gain control, which provides much more linear control than you will get from a pot.

As is my usual practice, the prototype was constructed from standard 5% carbon resistors. If I get good performance from this, then yours will be better if you use 1% metal film resistors - lower noise, and higher common mode rejection.

I also substituted some of the component values (only because I didn't have the correct ones immediately to hand), and the preamp worked flawlessly from the start. This means that you also have some flexibility, provided you understand the possible consequence of any substituted parts.

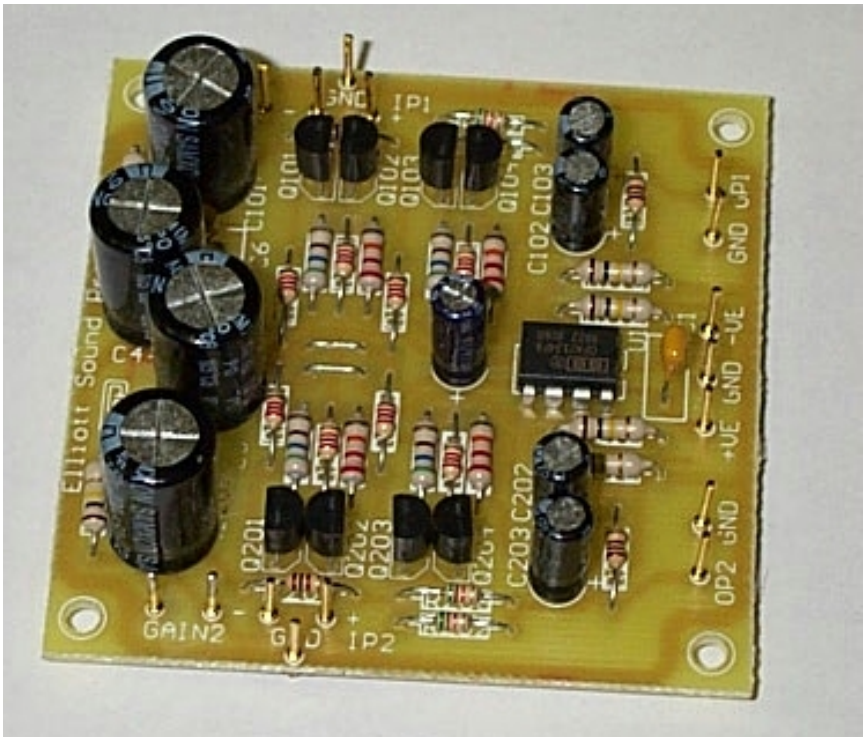

Figure 2 - Photo of the completed prototype PCB

In all, this preamp is highly recommended for professional or semi-professional use, wildlife recording or just experimenting. As you can see from the photo, the board is very compact, and I have described a phantom feed supply and distribution board elsewhere in the project section, along with a phantom powered microphone amplifier and a series of microphone projects.

MAXIM

Wideband Transconductance Amplifiers

General Description

The MAX435 and MAX436 are high-speed, wideband transconductance amplifiers (WTAs) with true differential, high-impedance inputs. Their unique architecture provides accurate gain without negative feedback, eliminating closed-loop phase shift — a primary cause of circuit oscillation in conventional high-speed amplifiers. The output of the WTA is a current that is proportional to the applied differential input voltage, providing inherent short-circuit protection for the outputs. Circuit gain is set by the ratio of two impedances and an internally set current gain factor (K).

The current output and the absence of negative feedback allow the differential output MAX435 to achieve a bandwidth of 275MHz, an 800V/µs slew rate, and a 1% settling time of 18ns to a 0.5V step input. The single-ended output MAX436 achieves a bandwidth of 200MHz, an 850V/µs slew rate, and a 1% settling time of 18ns to a 0.5V step input. Both amplifiers offer exceptional wideband common-mode rejection, with a CMRR of 53dB at 10MHz. 300µV input offset voltage offers a level of DC precision rarely found in high-speed op amps.

Unlike current-feedback amplifiers, the MAX435/MAX436 have fully symmetrical, high-impedance inputs that tolerate wide differential input voltages without destructive failure or amplifier saturation, virtually eliminating overload recovery time. The unique performance features of these WTAs suit them for a wide variety of applications, such as high-speed instrumentation amplifiers and wideband, high-gain bandpass amplifiers. And, with its differential output, the MAX435 can be used in high-speed differential line driver and receiver applications.

Applications

High-Speed Instrumentation Amplifiers

High-Speed Filters

Wideband, High-Gain Bandpass Amplifiers

Differential Line Receivers

Differential Line Drivers

Features

- ♦ **275MHz Bandwidth (MAX435)**
- ♦ **850V/µs Slew Rate**
- ♦ **18ns Settling Time to 1%**
- ♦ **53dB CMRR at 10MHz**
- ♦ **Low Noise, 7nV/√Hz at 1kHz**
- ♦ **No Feedback**
- ♦ **True Differential High-Impedance Inputs**
- ♦ **Shutdown Capability: 450µA (MAX435)**

Lead Temperature (soldering, 10 sec) ..... +300°C

Stresses beyond those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. These are stress ratings only, and functional operation of the device at these or any other conditions beyond those indicated in the operational sections of the specifications is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

Pin Description

PIN		NAME	FUNCTION
MAX435	MAX436		
1, 12, 14	1, 12, 14	V+	Positive Power Supply (+5V)
2	2	IN+	Noninverting Amplifier Input
3	3	Z+	Positive Transconductance Terminal
4	4, 9	N.C.	No Connect - Leave this pin open
5	5	Z-	Negative Transconductance Terminal
6	6	IN-	Inverting Amplifier Input Terminal
7, 8, 10	7, 8, 10	V-	Negative Power Supply (-5V)
9	–	I_{OUT-}	Inverting Differential Output
11	11	I_{SET}	Supply-Current Set Terminal
13	–	I_{OUT+}	Noninverting Differential Output
–	13	I_{OUT}	Amplifier Output Terminal

Theory of Operation

The MAX435/MAX436 are wideband transconductance amplifiers (WTA) that operate with no feedback. These amplifiers are intrinsically stable since closed-loop phase shift does not affect amplifier stability. Unlike conventional voltage-mode amplifiers, WTAs need no compensation from an internally set dominant pole. Voltage-mode amplifiers require this pole to roll off open-loop gain and prevent oscillation from high-frequency phase shift.

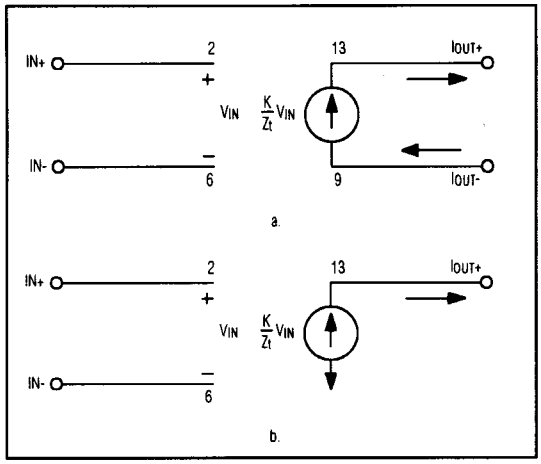

Figure 1. a) MAX435 Operational Model. b) MAX436 Operational Model.

The MAX435/MAX436's unique architecture allows single-ended (MAX436) or differential (MAX435) signal gain to be set by the ratio of two impedances: the user-selected transconductance element or network (Z_t), and the output load impedance (Z_L). The WTAs are essentially voltage-controlled current sources, as shown in Figure 1.

The MAX435/MAX436's output is a current proportional to the differential input voltage, and inversely proportional to the impedance of the user-selected transconductance element or network (Z_t). The current output provides inherent short-circuit protection for the output terminals.

A differential input voltage (V_{IN}) applied between the input terminals causes current to flow in the transconductance element (Z_t). This current is equal to V_{IN}/Z_t. The current in the transconductance element is multiplied by the preset current gain (K) of the WTA, and appears at the output terminal(s) as a current equal to (K) x (V_{IN})/Z_t. This current flows through the load impedance to produce an output voltage according to the following equation:

$$V_{OUT} = K\left(\frac{Z_L}{Z_t}\right)V_{IN}$$

Where: K = WTA Current-Gain Ratio
Z_L = Output Load Impedance
Z_t = Transconductance Element Impedance
V_{IN} = Differential Input Voltage

Unlike current-feedback amplifiers, the MAX435/MAX436 have symmetrical inputs with an input impedance of about 750kΩ. This allows true differential input applications to be realized, as shown in the MAX435 *Typical Operating Circuit*. And, because the input is symmetrical, opposite signal polarity can be obtained by swapping the input terminals.

With proper selection of component values, it is possible to implement an amplifier circuit that accepts differential input voltages covering the WTA's entire input voltage range (-2.5V to +2.5V), without overloading its output stage. This characteristic makes the MAX435/MAX436 ideal for use in wideband instrumentation amplifiers, differential receivers, and settling-time measurement circuits.

Design Procedure

Setting the Circuit Gain

The MAX435/MAX436 produce an output current by multiplying a differential input voltage, V_{IN}, by the transconductance, K/Z_t. The voltage gain (A_V) is set by the impedance of the transconductance network (Z_t) and the output load impedance (Z_L), according to the following formula:

$$A_V = K\left(\frac{Z_L}{Z_t}\right)$$

Wideband Transconductance Amplifiers

The factor K in the gain equation refers to the WTA's current gain. K is factory trimmed to provide a low-drift, stable circuit gain for WTA applications. K is trimmed to 4.0 ±2.5% for the MAX435, to 8.0 ±2.5% for the MAX436.

The factor Z_t in the gain equation is the impedance of a user-selected, 2-terminal transconductance element or network. This network is connected across the WTA's transconductance terminals, labeled as Z+ and Z-. The transconductance network should be selected, along with the output impedance, to provide the desired circuit gain and frequency shaping. To maintain linearity, the transconductance network should also be selected so that the current flowing through it, equal to V_{IN}/Z_t, does not exceed 2.5mA under worst-case conditions of maximum input voltage and minimum transconductance element impedance (Z_t). Output current should not exceed ±10mA per output for the MAX435, or ±20mA for the MAX436.

Supply Current (I_{SET}) Control

An external current source controls the WTA's internal current. Connecting an external resistor (R_{SET}) from the I_{SET} pin to the negative power supply (V-) controls the current source. The typical value for this resistor is 5.9kΩ, which provides an output-current drive capability of ±10mA per output for the MAX435, ±20mA for the MAX436. Connect a 0.22µF ceramic capacitor from the I_{SET} pin to V+, to decouple the current source.

A larger resistor value will reduce the devices' supply current, power dissipation, and output-current drive capability. A smaller resistor value may also be used to increase the output-current capability, but take care that the power dissipation rating for the device package type is not exceeded for the specific circuit operating conditions. It is especially important to consider the maximum load current and ambient operating temperature of the circuit. Refer to the graphs in the *Typical Operating Characteristics* section for typical values of load current and power dissipation for different values of R_{SET}.

Shutdown Mode

The WTA supply current varies with the value of R_{SET}, but it is relatively independent of the differential input voltage and the output load. The WTAs achieve much of their high-speed performance by maintaining a constant level of current within the internal transistors, and steering some of this current to the output when a differential input voltage is applied. To reduce power dissipation when the output load does not need to be actively driven, the I_{SET} pin can be used to place the WTA into a low-power shutdown mode. If the I_{SET} pin is disconnected from the R_{SET} resistor and left open, the supply current of the MAX435 is reduced to approximately 450µA, while the supply current of the MAX436 is reduced to approximately 850µA. To reactivate the WTA, simply reconnect the I_{SET} pin to the R_{SET} resistor.

PIN	R_{SET}	Supply Current (µA Typ, +25°C)	
		MAX435	MAX436
I_{SET} (11)	Open (00)	450	850

DC Accuracy

The DC accuracy of circuits implemented with the MAX435/MAX436 is affected by several parameters, including:

1) Input Offset Voltage
2) Output Offset Current
3) Accuracy of WTA Current Gain Factor (K)
4) Tolerance of External Transconductance and Load Impedances

The input offset voltage of the WTA is caused by a mismatch of V_{BE} voltages between the transistors in the amplifier input stage - the same mechanism that produces input offset voltages in ordinary bipolar amplifiers. The input offset voltage is measured as the voltage between the transconductance terminals (from Z+ to Z-), with each of the inputs (IN+ and IN-) grounded and no transconductance element in the circuit (Z+ and Z- are open).

In an actual application circuit, the input offset voltage causes a current to flow in the transconductance element when no differential voltage is applied at the input terminals. This current is then multiplied by K to produce an error current at the output terminal(s).

A second source of DC error is the output offset current. This parameter is measured with no transconductance element in the circuit (Z+ and Z- are open) and the input terminals (IN+ and IN-) grounded. Output offset current is the current that flows from an output terminal of the WTA under these conditions. The output offset current is the result of imperfect matching of devices in the output current mirror(s) of the WTA. The output current caused by the input offset voltage, as discussed previously, is NOT included in the Output Offset Current specification, since that component of the total output current will vary with the value of the transconductance element.

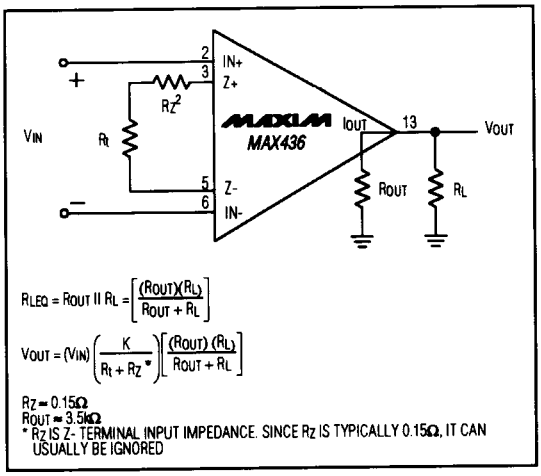

Figure 2. Finite Output-Impedance of WTA

The total DC output voltage error (at each output for the MAX435) due to the input offset voltage and output offset current is calculated with the following formulas:

MAX435:

$$V_{ERR+} = (R_{L+})\left[(I_{OS+}) + (K)\left(\frac{V_{OS}}{R_t}\right)\right]$$

$$V_{ERR-} = (R_{L-})\left[(I_{OS-}) - (K)\left(\frac{V_{OS}}{R_t}\right)\right]$$

$$V_{ERR(DIFF)} = (V_{ERR+}) - (V_{ERR-})$$

MAX436:

$$V_{ERR} = R_L\left(I_{OS} + K\frac{V_{OS}}{R_t}\right)$$

Where: V_{ERR} = Output-Voltage Error
R_L = Output Load Resistance
R_t = Transconductance Element Resistance
I_{OS} = Output Offset Current
V_{OS} = Input Offset Voltage (from Z+ to Z-)
K = WTA Current Gain

Variation of the current gain factor (K) between devices and over operating temperature is also a source of gain error in WTA applications. K for each of the devices is factory trimmed to an initial tolerance of ±2.5%. The variation of K with operating temperature is listed in the *Electrical Characteristics* tables.

The finite output impedance also affects the amplifier gain. The output(s) are voltage-controlled current sources. An ideal current source would have an infinite output impedance, so that the output current would be independent of the load impedance. In practice, the MAX435/MAX436's output impedance is about 3.5kΩ.

As shown in Figure 2, the WTA output impedance (R_{OUT}) is paralleled with the circuit load impedance (R_L), reducing the equivalent load impedance. After accounting for the finite WTA output impedance (R_{OUT}), the actual circuit gain is calculated with the following formula:

$$A_V = \frac{V_{OUT}}{V_{IN}} = \left(\frac{K}{R_t}\right)\left[\frac{(R_{OUT})(R_L)}{R_{OUT} + R_L}\right]$$

The voltage gain error (ΔA_V) with respect to the theoretical gain ($A_V = K \times R_L/R_t$) is equal to:

$$\frac{\Delta A_V}{A_V} = \frac{R_L}{R_L + R_{OUT}}$$

Power-Supply Bypassing and Board Layout

Although the WTA architecture eliminates closed-loop phase shift as a source of circuit oscillation, careful high-frequency circuit design methods should be used to optimize the performance of WTA circuits.

Proper power-supply bypassing and board layout deserve careful attention. It is recommended that a ground plane be used with the MAX435/MAX436. The ground plane should include the entire portion of the PC board that is not dedicated to a specific signal trace.

Sockets are not recommended with the WTAs, because the additional pin-to-pin capacitance they introduce degrades wideband performance. Keep the length of traces connecting to the WTA input terminals as short as possible to minimize signal reflections and/or inductive coupling of high-frequency signals to the WTA. If the input signals must travel more than a few inches, use controlled impedance lines or coaxial cables; all signals should be properly terminated. Minimize the PCB pad

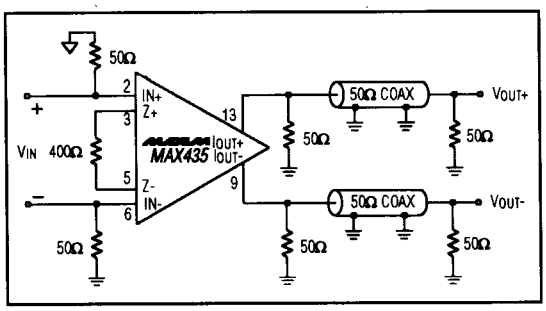

Figure 3. MAX435 Coaxial Cable Driving Circuit

Wideband Transconductance Amplifiers

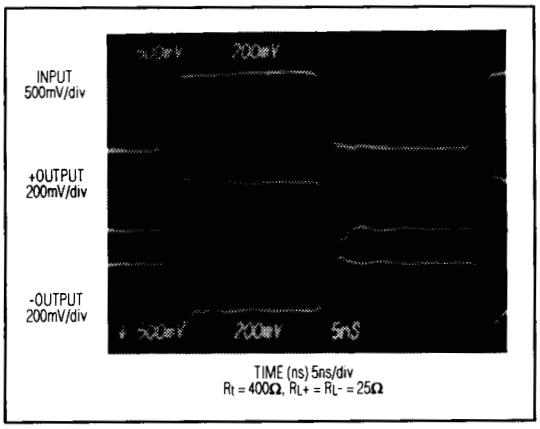

Figure 4. MAX435 Pulse Response

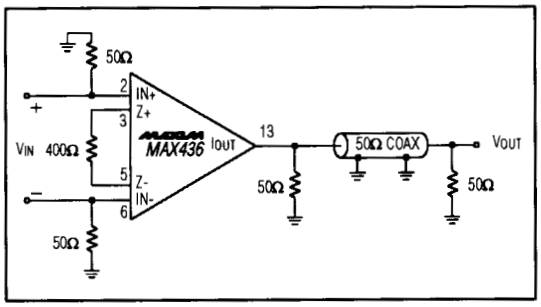

Figure 5. MAX436 Coaxial Cable Driving Circuit

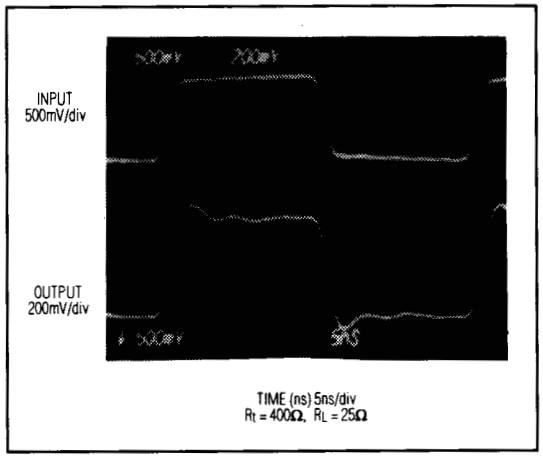

Figure 6. MAX436 Pulse Response

area for input connections, to prevent capacitive coupling of stray high-frequency signals.

Passive components used with the WTA should preferably be surface mount, to minimize stray inductance. If surface-mount components are not used, component lead lengths should be kept to an absolute minimum.

Bypass each power supply directly to the ground plane with a 0.22µF ceramic capacitor, placed as close to the supply pins as possible. Bypass the ISET pin with a 0.22µF ceramic capacitor to the V+ pin. Keep capacitor lead lengths as short as possible to minimize series inductance; surface-mount (chip) capacitors are ideal for this application.

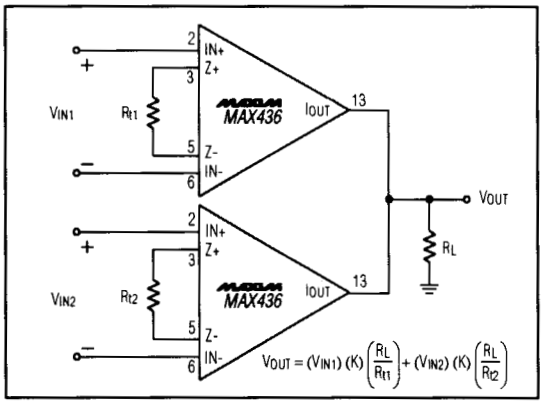

Figure 7. Summing Amplifier

Capacitive Load Driving

Since the WTA requires no feedback, phase shift due to capacitive loading of the output will not degrade the circuit stability. The primary effect of capacitive loading is a reduction in the output slew rate and bandwidth, which is limited by the rate at which the WTA output current can charge the capacitive load. Avoid capacitive coupling from the WTA output terminals to the input or transconductance terminals, since it introduces high- frequency feedback and possible oscillations.

Application Circuits

The WTA's unique architecture allows the implementation of many unique application circuits, some of which have been included here.

For the sake of clarity, bypass capacitors and the RSET resistor have not been shown in the following applications circuit schematics. The value of RSET is 5.9kΩ for every application circuit in Figures 3-16. For every application circuit in this data sheet, each power supply was bypassed to GND with a 0.22µF ceramic capacitor. The ISET pin was bypassed to V+ with a 0.22µF ceramic capacitor.

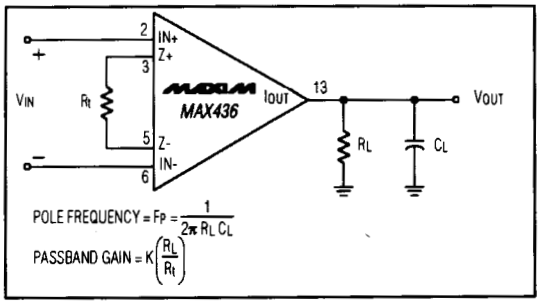

Figure 8. Lowpass Amplifier

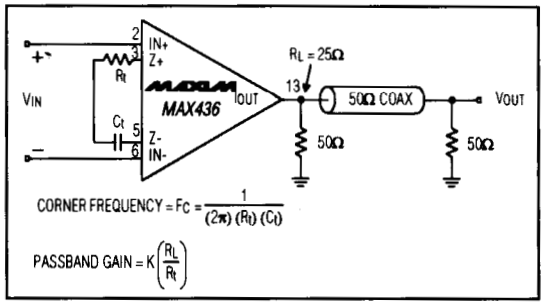

Figure 10. Highpass Amplifier

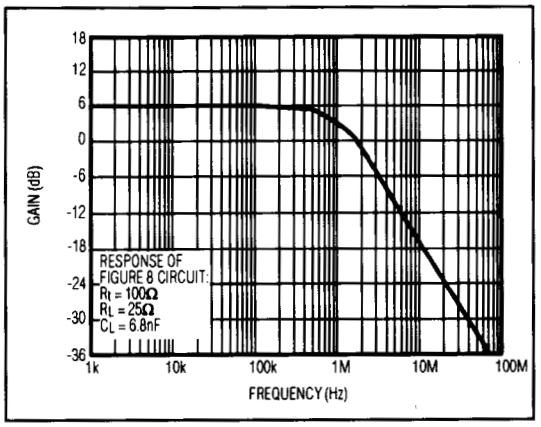

Figure 9. Lowpass Amplifier Gain vs. Frequency

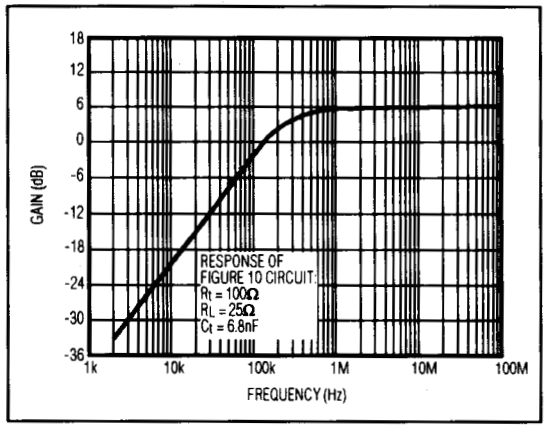

Figure 11. Highpass Amplifier Gain vs. Frequency

Coaxial Cable Drivers

To maximize power transfer and minimize distortion of high-speed signals, transmission lines must be terminated at the source and receiving ends with the characteristic impedance of the line itself. A 50Ω coaxial cable requires an impedance of 50Ω at each end for optimum performance.

With voltage-mode amplifiers, the transmitting end of a coaxial cable is typically back-terminated with a resistor in series with the amplifier output, since the voltage-mode amplifier's output has a very low impedance.

The WTA output is a current source, so its output impedance is relatively high (approximately 3.5kΩ). Therefore, when driving coaxial cables with the WTA, the back-termination resistor should be placed in parallel with the output impedance of the WTA, as shown in Figures 3 and 5. Note that back terminating cables in this manner will reduce the effective voltage gain of the circuit by a factor of 2.

The pulse response of the circuit in Figure 3 is shown in Figure 4, while Figure 6 is the pulse response of Figure 5's circuit.

Summing Amplifier

Two or more signals can be summed together by simply tying the output terminals of WTA's together as shown in Figure 7.

Lowpass Amplifier

A parallel RC network at the amplifier output will result in the lowpass amplifier circuit of Figure 8, with a -3dB corner frequency of:

$$FC = \frac{1}{(2\pi)\ (R_L)\ (C_L)}$$

The response of Figure 8's circuit with R_t = 100Ω, C_L = 6.8nF and R_L = 25Ω is plotted in Figure 9.

Highpass Amplifier

A series RC network between the transconductance terminals, as shown in the circuit of Figure 10, will produce a highpass amplifier. The response of this circuit is plotted in Figure 11, for R_t = 100Ω, C_t = 6.8nF and R_L = 25Ω.

Wideband Transconductance Amplifiers

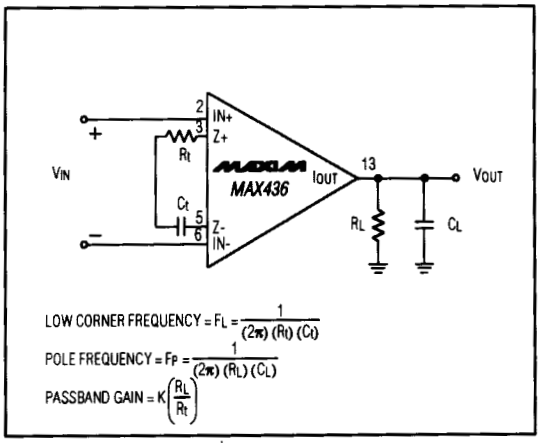

Figure 12. Bandpass Amplifier

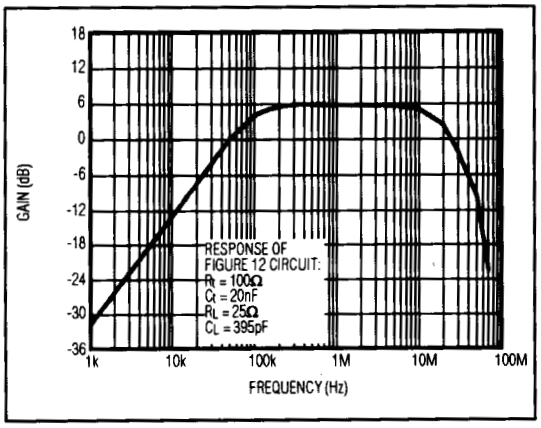

Figure 13. Bandpass Amplifier Gain vs. Frequency

Bandpass Amplifier

Since there is no interaction between the transconductance network impedance and the output load impedance, poles and zeros in the WTA transfer function can be independently set by the two impedance networks. The circuit in Figure 12 is a bandpass amplifier, with the low corner frequency set by the impedance of the transconductance network. The high corner frequency is set by the impedance of the RC network at the amplifier output. The passband gain is (K) x (RL/Rt).

Figure 13 is a plot of the response of the circuit in Figure 12, with R_t = 100Ω, C_t = 20nF, R_L = 25Ω, and C_L = 395pF.

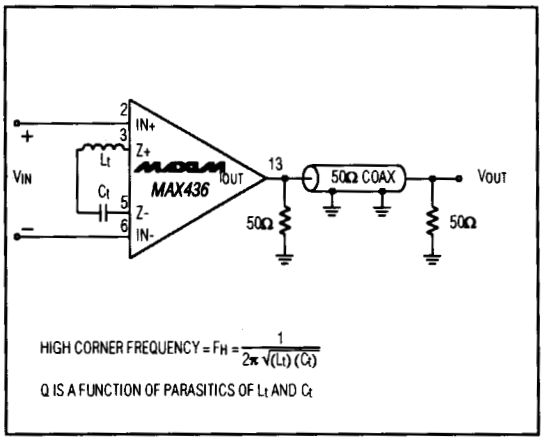

Figure 14. Tuned Amplifier

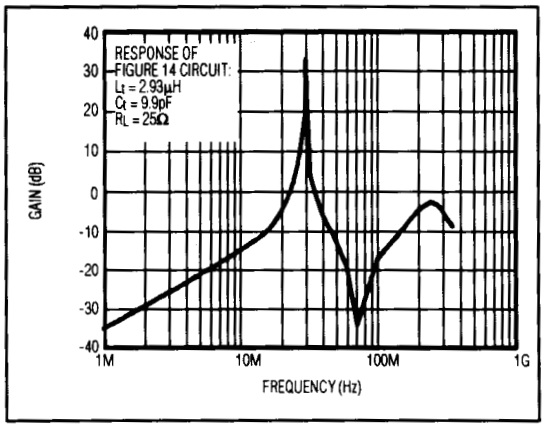

Figure 15. Tuned Amplifier Gain vs. Frequency

Tuned Amplifier

The circuit in Figure 14 is a tuned amplifier circuit, tuned to the resonant frequency of the LC transconductance network, or

$$FC = \frac{1}{2\pi\sqrt{Lt\ Ct}}$$

The impedance of the transconductance network is a minimum at the resonant frequency, providing maximum amplifier gain at that frequency. The Q of the amplifier is a function of the parasitic components associated with the LC network. Figure 15 is the frequency response of the circuit in Figure 14, with L_t = 2.93µH and C_t = 9.9pF.

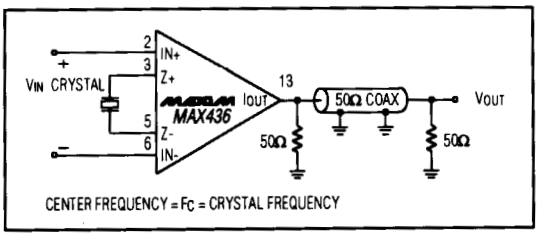

Figure 16. Crystal Tuned Amplifier

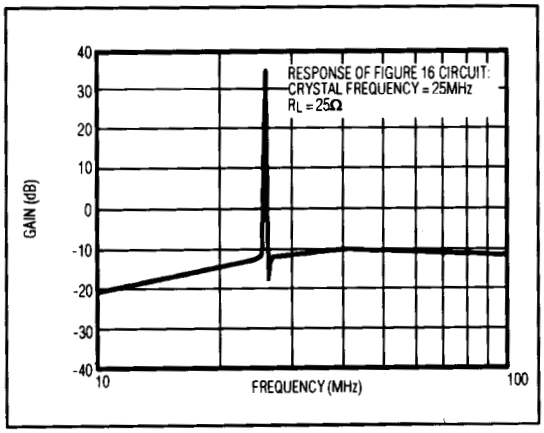

Figure 17. Crystal Tuned Amplifier Gain vs. Frequency

The high-frequency gain of this circuit (beyond the resonant frequency) can be further reduced by increasing the load capacitance.

Crystal Tuned Amplifier

If a higher Q and more accurate control of the tuned amplifier frequency is required, a crystal can replace the tuned LC network as the WTA transconductance element, as shown in the "Crystal Tuned Amplifier" circuit of Figure 16. The crystal's impedance is a minimum at its resonant frequency, resulting in maximum gain for the amplifier circuit at that frequency.

The frequency response of Figure 16's circuit with a 25MHz crystal is shown in Figure 17.

Video Twisted-Pair Driver/Receiver Circuit

For distances less than about 5000 ft. (1500m), a single channel of baseband (composite) video can be transmitted with surprisingly high quality across twisted-pair cabling, saving significant cost over traditional coaxial cabling. When using twisted pair as a transmission medium, two things are of highest importance: balanced (differential) transmission, to minimize common-mode noise, and proper termination to minimize reflections. The MAX435/MAX436, with 53dB CMRR at 10MHz and high input and output impedance, are well suited for this application.

Figure 18's circuit illustrates the MAX435 and MAX436 used as a driver/receiver circuit for twisted-pair video transmissions. One differential output MAX435 drives the balanced twisted pair from a ground-referred input signal, eliminating the need for a balun transformer or two single-ended output drivers.

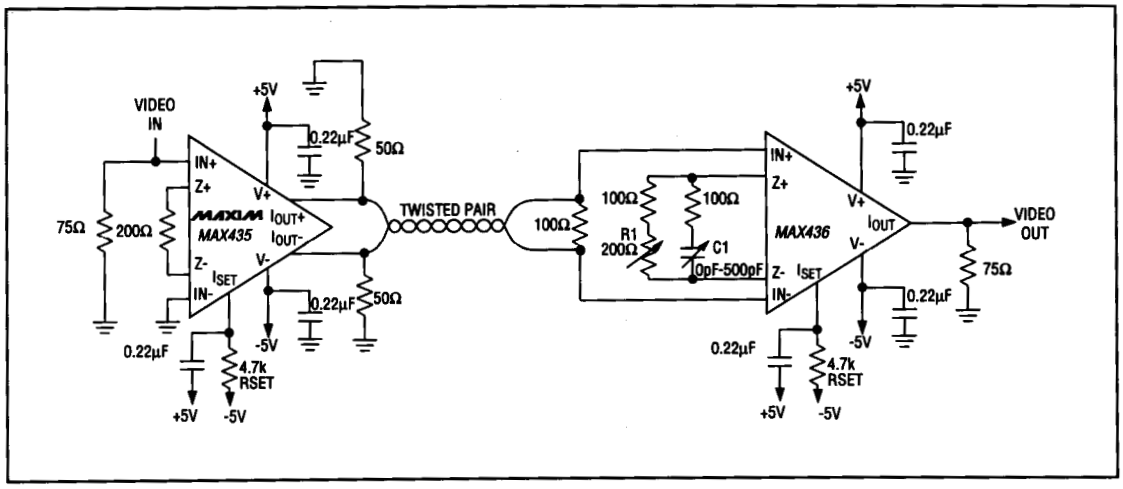

Figure 18. Video Twisted Pair Driver/Receiver Circuit

Wideband Transconductance Amplifiers

The receiver circuit uses the single-ended output MAX436 for balanced to single-ended line conversion. The 100Ω resistor from IN+ to IN- provides proper line termination. The transconductance network (from Z+ to Z-) performs the gain adjustment (+6dB), as well as line equalization. Line equalization is sometimes required to boost the high-frequency gain of the receiver to account for the limited bandwidth of the twisted pair.

In Figure 18's circuit, compensation is achieved by adjusting R1 for proper **brightness** (to boost overall gain to compensate for ohmic losses), and C1 for best **color** (to add a zero/pole pair to extend the bandwidth). Since this equalization is done on the receiver end, the end user simply views the screen and adjusts the controls for the best picture. For many NTSC applications, this line equalization may not be necessary, since the NTSC monitor performs a fair amount of loss equalization by calibrating to the test patterns in the vertical interval test signal (VITS).

The Audio Pages

Elliott Sound Products — Download Page

Page Last Updated - 31 Dec 2004

This page has links for all download files available from The Audio Pages, as well as some other useful resources. There are not a great many, but the ones here are all extremely useful (IMHO). Feel free to suggest others, or submit your own (submissions must be freeware, and not crippled or restricted in any way). Ad-ware (with embedded advertising) will not be accepted under any circumstances.

Windows DLL Files

If you get an error message at startup, it is probable that the Visual Basic runtime library is not installed on your computer. The error message will be along the lines of 'ERROR starting Program. A required DLL file, VB40032.DLL was not found'.

For Windows 98 and ME, the DLL (Dynamically Linked Library) should be in the ***\windows\system*** folder, or ***\windows\system32*** for XP, NT or 2000. The executable programs will not run if this file is missing, or is in the wrong location.

For those souls who have tried in vain to get a copy of the Visual Basic DLL, visit ... http://support.microsoft.com/support/kb/articles/q196/2/86.asp and select VB4run.exe as a download. Alternatively, download the VB40032.DLL file from here.

Programs

STORES - StoreSetup.zip (Compressed setup file - 291,866 bytes) The Stores program was written to replace my old stock management system, which was past its use-by date. Make sure you read the readme file (readme.txt).

Stores is a basic but extremely useful stock management program, that allows small manufacturers, repair shops and hobbyists to maintain a full database of all the parts they normally use. It is not limited to electronics, and can be used with anything, from tools, car parts to spares and finished goods in any industry. The version here is limited to a single database of 250 entries in a single database file, and has no reports (although the menu items are still there).

The setup file is set up to use a directory C:\Program Files\Stores which will be created during the installation. Simply run SetupStores to extract the files. If you are upgrading, don't allow "parts.txt" to be overwritten! This is the default database file. By default, the SetupStores program will not overwrite the database or config files.

The program may be registered, which will get you a CD-ROM and unlimited downloads of updates and additional functionality. The full version supports unlimited database size, 5 separate database files, stock value and re-order reports, job files, and more to come.

Both versions of the program have extensive help, and use a simple text database format. Even without indexing, a search on a 32,000 record database takes about 2 seconds on a Pentium 666MHz machine.

Registration is AU$40.00 (US$29.00), and includes a CD-ROM with the latest version and as a bonus also includes the ESP construction articles. The CD-ROM also contains the key to unlock future downloads.

CRON - cron.exe (14,428 bytes - self extracting archive) Very simple but useful job scheduler for Windows™ machines, and it has nothing to do with audio. Ideal for PCs or servers to schedule network backups (via a simple batch file), or to run other programs at the selected time(s). Can control up to 10 scheduled jobs.

ESP-SEMI - esp-semi.exe (37,735 Bytes - self extracting archive) This is a small program to find transistor data. Not everything is listed (1442 different devices). Download a copy, place it into the directory of choice and run the program, which is a self extracting archive. There are two extracted files - ESP-TRAN.EXE and BIPOLAR.TXT, being the executable and database respectively. ESP-SEMI.EXE may be deleted after extraction unless you want to give a copy to someone else. New stuff can be added as you find the data. If you add a lot of stuff, feel free to e-mail me a copy of the new database (compressed, *please*!), and I will add it to the database file.

For users who eschew Windows, the text file is still useful, as it can be read with any text editor or even a spreadsheet (TAB delimited format). Be careful with spreadsheets, as they like to try to convert some data into dates (really useful - not!).

ESP-LR - esp_lr.exe (53,760 bytes) Linkwitz-Riley crossover network calculator program. Shows the component values needed for the selected frequency, or will show the frequency for given component values. The help screen also has the standard E12 and E24 component value range for reference.

ESP-LR12 - esp-lr12.exe (66,560 bytes) Version 1.2 supports both 24dB/Octave and 12dB/Octave Linkwitz-Riley filters for greater flexibility and more options for the constructor.

MFB-FILTER - mfb-filter.exe (48,128 bytes) This program is designed to take the tedium from designing multiple feedback bandpass filters. These filters are commonly used in graphic equalisers, analysers and for special applications. A set of help screens are provided to assist with component value selection, and for determining the optimum frequency and Q of the filters for various applications.

WTIME - wtime.exe (180,224 bytes) WorldTime95 - An interesting and useful world time clock, submitted by Cyril Martin. Has 160 different cities, so time zone selection has never been easier. Requires Microsoft Visual Basic 6 runtime libraries.

REMINDER - reminder.exe (8,844 bytes) Reminder is an interesting and very useful little program to help you remember those important dates, such as birthdays, anniversaries, car repayments, and almost anything you dare not forget. In various forms, I have used this for over 9 years, and it has continued to prove itself (since I have been known to forget even my own birthday, the need for this program was fairly obvious :-)

Make sure that you create a shortcut in your startup folder, and you will be reminded each time you log in or start your computer. When you first run the program, click on "Edit" quickly (the program will exit by itself in 10 seconds if there is nothing for that day). Read the help info in the supplied demo file, delete the things you don't want, and enjoy.

LM3915 - lm3915.zip (12,583 bytes) If you have checked the data sheet for the LM3915 LED bargraph display, you know just how irksome it is to calculate the resistor values to get the correct sensitivity and LED current. Well fret no more, as this tiny program will do the work for you. (See Project 60 for the circuit details)

BOGUS - bogus.zip (192,900 bytes) This program is designed for anyone who has a website - small or large. By generating complete web pages full of bogus random e-mail addresses, the idea is to choke the spam-bots to death, and pollute the spammers' databases to the extent that they become unusable. Contains it's own dictionary, and a custom wordlist of words and phrases to make interesting (and sometimes amusing) web pages that you can upload to your site. BOGUS is freeware, and redistribution is encouraged. For more info, see the article Death to all Spammers. Note - requires VB6 runtime library to operate.

Note: Updated - there was an error in the program that would stop it from working on any system other than mine. My apologies, and it has now been fixed.

TERMS AND CONDITIONS: The ESP programs shown here are distributed as Freeware unless noted otherwise, and as such may be freely given away. The software must not be modified or changed in any way and no fee is to be charged for redistribution. Software is believed to be bug and virus free, but it is the user's responsibility absolutely to use the software and accept all or any consequences from the use thereof. ESP accepts no liability or responsibility for data or other loss howsoever caused. It is the user's responsibility to scan for viruses before using any program.

Please note that the executables are 32 bit, and need VB40032.DLL to run. This should be installed as described above. Sorry, but the programs are only available for Windows95™ or above.

Spreadsheets

linkxfrm.zip An updated version of the excellent Linkwitz Transform spreadsheet from True Audio (www.trueaudio.com). This has had additions from Dean Canafranca (one of my readers) and I added the ability to use litres or cubic feet in the new section. This is reproduced with the kind permission of True Audio. The spreadsheet is in Microsoft Excel format, and is zipped to reduce the download time.

This spreadsheet is essential if you plan on building the Linkwitz transform circuit (Project 71), since it supplies the component values to achieve the desired response.

TERMS AND CONDITIONS: The Linkwitz Transform spreadsheet is the intellectual property of True Audio, and permission to re-publish or otherwise distribute the program may be granted only by True Audio.

---

ls-param.zip Theile-Small loudspeaker parameters made easy. Use this spreadsheet to determine all the Theile Small parameters, with a few simple measurements (See the article Measuring Loudspeaker Driver Parameters for the details of the tests.

---

heatsink.zip (Zipped archive) This is a calculator to allow you to determine the thermal rating of a heatsink, based on the size of the fins and base. It is passably accurate, although slightly pessimistic compared to manufacturer ratings (either that, or it is more realistic). Heatsink dimensions can be in inches or millimetres, and the total heatsink thermal resistance is in degrees C/W. The spreadsheet is in Microsoft Excel format, and is zipped to reduce download time.

---

xover.zip Design passive crossover networks with ease - includes zobel network for woofer inductance compensation, notch filter for tweeter resonance supression, and 6dB/Octave and 12dB/Octave Linkwitz-Riley aligned passive networks. Refer to the article Design of Passive Crossovers for full details.

Miscellaneous

SIMetrix Intro - Circuit Simulator - SIMetrix is a low cost SPICE analog circuit simulation package and schematic editor for Windows 95 and NT. A free ("intro") version of the software may be downloaded from this site. This is an excellent simulator - and especially so as freeware! Highly recommended.

Warning, this is a big download, at over 6MB

HEATSINKS

by Harry Lythall - SM0VPO

Introduction
Power and heat
Heatsink characteristics
Size of heatsink
Making heatsinks
Use existing heatsinks
How big do we need it?
Mounting devices
And finally ...

INTRODUCTION

Projects often require a lot of heat to be conducted away from a device generating it. Constructors often guess at the size of heatsink then build. I used to be that way myself, but in the late 70s I began using power transistors and the tears began. I had to educate myself. After a few experiments I developed 'rough' formulas for estimating the size of heatsink needed.

POWER AND HEAT

A silicon transistor should not normally be allowed to become much hotter than about 100°C. Most transistors will happily operate hotter, but do not count upon it.

Let us take the case of the simple PSU described earlier. The PSU may deliver 3 amperes at up to 15 volts. W=VA (Watts = Volts x Amperes). The load is therefore dissipating 3 x 15 = 45 watts. With a pre-regulated voltage of 24 volts, the regulator transistor has the remaining 9 volts accross it, also at 3 amperes. The transistor is therefore turning 27 watts (9v x 3A) into heat.

If you now turn the output voltage of the PSU DOWN to 3 volts, the problem gets much worse. The load is now taking 3 x 3 = 9 watts and the transistor is dissipating (24v - 3v) x 3A = 63 watts as heat. What do we do with all this heat? - use a heatsink, of course, but how big?

HEATSINK CHARACTERISTICS

Heatsinks are given a characteristic ' °C/Watt '. A TO5 transistor (for example) without a heatsink has a case heatsink characteristic of somewhere in the region of 220°C per watt. So for every watt you make it dissipate it will increase its temperature by 220°C, or about 240 - 250°C at normal room temperatures. That's hot enough to melt solder!

A clip-on heatsink with a characteristic of 40°C/W will limit that device to 40°C + 30°C room temperature = 70°C. With the heatsink the transistor will therefore survive. The heatsink simply conducts heat away from the device and dissipates it into the room, so the larger the surface area, the lower (better) the °C/W rating that heatsink has.

SIZE OF HEATSINK

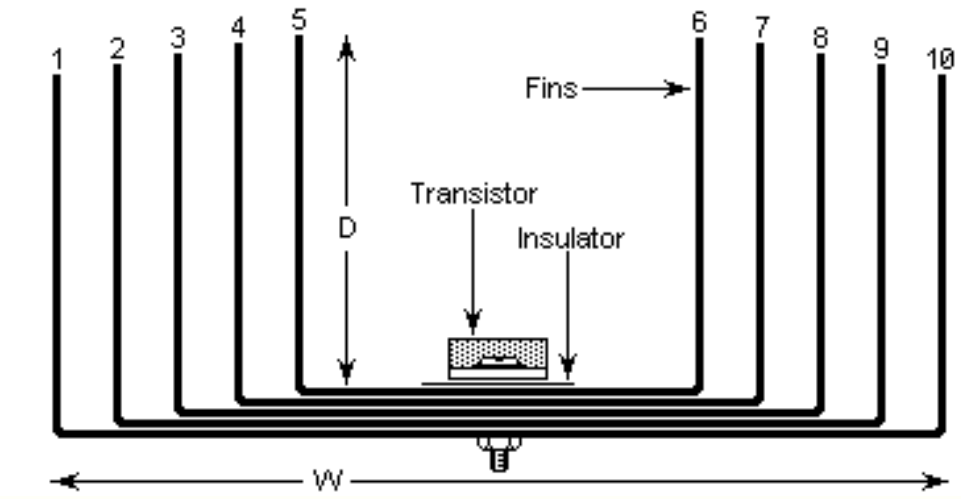
Our transistor in the PSU is dissipating 62 watts, so to keep the temperature below 100°C we should calculate the smallest heatsink required. The room temperature is assumed to be 30°C, so the transistor can increase its temperature by only 70°C. 70°C/62W = 1.13 so we will need a heatsink rated at 1.13°C/Watt, or less. Most component suppliers catalogues give a heatsinks °C/W characteristic.

MAKING HEATSINKS

You can evaluate home-made heatsinks by using the following 'ROUGH' formula:

$$\frac{50}{\sqrt{A}} = °C/watt \qquad A = \text{area (square CM)}$$

As an example, let us make a heatsink with 18 SWG aluminium sheet, folded as shown (viewed from above):



The heatsink is going to be 20cm wide (W), 10cm deep (D) and 12cm high (not shown). Each 'fin' is 10cm x 12cm = 120cm. Each fin also has two sides, area = 240 square cm. There are 10 fins so we have a total of 2400 square cm. The rear plate is also 2 sides x 20cm x 12cm = 480 square cm. Total area = 480 + 2400 = 2880 square cm.

Since $\frac{50}{\sqrt{A}} = °C/watt$ A = area (square CM) and the square root of 2880 = 53.66 we therefore have 50/53.66 = 0.932°C/watt. That would be an expensive heatsink to buy! It may not look pretty home-made, but it works just as well.

USE EXISTING HEAT SINKS

It is common practice to use the chassis of a unit as the heatsink, or part of it. An aluminium box 5cm x 10cm x 20cm would therefore have an OUTSIDE surface area of 5 x 10 x 20 = 1000 square cm. Square root of 1000 = 31.623 so our equipment case has a thermal dissipation of (50/31.623)°C/W = 1.58°C/W Since we need 1.13 we do not have enough, but we can use the case to cut down the size of the heatsink we need. Notice that the inside of the case was not taken into account. The case is a closed box so without ventilation the inside of the case will dissipate nothing.

HOW BIG DO WE NEED IT?

Ok, now let us work backwards using our PSU regulator transistor that is still dissipating over 60 watts without a heatsink. Let us mount it in the 5cm x 10cm x 20cm cabinet we found above. Transposing the formula we have:

$$A = \left(\frac{50}{°C/watt}\right)^2$$

We know we need a heatsink of 1.13°C/W so putting this into the formula we get 1957.9 square cm of heatsink required. We already have 1000 in the case, so we must provide the other 960 as fins on the back. 10 fins of 96 square cm (48 per side) will do the job. Each fin can therefore be 5cm x 10cm. Forget the backplane, that is part of the case. 5cm x 10cm is still quite big, but the case is only 5cm deep, so it is reasonable. Including heatsink, the case will now be 5cm x 20cm x 20cm. Note that only the fins were considered.

In reality, a 5cm tall case would be a little small so the case would not be able to accomodate the mains transformer, even if you used three 6.3v 3A fillament transformers. Increasing the height of the case by 1cm would reduce the size of the fins by 2cm; 6cm x 8cm (as opposed to 5cm x 10cm earlier).

MOUNTING DEVICES

Almost all devices that we need to mount on a heatsink have a metalic surface from which the heat is to be conducted. This surface is usually electrically connected to one of the terminals of the device. We therefore need to place an insulator between the device and the heat sink. In the case of transistors this is in the form of a mica washer or disk. The disk is lubricated with a heat conductive oil to help the heat to be transfered. The oil and the washer should never be omitted if the device is to be effectively protected.

Since aluminium is not the worlds best conductor of heat, I usually lay a strip of copper the full length of the heatsink. The device is mounted on the copper and the copper distributes the heat to the rest of the heatsink.

AND FINALLY ...

There are such things a temperature gradients, junction to case thermal resistance and many other parameters that could be investigated. If the subject of heatsinks were an English country mansion set in 110 acres of garden maintained by over 50 servants, I have just shown you the doorbell, or just enough to get you in the door (and out of trouble).

So, that is about all I want to say about heatsinking. Do have fun, but don't get your fingers burned! Best regards Harry, Lunda, Sweden.

'U' Clips 8
Extrusion Mounted Clips 8
Typical Clip Solution Suppliers 9

This Application Note is intended to outline the thermal options available to designers with regard to interface materials, clip types and the contact forces required to give good thermal contact and the performance that they might expect from each. The following topics will be covered:

- A brief revision of thermal resistance and its effects on system performance.
- Clip mounting of SUPER-220 devices to heat sinks, suppliers and interface materials

Mounting Guidelines for the SUPER-220

by Andrew Sawle and Arthur Woodworth

The impressive gains in power density born from the development of the 'SUPER' type power packages, *i.e. the SUPER-247*, has lead to a similar development of the TO-220 package. The removal of the hole and incorporation of new innovative ideas has lead to the SUPER-220. This new power package can now house areas of silicon that previously would have called for the use of a TO-247. These increases in power density allow designers to realise cost savings through reducing the number of paralleled devices required for a desired current rating and also reducing the areas of costly circuit board needed for their designs. Hence reductions in both the size and cost of designs are possible through the use of the SUPER-220 package.

However, increasing the power density within a design will mean that the designer needs to make careful consideration of the thermal aspects of the design aswell as the electrical. As with the SUPER-247 (see Application Note AN997) the SUPER-220 does not have a screw hole to facilitate bolting to a heatsink and therefore the package will need to be clip mounted. Clip mounting facilitates mass production techniques and good thermal performance but the latter will only be the case if the designer has made careful use of the thermal options available.

This Application Note is intended to outline the thermal options available to designers with regard to interface materials, clip types and the contact forces required to give good thermal contact and the performance that they might expect from each. The following topics will be covered:

- ➜ A brief revision of thermal resistance and its effects on system perfomance.
- ➜ Clip mounting of SUPER-220 devices to heatsinks, suppliers and interface materials.

Thermal Resistance and its Effects on System Performance

The thermal resistance ($Rth_{(junction\text{-}ambient)}$) of a system (system = package through to heatsink) is made up from a number of component parts as shown in Figure 1.1 below.

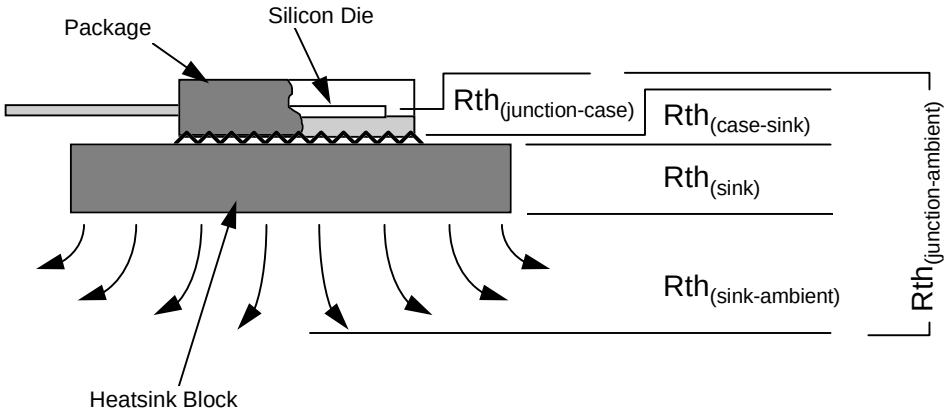

Figure 1.1 - Build-up of Thermal Resistance in a System

The designer of a system has varying amounts of influence over the component parts of the overall thermal resistance of his design:

- **$Rth_{(junction-case)}$** - this has been determined during the design and manufacture of the product. The system designer has no direct influence.
- **$Rth_{(case-sink)}$ (or Contact Thermal Resistance)** - determined by the size and quality of the contact areas between the package and the sink, the use of intermediate materials and the contact pressure. Hence, the system designer can have a large influence over this parameter.
- **$Rth_{(sink)}$ and $Rth_{(sink-ambient)}$** - determined by heatsink design, *i.e. material and shape.* The selection of a heatsink is done by trading off performance and cost requirements.

The thermal resistance of a system will determine the amount of power that can be dissipated by a device without exceeding the maximum junction temperature. Operating at temperatures above $T_{j(max)}$ will reduce the reliability of the device. Therefore by optimising the thermal performance of a system, a greater amount of power can be dissipated by each device thereby minimising the number of devices that need to be used.

Clip Mounting of the SUPER-220 Package

The removal of the hole from the TO-220 package to facilitate the greater area of silicon in the SUPER-220 package means that the new package can **NOT** be bolted to a heatsink. However the package lends itself to clip mounting, a technology that is quickly becoming popular as it holds a number of advantages over the older 'bolting' technology:

- Clips are quick to apply and therefore lend themselves to mass production assembly techniques.
- Clips maintain a constant assembly force even if the intermediate material deteriorates, unlike bolt assembly where the force diminishes.
- Clips impart their force on the central part of the package over the silicon, distributing the pressure evenly which creates a good thermal contact with the heatsink. Bolts however, impart the force at one end of the package and the pressure is uneven, see Figure 1.2.

Application of force off-centre (i.e. bolting a device to heatsink) leads to uneven themal contact. Using clip mounting ensures that the force is applied above the silicon and that the thermal contact is good.

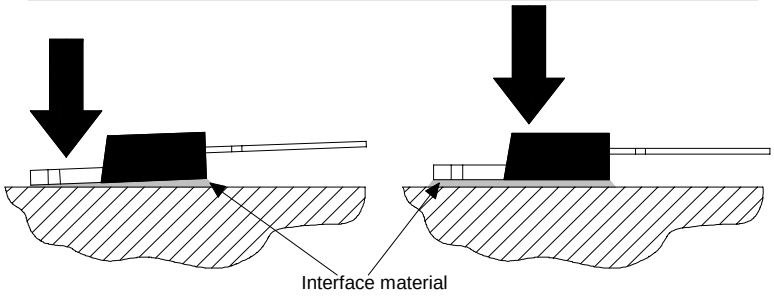

Figure 1.2 - Position of Force Application

The contact force and the way in which it is applied is therefore very important to the thermal performance of a system.

Why and How Does Contact Force Affect Thermal Resistance?

Package cases and heatsink surfaces are never perfectly flat. Hence contact between the two will only occur at several points allowing an air gap between the surfaces (as illustrated in Figure 1.3). Since air is a very good thermal insulator this means that the contact thermal resistance is much greater than it would be if the two surfaces were in perfect contact (no air gap). However, as the contact force (pushing the two surfaces together) increases then so will the number of points at which the two surfaces contact one another and the air-gap will be reduced, in turn reducing the contact thermal resistance.

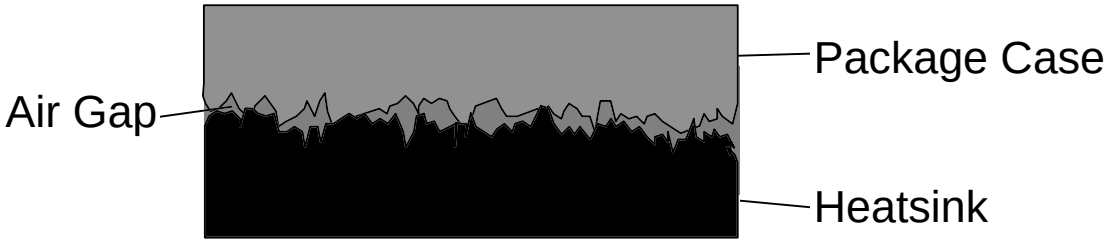

Figure 1.3 - Diagram Showing the Effect (Under High Magnification) When Two Non-perfect Surfaces Meet.

What is the minimum contact force that should be applied to gain good thermal contact?
The minimum force required for a good thermal contact will vary from package to package as it will depend on the surface finish, flatness of contact surface and area of contact. Contact thermal resistance reduces with increased contact force but the relationship is non-linear. In essence, diminishing returns in reduced thermal resistance are seen for increases in force. This relationship for the SUPER-220 on a heatsink with NO interface materials, *i.e. 'dry' conditions*, is shown in Figure 1.4. A minimum contact force of 20N is recommended.

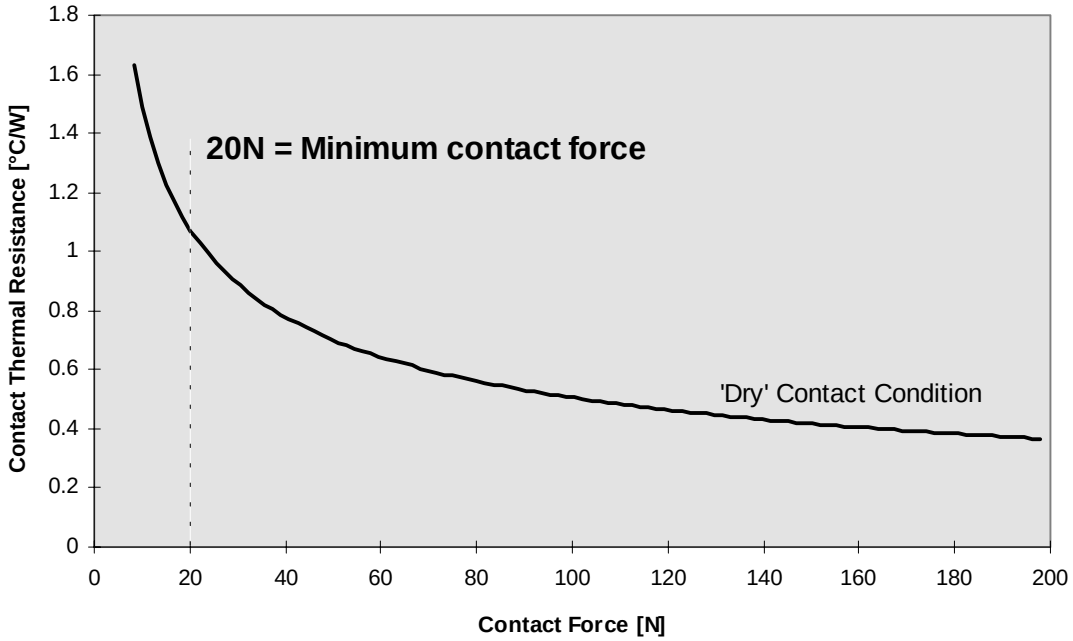

Figure 1.4 - Minimum Contact Force

Maximum Contact Force
The minimum contact force of 20N mentioned above is purely that, the MINIMUM force. Any force applied above that figure will still show gains in reduced contact thermal resistance until the maximum force that the package can withstand before the device characteristics are altered or the package is destroyed. This maximum limit figure has been measured to be 200N TYP. However, these gains are not free, for in general terms a greater contact force means a larger, more expensive clamping system. A contact force should therefore be chosen that optimises both the thermal and the cost requirements of the system.

Contact Conditions
As mentioned previously, the contact conditions between the package and the heatsink will affect the contact thermal resistance. Contact conditions encompass a number of areas including: surface roughness, surface cleanliness, paint finishes and intermediate materials. The surface roughness of the heatsinking material should be no greater than 0.02mm over the area where the device is to be mounted. Surface cleanliness during assembly of package and heatsink is imperative, even if a thermal grease or other material is subsequently added. Unclean

surfaces can be held apart by dirt or grease thus increasing the thermal resistance. However, normal paint finishes (up to 50 mm thick) have been shown to have little effect on thermal resistance, this therefore leaves intermediate materials as an area for discussion.

Interface Materials

Figure 1.4 above shows the force vs Rth relationship for ‘dry’ conditions, however, the use of no interface materials in an assembly is rare and usually one of two conditions is required:

- An interface material to improve the thermal performace of the contact area between device and heatsink.
- An interface material providing electrical isolation between the device and heatsink whilst minimising the adverse effects that it will have on the the thermal performance of the contact area. Isolation is usually required where more than one device is going to share the same heatsink.

Heatsink compound

A number of different companies offer heatsinking compound, these usually consist of silicon grease loaded with some electrically insulating, good thermally conducting material such as alumina. Thinly applied, these compounds are advantageous as they fill the air gaps and do not further increase the distances between the surfaces. Thickly applied they can hold the two surfaces apart and increase the contact thermal resistance. The following graph displayed in Figure 1.5 shows the contact thermal resistance for ‘dry’ conditions (no compound) and the thermal resistance using compound, both are plotted against contact force.

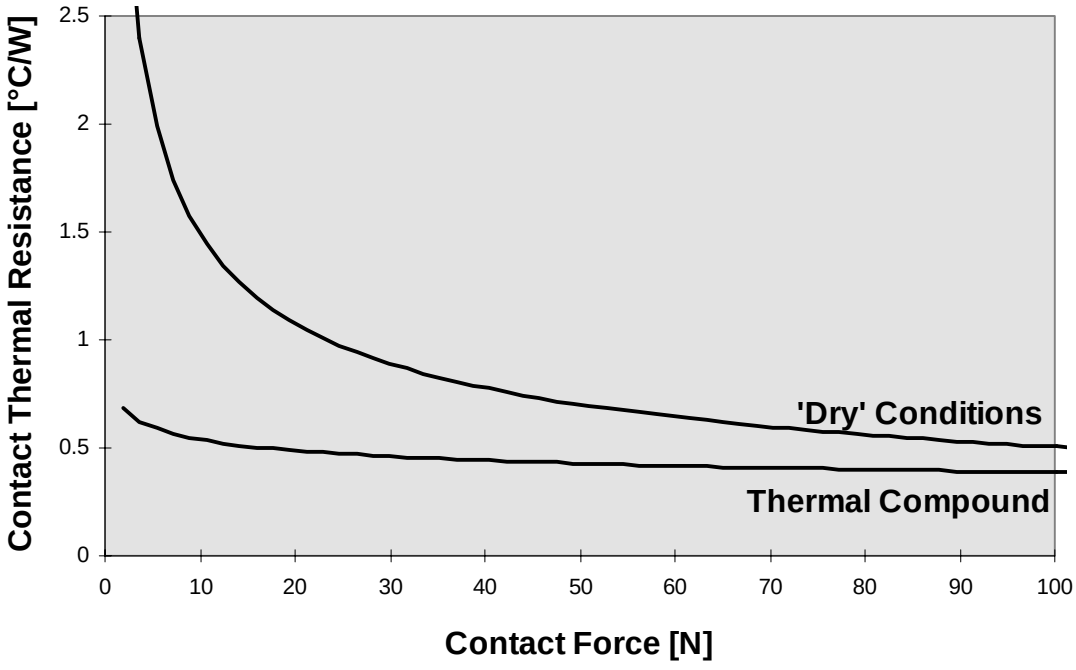

Figure 1.5 - Contact Thermal Resistance for ‘Dry’ and Compound Conditions, Plotted Against Contact Force

Interface Pads

The metal heatspreader on the back of the SUPER-220 package is non-electrically isolated from the pinouts of the device within, *i.e. the case is the drain contact for a MOSFET.* Hence in cases where devices are not electrically paralleled but share the same heatsink, it is necessary to insert an electrically isolating material between the package and the heatsink block. The isolator usually takes the form of a pad and many companies offer a range of pad material types and sizes dependant on requirements.

The pad obviously has a direct and detremental effect on the contact resistance as insertion adds an extra resistance into the build-up. Again, the contact thermal resistance is dependant on contact pressure. The following graph, shown in Figure 1.6, illustrates the higher thermal resistance when using an isolator pad. The isolator used for the line plot was a typical silicone loaded pad. Therefore, it should be noted that when electrically isolating a device from a heatsink the thermal resistance of the system will increase.

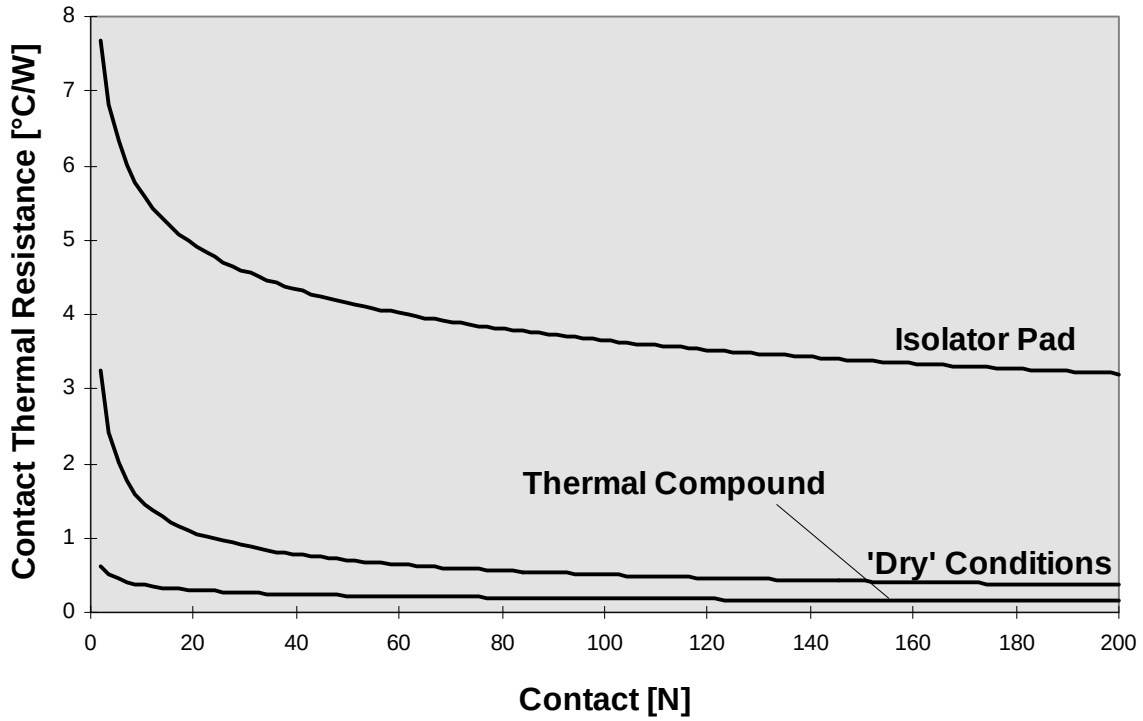

Figure 1.6 - Contact Thermal Resistance Plotted Against Contact Force

Phase Change Materials

One of the problems that interface pads have is that the forces required for good thermal contact are very high. This is because it is difficult to gain the amount of pad deformation necessary to fill the air-gaps in the heatspreader/pad and pad/heatsink interfaces. One of the solutions being offered by a number of suppliers is that of PHASE-CHANGE materials.

Phase change materials are a solid in nature until raised above a certain temperature (~50-65°C) at which point they become a viscous fluid, this change from solid to viscous occurs every time the temperature goes to this level. This fluidity means that with an adequate contact force the air-gaps can easily be filled and good thermal contact can be made. This good contact is maintained once the temperature is reduced as the material solidifies in place, filling the gaps.

The following chart in Figure 1.7 shows the contact thermal resistance using a typical phase-change isolating pad and a non-isolating pad.

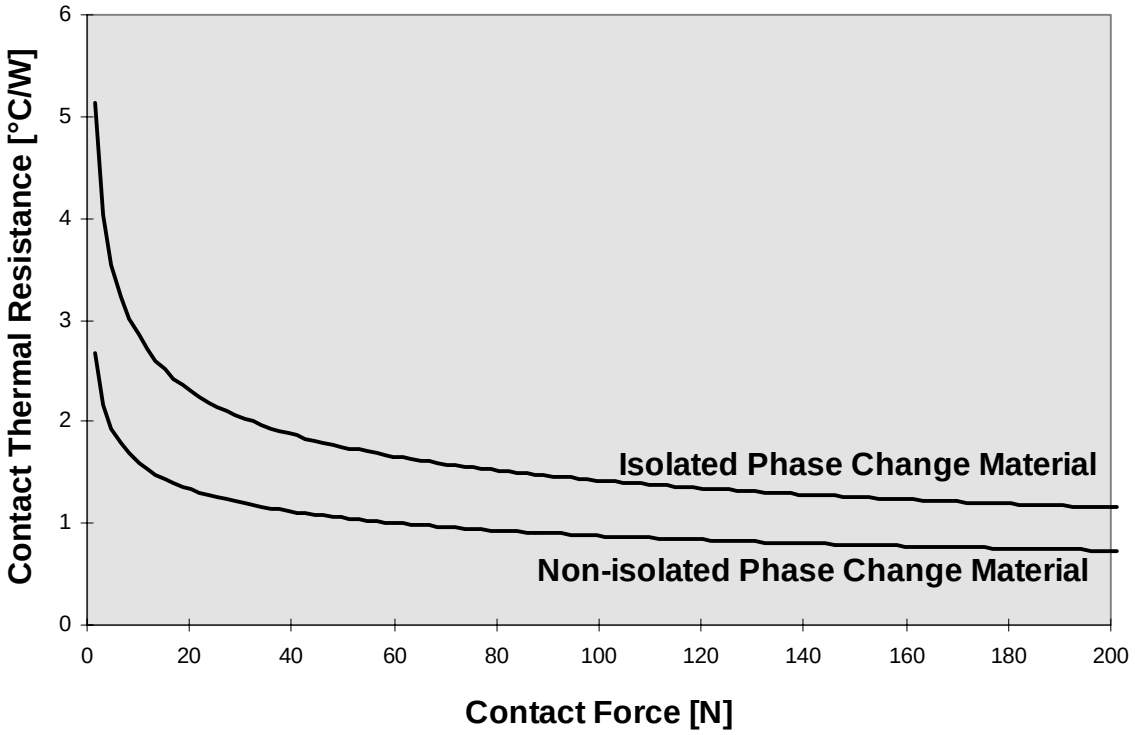

Figure 1.7 - Contact Thermal Resistance for Isolated and Non-isolated Phase Change Materials

It can be seen that phase change materials can offer lower contact thermal resistances when isolation is required over regular isolation pads. Two current manufacturers/suppliers of phase change materials are **Berquist** and **Orcus Inc**.

Heatsinks and Clips
A range of heatsinks and clips have been developed by a number of suppliers for the SUPER-220 package type. A number of these clip types are shown in the following diagrams. However, the clips shown are only a small selection and by no means encompass all available types and solutions.

Saddle Clips
An example of a SUPER-220 mounted to a heatsink using a saddle clip is shown in Figure 1.8.

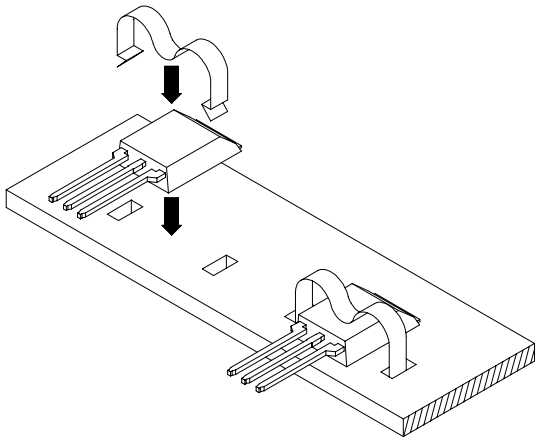

Figure 1.8 - SUPER-220 Mounted to Heatsink Using Saddle Clip

When using saddle clip type solutions, the heatsink materials are thin in cross-section, typically less than 5mm in thickness. The clips push into holes cut into heatsink material and lock against the back face of the heatsink. These clips produce contact forces in the range 15-50N.

'U' Clips
An example of a heatsink assembly utilising a 'U' clip is shown in Figure 1.9.

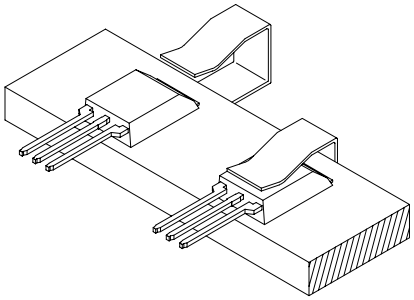

Figure 1.9 - SUPER-220 and a 'U' Clip Assembly

This clip type clamps the device and the heatsink material together. Variations on this clip type allow devices to be clamped to the front and back of the heatsink block using the same clip. 'U' clips can offer contact forces in the range 15-50N.

Extrusion Mounted Clips
There are a number of proprietary clip solutions offered where the clip is anchored in a feature in an extruded heatsink. One such solution is to use rails on extruded sinks for clip anchorage. This method is shown in Figure 1.10.

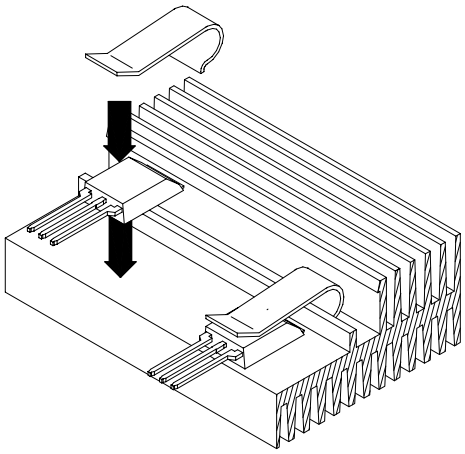

Figure 1.10 - Extrusion Mounted Clip (Rail Anchorage)

Clips on extruded sinks can offer contact forces in the range 25-50N

Mounting Considerations For Power Semiconductors

ON Semiconductor™

http://onsemi.com

Prepared by: Bill Roehr

APPLICATION NOTE

INTRODUCTION

Current and power ratings of semiconductors are inseparably linked to their thermal environment. Except for lead–mounted parts used at low currents, a heat exchanger is required to prevent the junction temperature from exceeding its rated limit, thereby running the risk of a high failure rate. Furthermore, the semiconductor industry's field history indicated that the failure rate of most silicon semiconductors decreases approximately by one–half for a decrease in junction temperature from 160°C to 135°C.(1) Guidelines for designers of military power supplies impose a 110°C limit upon junction temperature.(2) Proper mounting minimizes the temperature gradient between the semiconductor case and the heat exchanger.

Most early life field failures of power semiconductors can be traced to faulty mounting procedures. With metal packaged devices, faulty mounting generally causes unnecessarily high junction temperature, resulting in reduced component lifetime, although mechanical damage has occurred on occasion from improperly mounting to a warped surface. With the widespread use of various plastic–packaged semiconductors, the prospect of mechanical damage is very significant. Mechanical damage can impair the case moisture resistance or crack the semiconductor die.

Figure 1 shows an example of doing nearly everything wrong. A tab mount TO–220 package is shown being used as a replacement for a TO–213AA (TO–66) part which was socket mounted. To use the socket, the leads are bent – an operation which, if not properly done, can crack the package, break the internal bonding wires, or crack the die. The package is fastened with a sheet–metal screw through a 1/4″ hole containing a fiber–insulating sleeve. The force used to tighten the screw tends to pull the package into the hole, possibly causing enough distortion to crack the die. In addition, the contact area is small because of the area consumed by the large hole and the bowing of the package; the result is a much higher junction temperature than expected. If a rough heatsink surface and/or burrs around the hole were displayed in the illustration, most but not all, poor mounting practices would be covered.

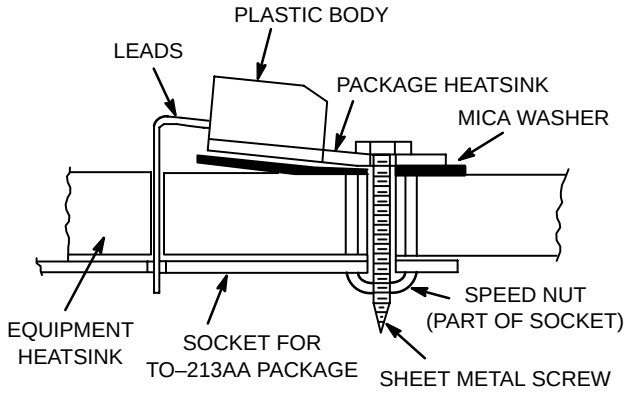

Figure 1. Extreme Case of Improperly Mounting a Semiconductor (Distortion Exaggerated)

In many situations, the case of the semiconductor must be electrically isolated from its mounting surface. The isolation material is, to some extent, a thermal isolator as well, which raises junction operating temperatures. In addition, the possibility of arc–over problems is introduced if high voltages are present. Various regulating agencies also impose creepage distance specifications which further complicates design. Electrical isolation thus places additional demands upon the mounting procedure.

Proper mounting procedures usually necessitate orderly attention to the following:

1. Preparing the mounting surface
2. Applying a thermal grease (if required)
3. Installing the insulator (if electrical isolation is desired)
4. Fastening the assembly
5. Connecting the terminals to the circuit

© Semiconductor Components Industries, LLC, 2001

In this note, mounting procedures are discussed in general terms for several generic classes of packages. As newer packages are developed, it is probable that they will fit into the generic classes discussed in this note. Unique requirements are given on data sheets pertaining to the particular package. The following classes are defined:

Stud Mount
Flange Mount
Pressfit
Plastic Body Mount
Tab Mount
Surface Mount

Appendix A contains a brief review of thermal resistance concepts. Appendix B discusses measurement difficulties with interface thermal resistance tests. Appendix C indicates the type of accessories supplied by a number of manufacturers.

MOUNTING SURFACE PREPARATION

In general, the heatsink mounting surface should have a flatness and finish comparable to that of the semiconductor package. In lower power applications, the heatsink surface is satisfactory if it appears flat against a straight edge and is free from deep scratches. In high–power applications, a more detailed examination of the surface is required. Mounting holes and surface treatment must also be considered.

Surface Flatness

Surface flatness is determined by comparing the variance in height (Δh) of the test specimen to that of a reference standard as indicated in Figure 2. Flatness is normally specified as a fraction of the Total Indicator Reading (TIR). The mounting surface flatness, i.e, Δh/TlR, if less than 4 mils per inch, normal for extruded aluminum, is satisfactory in most cases.

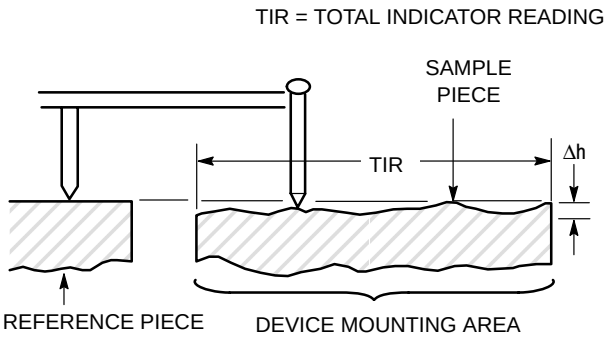

Figure 2. Surface Flatness Measurement

Surface Finish

Surface finish is the average of the deviations both above and below the mean value of surface height. For minimum interface resistance, a finish in the range of 50 to 60 microinches is satisfactory; a finer finish is costly to achieve and does not significantly lower contact resistance. Tests conducted by Thermalloy, Inc., using a copper TO–204 (TO–3) package with a typical 32–microinch finish, showed that heatsink finishes between 16 and 64 μ–in caused less than ± 2.5% difference in interface thermal resistance when the voids and scratches were filled with a thermal joint compound.[3] Most commercially available cast or extruded heatsinks will require spotfacing when used in high–power applications. In general, milled or machined surfaces are satisfactory if prepared with tools in good working condition.

Mounting Holes

Mounting holes generally should only be large enough to allow clearance of the fastener. The larger thick flange type packages having mounting holes removed from the semiconductor die location, such as the TO–3, may successfully be used with larger holes to accommodate an insulating bushing, but many plastic encapsulated packages are intolerant of this condition. For these packages, a smaller screw size must be used such that the hole for the bushing does not exceed the hole in the package.

Punched mounting holes have been a source of trouble because if not properly done, the area around a punched hole is depressed in the process. This “crater” in the heatsink around the mounting hole can cause two problems. The device can be damaged by distortion of the package as the mounting pressure attempts to conform it to the shape of the heatsink indentation, or the device may only bridge the crater and leave a significant percentage of its heat–dissipating surface out of contact with the heatsink. The first effect may often be detected immediately by visual cracks in the package (if plastic), but usually an unnatural stress is imposed, which results in an early–life failure. The second effect results in hotter operation and is not manifested until much later.

Although punched holes are seldom acceptable in the relatively thick material used for extruded aluminum heatsinks, several manufacturers are capable of properly utilizing the capabilities inherent in both fine–edge blanking or sheared–through holes when applied to sheet metal as commonly used for stamped heatsinks. The holes are pierced using Class A progressive dies mounted on four–post die sets equipped with proper pressure pads and holding fixtures.

When mounting holes are drilled, a general practice with extruded aluminum, surface cleanup is important. Chamfers must be avoided because they reduce heat transfer surface and increase mounting stress. However, the edges must be broken to remove burrs which cause poor contact between device and heatsink and may puncture isolation material.

Surface Treatment

Many aluminum heatsinks are black–anodized to improve radiation ability and prevent corrosion. Anodizing results in significant electrical, but negligible thermal insulation; it need only be removed from the mounting area when electrical contact is required. Heatsinks are also available which have a nickel plated copper insert under the semiconductor mounting area. No treatment of this surface is necessary.

Another treated aluminum finish is iridite, or chromateacid dip, which offers low resistance because of its thin surface, yet has good electrical properties because it resists oxidation. It need only be cleaned of the oils and films that collect in the manufacture and storage of the sinks, a practice which should be applied to all heatsinks.

For economy, paint is sometimes used for sinks; removal of the paint where the semiconductor is attached is usually required because of paint's high thermal resistance. However, when it is necessary to insulate the semiconductor package from the heatsink, hard anodized or painted surfaces allow an easy installation for low voltage applications. Some manufacturers will provide anodized or painted surfaces meeting specific insulation voltage requirements, usually up to 400 volts.

It is also necessary that the surface be free from all foreign material, film, and oxide (freshly bared aluminum forms an oxide layer in a few seconds). Immediately prior to assembly, it is a good practice to polish the mounting area with No. 000 steel wool, followed by an acetone or alcohol rinse.

INTERFACE DECISIONS

When any significant amount of power is being dissipated, something must be done to fill the air voids between mating surfaces in the thermal path. Otherwise, the interface thermal resistance will be unnecessarily high and quite dependent upon the surface finishes.

For several years, thermal joint compounds, often called grease, have been used in the interface. They have a resistivity of approximately 60°C/W/in whereas air has 1200°C/W/in. Since surfaces are highly pock–marked with minute voids, use of a compound makes a significant reduction in the interface thermal resistance of the joint. However, the grease causes a number of problems, as discussed in the following section.

To avoid using grease, manufacturers have developed dry conductive and insulating pads to replace the more traditional materials. These pads are conformal, therefore, they partially fill voids when under pressure.

Thermal Compounds (Grease)

Joint compounds are a formulation of fine zinc or other conductive particles in a silicone oil or other synthetic base fluid which maintains a grease–like consistency with time and temperature. Since some of these compounds do not spread well, they should be evenly applied in a very thin layer using a spatula or lintless brush, and wiped lightly to remove excess material. Some cyclic rotation of the package will help the compound spread evenly over the entire contact area. Some experimentation is necessary to determine the correct quantity; too little will not fill all the voids, while too much may permit some compound to remain between well–mated metal surfaces where it will substantially increase the thermal resistance of the joint.

To determine the correct amount, several semiconductor samples and heatsinks should be assembled with different amounts of grease applied evenly to one side of each mating surface. When the amount is correct, a very small amount of grease should appear around the perimeter of each mating surface as the assembly is slowly torqued to the recommended value. Examination of a dismantled assembly should reveal even wetting across each mating surface. In production, assemblers should be trained to slowly apply the specified torque even though an excessive amount of grease appears at the edges of mating surfaces. Insufficient torque causes a significant increase in the thermal resistance of the interface.

To prevent accumulation of airborne particulate matter, excess compound should be wiped away using a cloth moistened with acetone or alcohol. These solvents should not contact plastic–encapsulated devices, as they may enter the package and cause a leakage path or carry in substances which might attack the semiconductor chip.

The silicone oil used in most greases has been found to evaporate from hot surfaces with time and become deposited on other cooler surfaces. Consequently, manufacturers must determine whether a microscopically thin coating of silicone oil on the entire assembly will pose any problems. It may be necessary to enclose components using grease. The newer synthetic base greases show far less tendency to migrate or creep than those made with a silicone oil base. However, their currently observed working temperature range is less, they are slightly poorer on thermal conductivity and dielectric strength and their cost is higher.

Data showing the effect of compounds on several package types under different mounting conditions is shown in Table 1. The rougher the surface, the more valuable the grease becomes in lowering contact resistance; therefore, when mica insulating washers are used, use of grease is generally mandatory. The joint compound also improves the breakdown rating of the insulator.

Conductive Pads

Because of the difficulty of assembly using grease and the evaporation problem, some equipment manufacturers will not, or cannot, use grease. To minimize the need for grease, several vendors offer dry conductive pads which approximate performance obtained with grease. Data for a greased bare joint and a joint using Grafoil®, a dry graphite compound, is shown in the data of Figure 3 through Figure 6. Grafoil is claimed to be a replacement for grease when no electrical isolation is required; the data indicates it does indeed perform as well as grease. Another conductive pad available from Aavid is called Kon–Dux™. It is made with a unique, grain oriented, flake–like structure (patent pending). Highly compressible, it becomes formed to the surface roughness of both the heatsink and semiconductor. Manufacturer's data shows it to provide an interface thermal resistance better than a metal interface with filled silicone grease. Similar dry conductive pads are available from other manufacturers. They are a fairly recent development; long term problems, if they exist, have not yet become evident.

Table 1. Approximate Values for Interface Thermal Resistance Data from Measurements Performed in ON Semiconductor Applications Engineering Laboratory

Dry interface values are subject to wide variation because of extreme dependence upon surface conditions. Unless otherwise noted, the case temperature is monitored by a thermocouple located directly under the die reached through a hole in the heatsink. (See Appendix B for a discussion of Interface Thermal Resistance Measurements.)

Package Type and Data		Interface Thermal Resistance (°C/W)

INSULATION CONSIDERATIONS

Since most power semiconductors use vertical device construction, it is common to manufacture power semiconductors with the output electrode (anode, collector or drain) electrically common to the case; the problem of isolating this terminal from ground is a common one. For lowest overall thermal resistance, which is quite important when high power must be dissipated, it is best to isolate the entire heatsink/semiconductor structure from ground, rather than to use an insulator between the semiconductor and the heatsink. Heatsink isolation is not always possible, however, because of EMI requirements, safety reasons, instances where a chassis serves as a heatsink or where a heatsink is common to several non–isolated packages. In these situations, insulators are used to isolate the individual components from the heatsink. Newer packages, such as the ON Semiconductor FULLPAK™ and EMS modules, contain the electrical isolation material within, thereby saving the equipment manufacturer the burden of addressing the isolation problem.

Insulator Thermal Resistance

When an insulator is used, thermal grease is of greater importance than with a metal–to–metal contact, because two interfaces exist instead of one and some materials, such as mica, have a hard, markedly uneven surface. With many isolation materials, reduction of interface thermal resistance of between 2 to 1 and 3 to 1 are typical when grease is used.

Data obtained by Thermalloy, showing interface resistance for different insulators and torques applied to TO–204 (TO–3) and TO–220 packages, are shown in Figure 3 through Figure 6, for bare and greased surfaces. Similar materials to those shown are available from several manufacturers. It is obvious that with some arrangements, the interface thermal resistance exceeds that of the semiconductor (junction to case).

Referring to Figure 3 through Figure 6, one may conclude that when high power is handled, beryllium oxide is unquestionably the best. However, it is an expensive choice. (It should not be cut or abraded, as the dust is highly toxic.) Thermafilm® is a filled polymide material which is used for isolation (variation of Kapton®). It is a popular material for low power applications because of its low cost ability to withstand high temperatures, and ease of handling in contrast to mica which chips and flakes easily.

A number of other insulating materials are also shown. They cover a wide range of insulation resistance, thermal resistance and ease of handling. Mica has been widely used in the past because it offers high breakdown voltage and fairly low thermal resistance at a low cost, but it certainly should be used with grease.

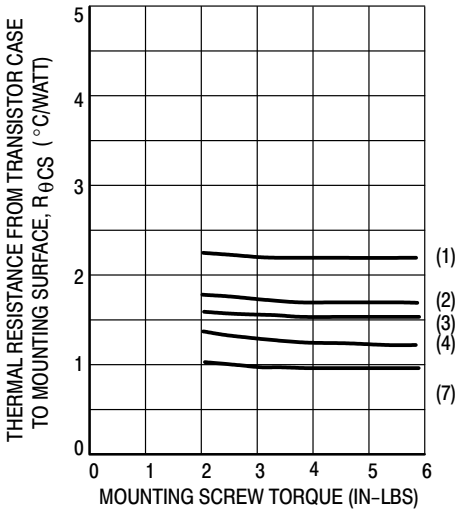

Figure 6. TO–220 With Thermal Grease

INTERFACE THERMAL RESISTANCE FOR TO–204, TO–3, AND TO–220 PACKAGES USING DIFFERENT INSULATING MATERIALS AS A FUNCTION OF MOUNTING SCREW TORQUE (DATA COURTESY THERMALLOY)

Silicone rubber insulators have gained favor because they are somewhat conformal under pressure. Their ability to fill in most of the metal voids at the interface reduces the need for thermal grease. When first introduced, they suffered from cut–through after a few years in service. The ones presently available have solved this problem by having imbedded pads of Kapton or fiberglass. By comparing Figure 5 and Figure 6, it can be noted that Thermasil™, a filled silicone rubber, without grease, has about the same interface thermal resistance as greased mica for the TO–220 package.

A number of manufacturers offer silicone rubber insulators. Table 2 shows measured performance of a number of these insulators under carefully controlled, nearly identical conditions. The interface thermal resistance extremes are over 2:1 for the various materials. It is also clear that some of the insulators are much more tolerant than others of out–of–flat surfaces. Since the tests were performed, newer products have been introduced. The Bergquist K–10® pad, for example, is described as having about 2/3 the interface resistance of the Sil–Pad® 1000 which would place its performance close to the Chomerics 1671 pad. Aavid also offers an isolated pad called Rubber–Duc™, however, it is only available vulcanized to a heatsink and, therefore, was not included in the comparison. Published data from Aavid shows $R_{\theta CS}$ below 0.3°C/W for pressures above 500 psi. However, surface flatness and other details are not specified, so a comparison cannot be made with other data in this note.

Table 2. Thermal Resistance of Silicone Rubber Pads

Manufacturer	Product	$R_{\theta CS}$ @ 3 Mils*	$R_{\theta CS}$ @ 7.5 Mils*
Wakefield	Delta Pad 173–7	.790	1.175
Bergquist	Sil–Pad K–4®	.752	1.470

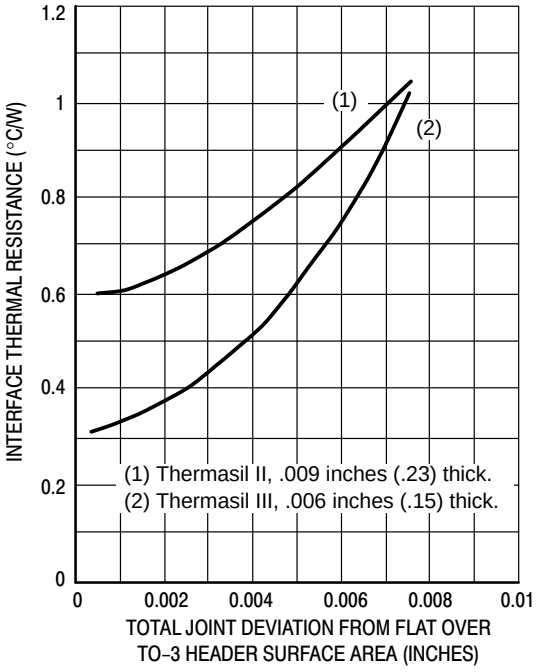
Chomerics	1671	.367	.655

*Test Fixture Deviation from flat from Thermalloy EIR86–1010.

The thermal resistance of some silicone rubber insulators is sensitive to surface flatness when used under a fairly rigid base package. Data for a TO–204AA (TO–3) package insulated with Thermasil is shown in Figure 7. Observe that the “worst case” encountered (7.5 mils) yields results having about twice the thermal resistance of the “typical case” (3 mils), for the more conductive insulator. In order for Thermasil III to exceed the performance of greased mica, total surface flatness must be under 2 mils, a situation that requires spot finishing.



Data courtesy of Thermalloy

Figure 7. Effect of Total Surface Flatness on Interface Resistance Using Silicon Rubber Insulators

Silicon rubber insulators have a number of unusual characteristics. Besides being affected by surface flatness and initial contact pressure, time is a factor. For example, in a study of the CHO–THERM® 1688 pad thermal interface impedance dropped from 0.90°C/W to 0.70°C/W at the end of 1000 hours. Most of the change occurred during the first 200 hours where $R_{\theta CS}$ measured 0.74°C/W. The torque on the conventional mounting hardware had decreased to 3 in–lb from an initial 6 in–lb. With nonconformal materials, a reduction in torque would have increased the interface thermal resistance.

Because of the difficulties in controlling all variables affecting tests of interface thermal resistance, data from different manufacturers is not in good agreement. Table 3 shows data obtained from two sources. The relative performance is the same, except for mica which varies widely in thickness. Appendix B discusses the variables which need to be controlled. At the time of this writing, ASTM Committee D9 is developing a standard for interface measurements.

The conclusions to be drawn from all this data is that some types of silicon rubber pads, mounted dry, will outperform the commonly used mica with grease. Cost may be a determining factor in making a selection.

Table 3. Performance of Silicon Rubber Insulators Tested Per MIL–I–49456

Material	Measured Thermal Resistance (°C/W)

Insulation Resistance

When using insulators, care must be taken to keep the matting surfaces clean. Small particles of foreign matter can puncture the insulation, rendering it useless or seriously lowering its dielectric strength. In addition, particularly when voltages higher than 300 V are encountered, problems with creepage may occur. Dust and other foreign material can shorten creepage distances significantly; so having a clean assembly area is important. Surface roughness and humidity also lower insulation resistance. Use of thermal grease usually raises the withstand voltage of the insulation system, but excess must be removed to avoid collecting dust. Because of these factors, which are not amenable to analysis, hi–pot testing should be done on prototypes and a large margin of safety employed.

Insulated Electrode Packages

Because of the nuisance of handling and installing the accessories needed for an insulated semiconductor mounting, equipment manufacturers have longed for cost–effective insulated packages since the 1950's. The first to appear were stud mount types which usually have a layer of beryllium oxide between the stud hex and the can. Although effective, the assembly is costly and requires manual mounting and lead wire soldering to terminals on top of the case. In the late 80's, a number of electrically isolated parts became available from various semiconductor manufacturers. These offerings presently consist of multiple chips and integrated circuits as well as the more conventional single chip devices.

The newer insulated packages can be grouped into two categories. The first has insulation between the semiconductor chips and the mounting base; an exposed area of the mounting base is used to secure the part. The Energy Management Series (EMS) modules, shown in Figure 16, Case 806 (ICePAK™) and Case 388A (TO–258AA) (see Figure 16) are examples of parts in this category. The second category contains parts which have a plastic overmold covering the metal mounting base. The isolated, Case 221C, illustrated in 21, is an example of parts in the second category.

Parts in the first category (those with an exposed metal flange or tab) are mounted the same as their non–insulated counterparts. However, as with any mounting system where pressure is bearing on plastic, the overmolded type should be used with a conical compression washer, described later in this note.

FASTENER AND HARDWARE CHARACTERISTICS

Characteristics of fasteners, associated hardware, and the tools to secure them determine their suitability for use in mounting the various packages. Since many problems have arisen because of improper choices, the basic characteristics of several types of hardware are discussed next.

Compression Hardware

Normal split ring lock washers are not the best choice for mounting power semiconductors. A typical #6 washer flattens at about 50 pounds, whereas 150 to 300 pounds is needed for good heat transfer at the interface. A very useful piece of hardware is the conical, sometimes called a Belleville washer, compression washer. As shown in Figure 8, it has the ability to maintain a fairly constant pressure over a wide range of its physical deflection – generally 20% to 80%. When installing, the assembler applies torque until the washer depresses to half its original height. (Tests should be run prior to setting up the assembly line to determine the proper torque for the fastener used to achieve 50% deflection.) The washer will absorb any cyclic expansion of the package, insulating washer or other materials caused by temperature changes. Conical washers are the key to successful mounting of devices requiring strict control of the mounting force or when plastic hardware is used in the mounting scheme. They are used with the large face contacting the packages. A new variation of the conical washer includes it as part of a nut assembly. Called a "sync nut," the patented device can be soldered to a PC board and the semiconductor mounted with a 6–32 machine screw.(4)

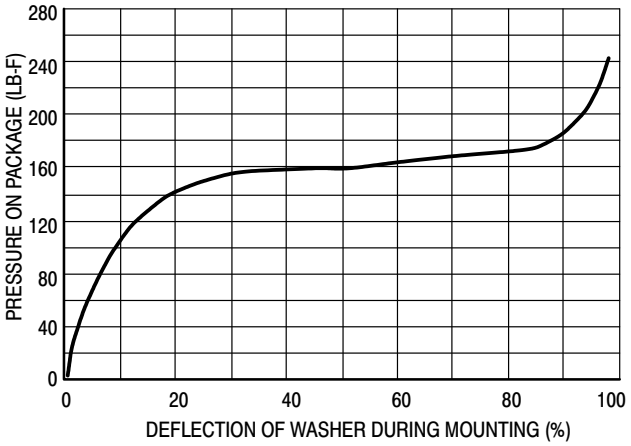

Figure 8. Characteristics of the Conical Compression Washers Designed for Use with Plastic Body Mounted Semiconductors

Clips

Fast assembly is accomplished with clips. When only a few watts are being dissipated, the small board–mounted or free–standing heat dissipaters with an integral clip, offered by several manufacturers, result in a low cost assembly. When higher power is being handled, a separate clip may be used with larger heatsinks. In order to provide proper pressure, the clip must be specially designed for a particular heatsink thickness and semiconductor package.

Clips are especially popular with plastic packages such as the TO–220 and TO–126. In addition to fast assembly, the clip provides lower interface thermal resistance than other assembly methods when it is designed for proper pressure to bear on the top of the plastic over the die. The TO–220 package usually is lifted up under the die location when mounted with a single fastener through the hole in the tab because of the high pressure at one end.

Machine Screws

Machine screws, conical washers, and nuts (or sync nuts) can form a trouble–free fastener system for all types of packages which have mounting holes. However, proper torque is necessary. Torque ratings apply when dry; therefore, care must be exercised when using thermal grease to prevent it from getting on the threads as inconsistent torque readings result. Machine screw heads should not directly contact the surface of plastic packages types as the screw heads are not sufficiently flat to provide properly distributed force. Without a washer, cracking of the plastic case could occur.

Self–Tapping Screws

Under carefully controlled conditions, sheet–metal screws are acceptable. However, during the tapping process with a standard screw, a volcano–like protrusion will develop in the metal being threaded; an unacceptable surface that could increase the thermal resistance may result. When standard sheet metal screws are used, they must be used in a clearance hole to engage a speednut. If a self–tapping process is desired, the screw type must be used which roll–forms machine screw threads.

Rivets

Rivets are not a recommended fastener for any of the plastic packages. When a rugged metal flange–mount package or EMS module is being mounted directly to a heatsink, rivets can be used provided press–riveting is used. Crimping force must be applied slowly and evenly. Pop–riveting should never be used because the high crimping force could cause deformation of most semiconductor packages. Aluminum rivets are much preferred over steel because less pressure is required to set the rivet and thermal conductivity is improved.

The hollow rivet, or eyelet, is preferred over solid rivets. An adjustable, regulated pressure press is used such that a gradually increasing pressure is used to pan the eyelet. Use of sharp blows could damage the semiconductor die.

Solder

Until the advent of the surface mount assembly technique, solder was not considered a suitable fastener for power semiconductors. However, user demand has led to the development of new packages for this application. Acceptable soldering methods include conventional belt–furnace, irons, vapor–phase reflow, and infrared reflow. It is important that the semiconductor temperature not exceed the specified maximum (usually 260°C) or the die bond to the case could be damaged. A degraded die bond has excessive thermal resistance which often leads to a failure under power cycling.

Adhesives

Adhesives are available which have coefficients of expansion compatible with copper and aluminum.[5] Highly conductive types are available; a 10 mil layer has approximately 0.3°C/W interface thermal resistance. Different types are offered: high strength types for non–field serviceable systems or low strength types for field serviceable systems. Adhesive bonding is attractive when case–mounted parts are used in wave soldering assembly because thermal greases are not compatible with the conformal coatings used and the greases foul the solder process.

Plastic Hardware

Most plastic materials will flow, but differ widely in this characteristic. When plastic materials form parts of the fastening system, compression washers are highly valuable to assure that the assembly will not loosen with time and temperature cycling. As previously discussed, loss of contact pressure will increase interface thermal resistance.

FASTENING TECHNIQUES

Each of the various classes of packages in use requires different fastening techniques. Details pertaining to each type are discussed in the following sections. Some general considerations follow.

To prevent galvanic action from occurring when devices are used on aluminum heatsinks in a corrosive atmosphere, many devices are nickel– or gold–plated. Consequently, precautions must be taken not to mar the finish.

Another factor to be considered is that when a copper–based part is rigidly mounted to an aluminum heatsink, a bi–metallic system results which will bend with temperature changes. Not only is the thermal coefficient of expansion different for copper and aluminum, but the temperature gradient through each metal also causes each component to bend. If bending is excessive and the package is mounted by two or more screws, the semiconductor chip could be damaged.

Bending can be minimized by:

1. Mounting the component parallel to the heatsink fins to provide increased stiffness.
2. Allowing the heatsink holes to be a bit oversized so that some can slip between surfaces as the temperature changes.
3. Using a highly conductive thermal grease or mounting pad between the heatsink and semiconductor to minimize the temperature gradient and allow for movement.

Stud Mount

Parts which fall into the stud–mount classification are shown in Figure 8 through Figure 11. Mounting errors with non–insulated stud–mounted parts are generally confined to application of excessive torque or tapping the stud into a threaded heatsink hole. Both of these practices may cause a warpage of the hex base which may crack the semiconductor die. The only recommended fastening method is to use a nut and washer. The details are shown in Figure 12.

Figure 11. RF Stripline Opposed Emitter (SOE) Series

A VARIETY OF STUD–MOUNT PARTS

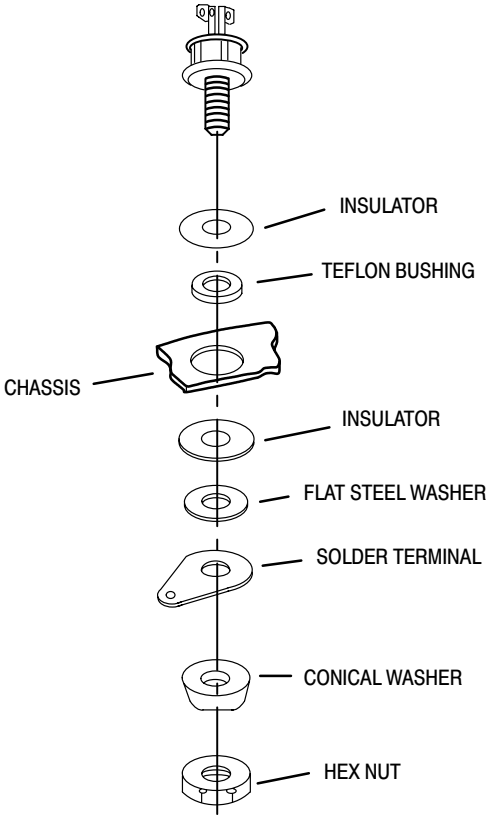

Figure 12. Isolating Hardware Used for a Non–Isolated Stud–Mount Package

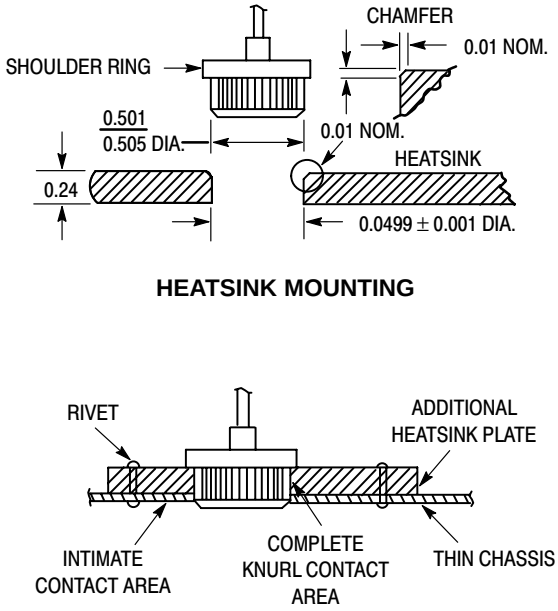
Insulated electrode packages on a stud mount base require less hardware. They are mounted the same as their non–insulated counterparts, but care must be exercised to avoid applying a shear or tension stress to the insulation layer, usually a beryllium oxide (BeO) ceramic. This requirement dictates that the leads must be attached to the circuit with flexible wire. In addition, the stud hex should be used to hold the part while the nut is torqued.

RF transistors in the stud–mount Stripline Opposed Emitter (SOE) package impose some additional constraints because of the unique construction of the package. Special techniques to make connections to the stripline leads and to mount the part so no tension or shear forces are applied to any ceramic – metal interface are discussed in the section entitled, “Connecting and Handling Terminals.”

Press Fit

For most applications, the press–fit case should be mounted according to the instructions shown in Figure 13. A special fixture, meeting the necessary requirements, must be used.



The hole edge must be chamfered as shown to prevent shearing off the knurled edge of the case during press–in. The pressing force should be applied evenly on the shoulder ring to avoid tilting or canting of the case in the hole during the pressing operation. Also, the use of a thermal joint compound will be of considerable aid. The pressing force will vary from 250 to 1000 pounds, depending upon the heatsink material. Recommended hardnesses are: copper–less than 50 on the Rockwell F scale; aluminum–less than 65 on the Brinell scale. A heatsink as thin as 1/8″ may be used, but the interface thermal resistance will increase in direct proportion to the contact area. A thin chassis requires the addition of a backup plate.

Figure 13. Press–Fit Package

Flange Mount

A large variety of parts fit into the flange mount category as shown in Figure 14 through Figure 17. Few known mounting difficulties exist with the smaller flange mount packages, such as the TO–204 (TO–3). The rugged base and distance between die and mounting holes combine to make it extremely difficult to cause any warpage unless mounted on a surface which is badly bowed or unless one side is tightened excessively before the other screw is started. It is, therefore, good practice to alternate tightening of the screws so that pressure is evenly applied. After the screws are finger–tight, the hardware should be torqued to its final specification in at least two sequential steps. A typical mounting installation for a popular flange type part is shown in Figure 18. Machine screws (preferred), self–tapping screws, eyelets, or rivets may be used to secure the package using guidelines in the previous section, “Fastener and Hardware Characteristics.”

The copper flange of the Energy Management Series (EMS) modules is very thick. Consequently, the parts are rugged and indestructible for all practical purposes. No special precautions are necessary when fastening these parts to a heatsink.

Some packages specify a tightening procedure. For example, with the Power Tap package, 15, final torque should be applied first to the center position.

The RF power modules (MHW series) are more sensitive to the flatness of the heatsink than other packages because a ceramic (BeO) substrate is attached to a relatively thin, fairly long, flange. The maximum allowable flange bending to avoid mechanical damage has been determined and presented in detail in Engineering Bulletin EB107/D, “Mounting Considerations for ON Semiconductor RF Power Modules.” Many of the parts can handle a combined heatsink and flange deviation from flat of 7 to 8 mils which is commonly available. Others must be held to 1.5 mils, which requires that the heatsink have nearly perfect flatness.

A LARGE ARRAY OF PARTS FIT INTO THE FLANGE–MOUNT CLASSIFICATION

Specific mounting recommendations are critical to RF devices in isolated packages because of the internal ceramic substrate. The large area, Case 368–03 (HOG PAC), will be used to illustrate problem areas. It is more sensitive to proper mounting techniques than most other RF power devices.

Although the data sheets contain information on recommended mounting procedures, experience indicates that they are often ignored. For example, the recommended maximum torque on the 4–40 mounting screws is 5 in./lbs. Spring and flat washers are recommended. Over–torquing is a common problem. In some parts returned for failure analysis, indentions up to 10 mils deep in the mounting screw areas, have been observed.

Calculations indicate that the length of the flange increases in excess of two mils with a temperature change of 75°C. In such cases, if the mounting screw torque is excessive, the flange is prevented from expanding in length; instead, it bends upward in the mid–section, cracking the BeO and the die. A similar result can also occur during the initial mounting of the device if an excessive amount of thermal compound is applied. With

sufficient torque, the thermal compound will squeeze out of the mounting hole areas, but will remain under the center of the flange, deforming it. Deformations of 2 – 3 mils have been measured between the center and the ends under such conditions (enough to crack internal ceramic).

Another problem arises because the thickness of the flange changes with temperature. For the 75°C temperature excursion mentioned, the increased amount is around 0.25 mils which results in further tightening of the mounting screws, thus increasing the effective torque from the initial value. With a decrease in temperature, the opposite effect occurs. Therefore, thermal cycling not only causes risk of structural damage but often causes the assembly to loosen which raises the interface resistance. Use of compression hardware can eliminate this problem.

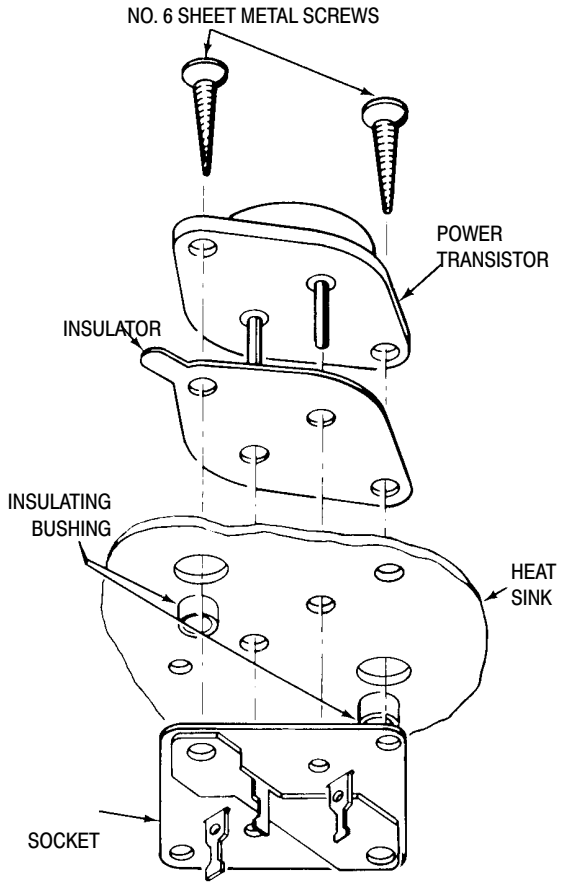

Figure 18. Hardware Used for a TO–204AA (TO–3) Flange Mount Part

Tab Mount

The tab mount class is composed of a wide array of packages as illustrated in Figure 19. Mounting considerations for all varieties are similar to that for the popular TO–220 package, whose suggested mounting arrangements and hardware are shown in Figure 20. The rectangular washer shown in Figure 20a is used to minimize distortion of the mounting flange; excessive distortion could cause damage to the semiconductor chip. Use of the washer is only important when the size of the mounting hole exceeds 0.140 in. (6–32 clearance). Larger holes are needed to accommodate the lower insulating bushing when the screw is electrically connected to the case; however, the holes should not be larger than necessary to provide hardware clearance and should never exceed a diameter of 0.250 inch. Flange distortion is also possible if excessive torque is used during mounting. A maximum torque of 8 in./lbs is suggested when using a 6–32 screw.

Care should be exercised to assure that the tool used to drive the mounting screw never comes in contact with the plastic body during the driving operation. Such contact can result in damage to the plastic body and internal device connections. To minimize this problem, ON Semiconductor TO–220 packages have a chamfer on one end. TO–220 packages of other manufacturers may need a spacer or combination spacer and isolation bushing to raise the screw head above the top surface of the plastic.

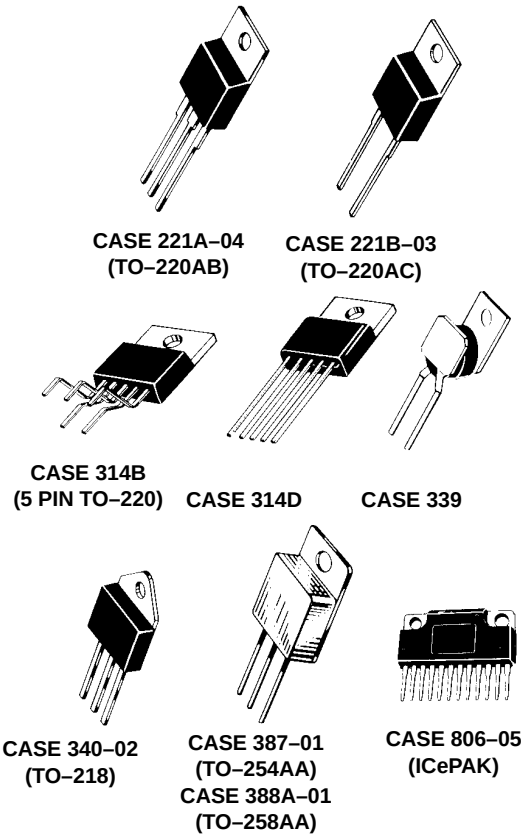

Figure 19. Several Types of Tab–Mount Parts

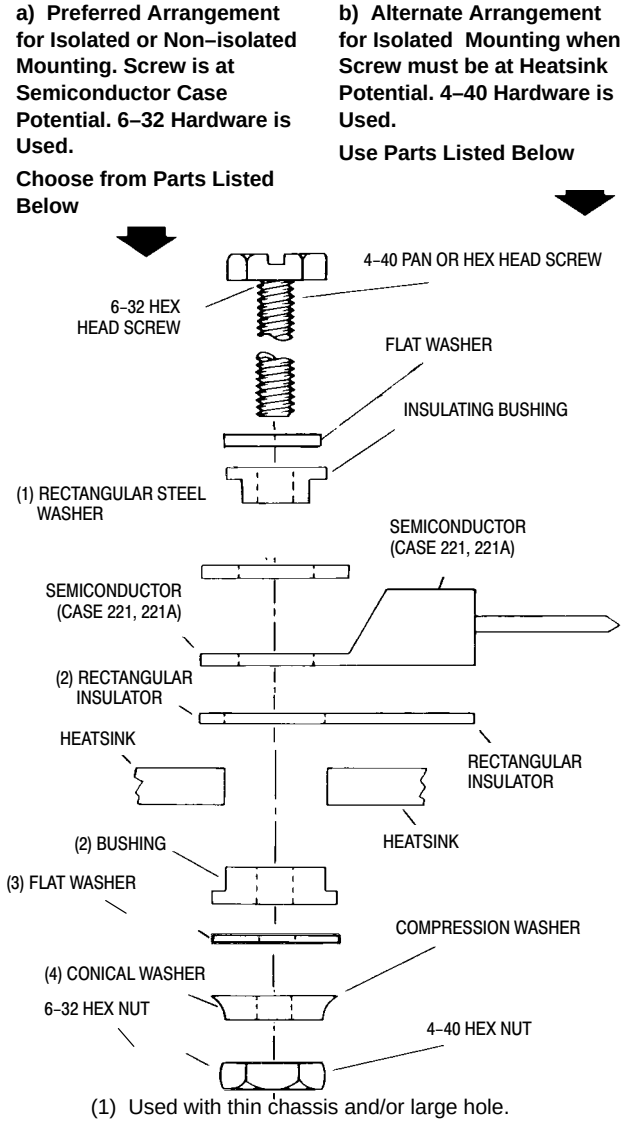
The popular TO–220 Package and others of similar construction lift off the mounting surface as pressure is applied to one end. (See Appendix B, Figure 36.) To counter this tendency, at least one hardware manufacturer offers a hard plastic cantilever beam which applies more even pressure on the tab.[6] In addition, it separates the mounting screw from the metal tab. Tab mount parts may also be effectively mounted with clips as shown in Figure 27.

To obtain high pressure without cracking the case, a pressure spreader bar should be used under the clip. Interface thermal resistance with the cantilever beam or clips can be lower than with screw mounting.

The ICePAK (Case 806–05) is basically an elongated TO–220 package with isolated chips. The mounting precautions for the TO–220 consequently apply. In addition, since two mounting screws are required, the alternate tightening procedure described for the flange mount package should be used.

In situations where a tab mount package is making direct contact with the heatsink, an eyelet may be used, provided sharp blows or impact shock is avoided.



(1) Used with thin chassis and/or large hole.
(2) Used when isolation is required.
(3) Required when nylon bushing is used.

Figure 20. Mounting Arrangements for Tab Mount TO–220

Plastic Body Mount

The Thermopad™ and isolated plastic power packages shown in Figure 21 are typical of packages in this group. They have been designed to feature minimum size with no compromise in thermal resistance. For the Thermopad (Case 77) parts, this is accomplished by die–bonding the silicon chip on one side of a thin copper sheet; the opposite side is exposed as a mounting surface. The copper sheet has a hole for mounting; plastic is molded enveloping the chip but leaving the mounting hole open. The low thermal resistance of this construction is obtained at the expense of a requirement that strict attention be paid to the mounting procedure.

The isolated (Case 221C–02) is similar to a TO–220 except that the tab is encased in plastic. Because the mounting force is applied to plastic, the mounting procedure differs from a standard TO–220 and is similar to that of the Thermopad.

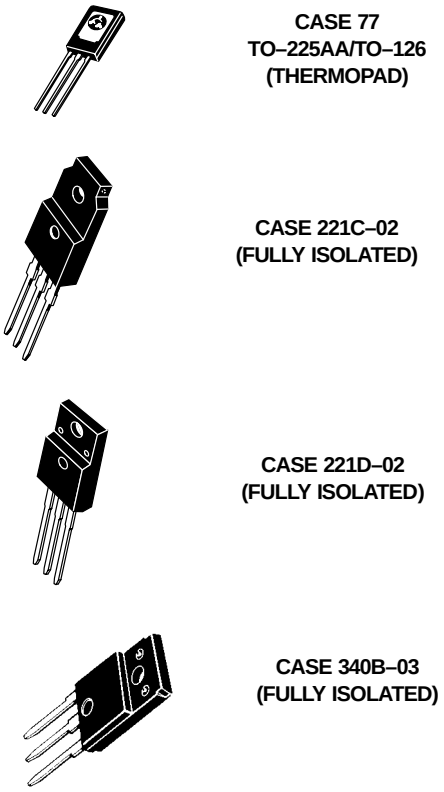


Figure 21. Plastic Body–Mount Packages

Several types of fasteners may be used to secure these packages; machine screws, eyelets, or clips are preferred. With screws or eyelets, a conical washer should be used which applies the proper force to the package over a fairly wide range of deflection and distributes the force over a fairly large surface area. Screws should not be tightened with any type of air–driven torque gun or equipment which may cause high impact. Characteristics of a suitable conical washer is shown in Figure 8.

Figure 22 through Figure 24 shows details of mounting Case 77 devices. Clip mounting is fast and requires minimum hardware, however, the clip must be properly chosen to insure that the proper mounting force is applied. When electrical isolation is required with screw mounting, a bushing inside the mounting hole will insure that the screw threads do not contact the metal base.

The isolated, (Case 221C, 221D, and 340B) permits the mounting procedure to be greatly simplified over that of a standard TO–220. As shown in Figure 27, one properly chosen clip, inserted into two slotted holes in the heatsink, is all the hardware needed. Even though clip pressure is much lower than obtained with a screw, the thermal resistance is about the same for either method. This occurs because the clip bears directly on top of the die and holds the package flat while the screw causes the package to lift up somewhat under the die. (See Figure 36 of Appendix B.) The interface should consist of a layer of thermal grease or a highly conductive thermal pad. Of course, screw mounting shown in Figure 26 may also be used, but a conical compression washer should be included. Both methods afford a major reduction in hardware as compared to the conventional mounting method with a TO–220 package which is shown in Figure 25.

Surface Mount

Although many of the tab mount parts have been surface mounted, special small footprint packages for mounting power semiconductors using surface mount assembly techniques have been developed. The DPAK, shown in Figure 28, for example, will accommodate a die up to 112 mils x 112 mils, and has a typical thermal resistance around 2°C/W junction to case. The thermal resistance values of the solder interface is well under 1°C/W. The printed circuit board also serves as the heatsink.

Figure 28. Surface Mount D–PAK Parts

Standard Glass–Epoxy 2–ounce boards do not make very good heatsinks because the thin foil has a high thermal resistance. As Figure 29 shows, thermal resistance asymptotes to about 20°C/W at 10 square inches of board area, although a point of diminishing returns occurs at about 3 square inches.

Boards are offered that have thick aluminum or copper substrates. A dielectric coating designed for low thermal resistance is overlaid with one– or two–ounce copper foil for the preparation of printed conductor traces. Tests run on such a product indicate that case to substrate thermal resistance is in the vicinity of 1°C/W, exact values depending upon board type.[7] The substrate may be an effective heatsink itself, or it can be attached to a conventional finned heatsink for improved performance.

Since DPAK and other surface mount packages are designed to be compatible with surface mount assembly techniques, no special precautions are needed other than to insure that maximum temperature/time profiles are not exceeded.

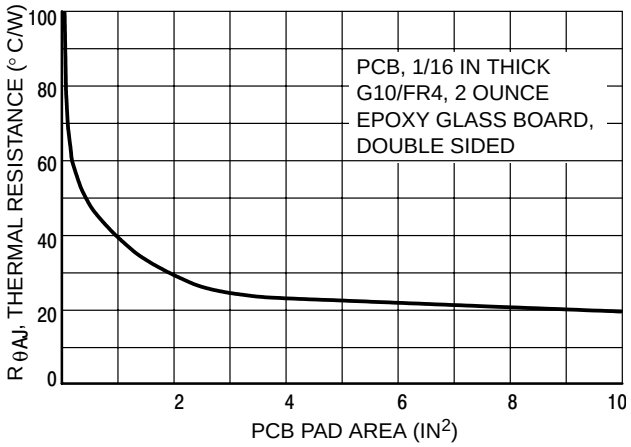

Figure 29. Effect of Footprint Area on Thermal Resistance of DPAK Mounted on a Glass–Epoxy Board

FREE AIR AND SOCKET MOUNTING

In applications where average power dissipation is on the order of a watt or so, most power semiconductors may be mounted with little or no heatsinking. The leads of the various metal power packages are not designed to support the packages; their cases must be firmly supported to avoid the possibility of cracked seals around the leads. Many plastic packages may be supported by their leads in applications where high shock and vibration stresses are not encountered and where no heatsink is used. The leads should be as short as possible to increase vibration resistance and reduce thermal resistance. As a general practice, however, it is better to support the package. A plastic support for the TO–220 Package and other similar types is offered by heatsink accessory vendors.

In many situations, because its leads are fairly heavy, the Case 77 (TO–225AA) (TO–127) package has supported a small heatsink; however, no definitive data is available. When using a small heatsink, it is good practice to have the sink rigidly mounted such that the sink or the board is providing total support for the semiconductor. Two possible arrangements are shown in Figure 30 and Figure 31. The arrangement of Figure 30 could be used with any plastic package, but the scheme of Figure 31 is more practical with Case 77 Thermopad devices. With the other package types, mounting the transistor on top of the heatsink is more practical.

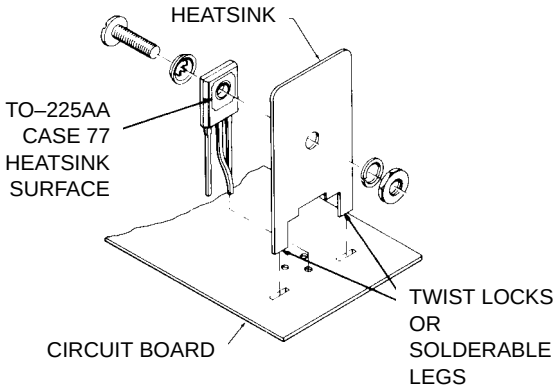

Figure 30. Simple Plate, Vertically Mounted

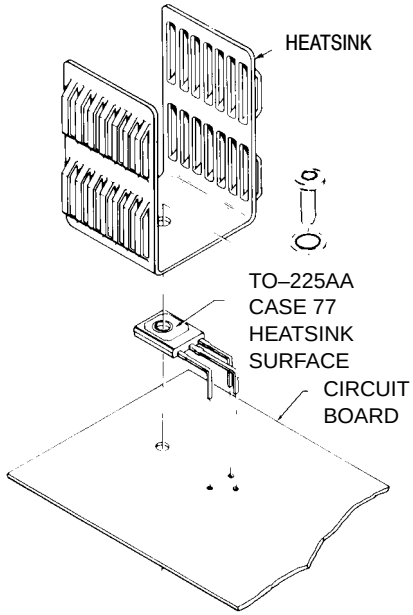

Figure 31. Commercial Sink, Horizontally Mounted

METHODS OF USING SMALL HEATSINKS WITH PLASTIC SEMICONDUCTOR PACKAGES

In certain situations, in particular where semiconductor testing is required or prototypes are being developed, sockets are desirable. Manufacturers have provided sockets for many of the packages available from ON Semiconductor. The user is urged to consult manufacturers' catalogs for specific details. Sockets with Kelvin connections are necessary to obtain accurate voltage readings across semiconductor terminals.

CONNECTING AND HANDLING TERMINALS

Pins, leads, and tabs must be handled and connected properly to avoid undue mechanical stress which could cause semiconductor failure. Change in mechanical dimensions, as a result of thermal cycling over operating temperature extremes, must be considered. Standard metal, plastic, and RF stripline packages each have some special considerations.

Metal Packages

The pins and lugs of metal packaged devices using glass to metal seals are not designed to handle any significant bending or stress. If abused, the seals could crack. Wires may be attached using sockets, crimp connectors or solder, provided the data sheet ratings are observed. When wires are attached directly to the pins, flexible or braided leads are recommended in order to provide strain relief.

EMS Modules

The screw terminals of the EMS modules look deceptively rugged. Since the flange base is mounted to a rigid heatsink, the connection to the terminals must allow some flexibility. A rigid buss bar should not be bolted to terminals. Lugs with braid are preferred.

Plastic Packages

The leads of the plastic packages are somewhat flexible and can be reshaped, although this is not a recommended procedure. In many cases, a heatsink can be chosen which makes lead–bending unnecessary. Numerous lead and tab–forming options are available from ON Semiconductor on large quantity orders. Preformed leads remove the users' risk of device damage caused by bending.

If, however, lead–bending is done by the user, several basic considerations should be observed. When bending the lead, support must be placed between the point of bending and the package. For forming small quantities of units, a pair of pliers may be used to clamp the leads at the case, while bending with the fingers or another pair of pliers. For production quantities, a suitable fixture should be made.

The following rules should be observed to avoid damage to the package.

1. A leadbend radius greater than 1/16 inch is advisable for TO–225AA (CASE 77) and 1/32 inch for TO–220.
2. No twisting of leads should be done at the case.
3. No axial motion of the lead should be allowed with respect to the case.

The leads of plastic packages are not designed to withstand excessive axial pull. Force in this direction greater than 4 pounds may result in permanent damage to the device. If the mounting arrangement imposes axial stress on the leads, a condition which may be caused by thermal cycling, some method of strain relief should be devised. When wires are used for connections, care should be exercised to assure that movement of the wire does not cause movement of the lead at the lead–to–plastic junctions. Highly flexible or braided wires are good for providing strain relief.

Wire–wrapping of the leads is permissible, provided that the lead is restrained between the plastic case and the point of the wrapping. The leads may be soldered; the maximum soldering temperature, however, must not exceed 260°C and must be applied for not more than 5 seconds at a distance greater than 1/8 inch from the plastic case.

Stripline Packages

The leads of stripline packages normally are soldered into a board while the case is recessed to contact a heatsink as shown in Figure 32 through Figure 34. The following rules should be observed:

1. The device should never be mounted in such a manner as to place ceramic–to–metal joints in tension.
2. The device should never be mounted in such a manner as to apply force on the strip leads in a vertical direction towards the cap.
3. When the device is mounted in a printed circuit board with the copper stud and BeO portion of the header passing through a hole in the circuit boards, adequate clearance must be provided for the BeO to prevent shear forces from being applied to the leads.
4. Some clearance must be allowed between the leads and the circuit board when the device is secured to the heatsink.
5. The device should be properly secured into the heatsinks before its leads are attached into the circuit.
6. The leads on stud type devices must not be used to prevent device rotation during stud torque application. A wrench flat is provided for this purpose.

Figure 33 shows a cross–section of a printed circuit board and heatsink assembly for mounting a stud–type stripline device. H is the distance from the top surface of the printed circuit board to the D–flat heatsink surface. If H is less than the minimum distance from the bottom of the lead material to the mounting surface of the package, there is no possibility of tensile forces in the copper stud – BeO ceramic joint. If, however, H is greater than the package dimension, considerable force is applied to the cap to BeO joint and the BeO to stud joint. Two occurrences are possible at this point. The first is a cap joint failure when the structure is heated, as might occur during the lead–soldering operation; while the second is BeO to stud failure if the force generated is high enough. Lack of contact between the device and the heatsink surface will

occur as the differences between H and the package dimension become larger; this may result in device failure as power is applied.

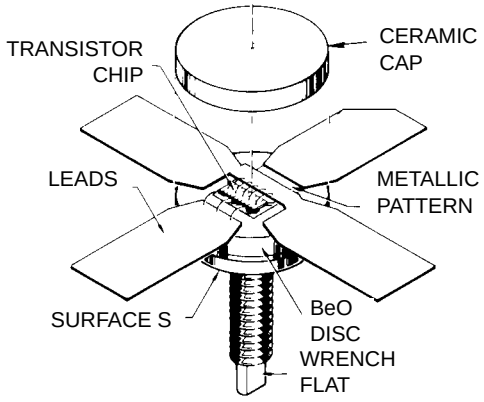

Figure 32. Component Parts of a Stud Mount Stripline Package. Flange Mounted Packages are Similarly Constructed

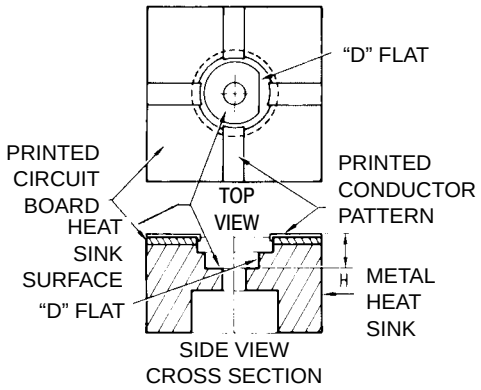

Figure 33. Typical Stud Type SOE Transistor Mounting Method

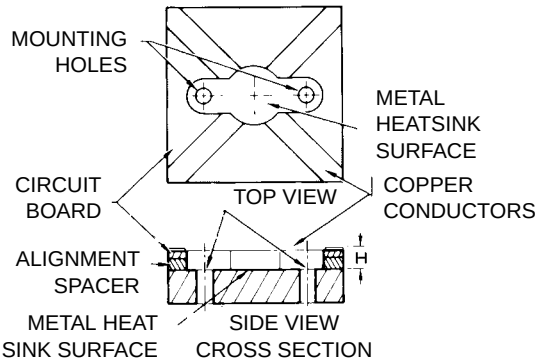

Figure 34. Flange Type SOE Transistor Mounting Method

MOUNTING DETAILS FOR SOE TRANSISTORS

Figure 34 shows a typical mounting technique for flange–type stripline transistors. Again, H is defined as the distance from the top of the printed circuit board to the heatsink surface. If distance H is less than the minimum distance from the bottom of transistor lead to the bottom surface of the flange, tensile forces at the various joints in the package are avoided. However, if distance H exceeds the package dimension, problems similar to those discussed for the stud type devices can occur.

CLEANING CIRCUIT BOARDS

It is important that any solvents or cleaning chemicals used in the process of degreasing or flux removal do not affect the reliability of the devices. Alcohol and unchlorinated Freon solvents are generally satisfactory for use with plastic devices, since they do not damage the package. Hydrocarbons such as gasoline and chlorinated Freon may cause the encapsulant to swell, possibly damaging the transistor die.

When using an ultrasonic cleaner for cleaning circuit boards, care should be taken with regard to ultrasonic energy and time of application. This is particularly true if any packages are free–standing without support.

THERMAL SYSTEM EVALUATION

Assuming that a suitable method of mounting the semiconductor without incurring damage has been achieved, it is important to ascertain whether the junction temperature is within bounds.

In applications where the power dissipated in the semiconductor consists of pulses at a low duty cycle, the instantaneous or peak junction temperature, not average temperature, may be the limiting condition. In this case, use must be made of transient thermal resistance data. For a full explanation of its use, see ON Semiconductor Application Note, AN569/D.

Other applications, notably RF power amplifiers or switches driving highly reactive loads, may create severe current crowding conditions which render the traditional concepts of thermal resistance or transient thermal impedance invalid. In this case, transistor safe operating area, thyristor di/dt limits, or equivalent ratings as applicable, must be observed.

Fortunately, in many applications, a calculation of the average junction temperature is sufficient. It is based on the concept of thermal resistance between the junction and a temperature reference point on the case. (See Appendix A.) A fine wire thermocouple should be used, such as #36 AWG, to determine case temperature. Average operating junction temperature can be computed from the following equation:

$$T_J = T_C + R_{\theta JC} \times P_D$$

where T_J = junction temperature (°C)
T_C = case temperature (°C)
$R_{\theta JC}$ = thermal resistance junction–to case as specified on the data sheet (°C/W)
P_D = power dissipated in the device (W)

The difficulty in applying the equation often lies in determining the power dissipation. Two commonly used empirical methods are graphical integration and substitution.

Graphical Integration

Graphical integration may be performed by taking oscilloscope pictures of a complete cycle of the voltage and current waveforms, using a limit device. The pictures should be taken with the temperature stabilized. Corresponding points are then read from each photo at a suitable number of time increments. Each pair of voltage and current values are multiplied together to give instantaneous values of power. The results are plotted on linear graph paper, the number of squares within the curve counted, and the total divided by the number of squares along the time axis. The quotient is the average power dissipation. Oscilloscopes are available to perform these measurements and make the necessary calculations.

Substitution

This method is based upon substituting an easily measurable, smooth dc source for a complex waveform. A switching arrangement is provided which allows operating the load with the device under test, until it stabilizes in temperature. Case temperature is monitored. By throwing the switch to the “test” position, the device under test is connected to a dc power supply, while another pole of the switch supplies the normal power to the load to keep it operating at full power level. The dc supply is adjusted so that the semiconductor case temperature remains approximately constant when the switch is thrown to each position for about 10 seconds. The dc voltage and current values are multiplied together to obtain average power. It is generally necessary that a Kelvin connection be used for the device voltage measurement.

APPENDIX A
THERMAL RESISTANCE CONCEPTS

The basic equation for heat transfer under steady–state conditions is generally written as:

$$q = hA\Delta T \quad (1)$$

where q = rate of heat transfer or power dissipation (P_D)
h = heat transfer coefficient,
A = area involved in heat transfer,
ΔT = temperature difference between regions of heat transfer.

However, electrical engineers generally find it easier to work in terms of thermal resistance, defined as the ratio of temperature to power. From Equation 1, thermal resistance, R_θ, is

$$R_\theta = \Delta T/q = 1/hA \quad (2)$$

The coefficient (h) depends upon the heat transfer mechanism used and various factors involved in that particular mechanism.

An analogy between Equation (2) and Ohm's Law is often made to form models of heat flow. Note that T could be thought of as a voltage thermal resistance corresponds to electrical resistance (R); and, power (q) is analogous to current (I). This gives rise to a basic thermal resistance model for a semiconductor as indicated by Figure 35.

The equivalent electrical circuit may be analyzed by using Kirchoff's Law and the following equation results:

$$T_J = P_D (R_{\theta JC} + P_{\theta CS} + R_{\theta SA}) + T_A \quad (3)$$

where T_J = junction temperature,
PD = power dissipation
$R_{\theta JC}$ = semiconductor thermal resistance (junction to case),
$R_{\theta CS}$ = interface thermal resistance (case to heat–sink),
$R_{\theta SA}$ = heat sink thermal resistance (heatsink to ambient),
T_A = ambient temperature.

The thermal resistance junction to ambient is the sum of the individual components. Each component must be minimized if the lowest junction temperature is to result.

The value for the interface thermal resistance, $R_{\theta CS}$, may be significant compared to the other thermal resistance terms. A proper mounting procedure can minimize $R_{\theta CS}$.

The thermal resistance of the heatsink is not absolutely constant; its thermal efficiency increases as ambient temperature increases and it is also affected by orientation of the sink. The thermal resistance of the semiconductor is also variable; it is a function of biasing and temperature. Semiconductor thermal resistance specifications are normally at conditions where current density is fairly uniform. In some applications, such as in RF power amplifiers and short–pulse applications, current density is not uniform and localized heating in the semiconductor chip will be the controlling factor in determining power handling ability.

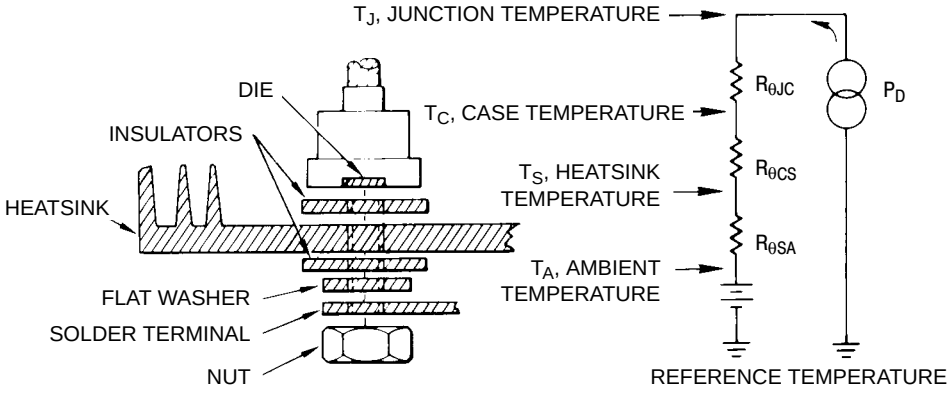

Figure 35. Basic Thermal Resistance Model Showing Thermal to Electrical Analogy for a Semiconductor

APPENDIX B
MEASUREMENT OF INTERFACE THERMAL RESISTANCE

Measuring the interface thermal resistance $R_{\theta CS}$ appears deceptively simple. All that's apparently needed is a thermocouple on the semiconductor case, a thermocouple on the heatsink, and a means of applying and measuring DC power. However, $R_{\theta CS}$ is proportional to the amount of contact area between the surfaces and consequently is affected by surface flatness and finish and the amount of pressure on the surfaces. The fastening method may also be a factor. In addition, placement of the thermocouples can have a significant influence upon the results. Consequently, values for interface thermal resistance presented by different manufacturers are not in good agreement. Fastening methods and thermocouple locations are considered in this Appendix.

When fastening the test package in place with screws, thermal conduction may take place through the screws, for example, from the flange ear on a TO–3 package directly to the heatsink. This shunt path yields values which are artificially low for the insulation material and dependent upon screw head contact area and screw material. MIL–I–49456 allows screws to be used in tests for interface thermal resistance probably because it can be argued that this is "application oriented."

Thermalloy takes pains to insulate all possible shunt conduction paths in order to more accurately evaluate insulation materials. The ON Semiconductor fixture uses an insulated clamp arrangement to secure the package which also does not provide a conduction path.

As described previously, some packages, such as a TO–220, may be mounted with either a screw through the tab or a clip bearing on the plastic body. These two methods often yield different values for interface thermal resistance. Another discrepancy can occur if the top of the package is exposed to the ambient air where radiation and convection can take place. To avoid this, the package should be covered with insulating foam. It has been estimated that a 15 to 20% error in $R_{\theta CS}$ can be incurred from this source.

Another significant cause for measurement discrepancies is the placement of the thermocouple to measure the semiconductor case temperature. Consider the TO–220 package shown in 36. The mounting pressure at one end causes the other end – where the die is located – to lift off the mounting surface slightly. To improve contact, ON Semiconductor TO–220 Packages are slightly concave. Use of a spreader bar under the screw lessens the lifting, but some is inevitable with a package of this structure. Three thermocouple locations are shown:

1. The ON Semiconductor location is directly under the die reached through a hole in the heatsink. The thermocouple is held in place by a spring which forces the thermocouple into intimate contact with the bottom of the semi's case.
2. The JEDEC location is close to the die on the top surface of the package base reached through a blind hole drilled through the molded body. The thermocouple is swaged in place.
3. The Thermalloy location is on the top portion of the tab between the molded body and the mounting screw. The thermocouple is soldered into position.

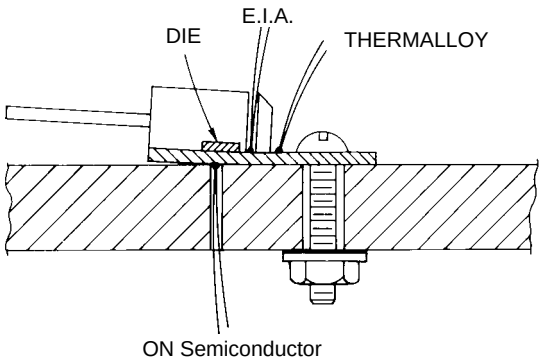

Figure 36. JEDEC TO–220 Package Mounted to Heatsink Showing Various Thermocouple Locations and Lifting Caused by Pressure at One End

Temperatures at the three locations are generally not the same. Consider the situation depicted in the figure. Because the only area of direct contact is around the mounting screw, nearly all the heat travels horizontally along the tab from the die to the contact area. Consequently, the temperature at the JEDEC location is hotter than at the Thermalloy location and the ON Semiconductor location is even hotter. Since junction–to–sink thermal resistance must be constant for a given test setup, the calculated junction–to–case thermal resistance values decrease and case–to–sink values increase as the "case" temperature thermocouple readings become warmer. Thus, the choice of reference point for the "case" temperature is quite important.

There are examples where the relationship between the thermocouple temperatures are different from the previous situation. If a mica washer with grease is installed between the semiconductor package and the heatsink, tightening the screw will not bow the package; instead, the mica will be deformed. The primary heat conduction path is from the die through the mica to the heatsink. In this case, a small temperature drop will exist across the vertical dimension of the package mounting base so that the thermocouple at the EIA location will be the hottest. The thermocouple temperature at the Thermalloy location will be lower, but close to the temperature at the EIA location as the lateral heat flow is generally small. The ON Semiconductor location will be coolest.

The EIA location is chosen to obtain the highest temperature on the case. It is of significance because power ratings are supposed to be based on this reference point. Unfortunately, the placement of the thermocouple is tedious and leaves the semiconductor in a condition unfit for sale.

The ON Semiconductor location is chosen to obtain the highest temperature of the case at a point where, hopefully, the case is making contact to the heatsink. Once the special heatsink, to accommodate the thermocouple has been fabricated, this method lends itself to production testing and does not mark the device. However, this location is not easily accessible to the user.

The Thermalloy location is convenient and is often chosen by equipment manufacturers. However, it also blemishes the case and may yield results differing up to 1°C/W for a TO–220 package mounted to a heatsink without thermal grease and no insulator. This error is small when compared to the thermal resistance of heat dissipaters often used with this package, since power dissipation is usually a few watts. When compared to the specified junction–to–case values of some of the higher power semiconductors becoming available, however, the difference becomes significant and it is important that the semiconductor manufacturer and equipment manufacturer use the same reference point.

Another EIA method of establishing reference temperatures utilizes a soft copper washer (thermal grease is used) between the semiconductor package and the heatsink. The washer is flat to within 1 mil/inch, has a finish better than 63 μ–inch, and has an imbedded thermocouple near its center. This reference includes the interface resistance under nearly ideal conditions and is, therefore, application–oriented. It is also easy to use, but has not become widely accepted.

A good way to improve confidence in the choice of case reference point is to also test for junction–to–case thermal resistance while testing for interface thermal resistance. If the junction–to–case values remain relatively constant as insulators are changed, torque varied, etc., then the case reference point is satisfactory.

APPENDIX C
Sources of Accessories

PACKAGE INDEX

PREFACE

When the JEDEC registration system for package outlines started in 1957, numbers were assigned sequentially whenever manufacturers wished to establish a package as an industry standard. As minor variations developed from these industry standards, either a new, non–related number was issued by JEDEC or manufacturers would attempt to relate the part to an industry standard via some appended description.

In an attempt to ease confusion, JEDEC established the present system in late 1968 in which new packages are assigned into a category, based on their general physical appearance. Differences between specific packages in a category are denoted by suffix letters. The older package designations were re–registered to the new system as time permitted.

For example the venerable TO–3 has many variations. Can heights differ and it is available with 30, 40, 50, and 60 mil pins, with and without lugs. It is now classified in the TO–204 family. The TO–204AA conforms to the original outline for the TO–3 having 40 mil pins while the TO–204AE has 60 mil pins, for example.

The new numbers for the old parts really haven't caught on very well. It seems that the DO–4, DO–5 and TO–3 still convey sufficient meaning for general verbal communication.

Phono Preamps For All

Diagrams by Richard Crowley, Text by Rod Elliott

Introduction

This is a collection of phono (black vinyl for the youngsters) preamps and equalisation circuits, one of which is sure to meet your requirements. These are not my circuits, but were contributed by a reader (see above), so I am not really in a position to make any specific recommendations. They are provided as a service to the experimenters out there, and may be found useful for other applications as well.

Moving Coil Preamps

The first set of offerings are moving coil preamps, specifically intended for the very low output voltage and impedance of the majority of moving coil pickups. These were much favoured in their day for superior quality over the entire audio range, and for any serious listening I still use my moving coil pickup.

MC Preamp #1

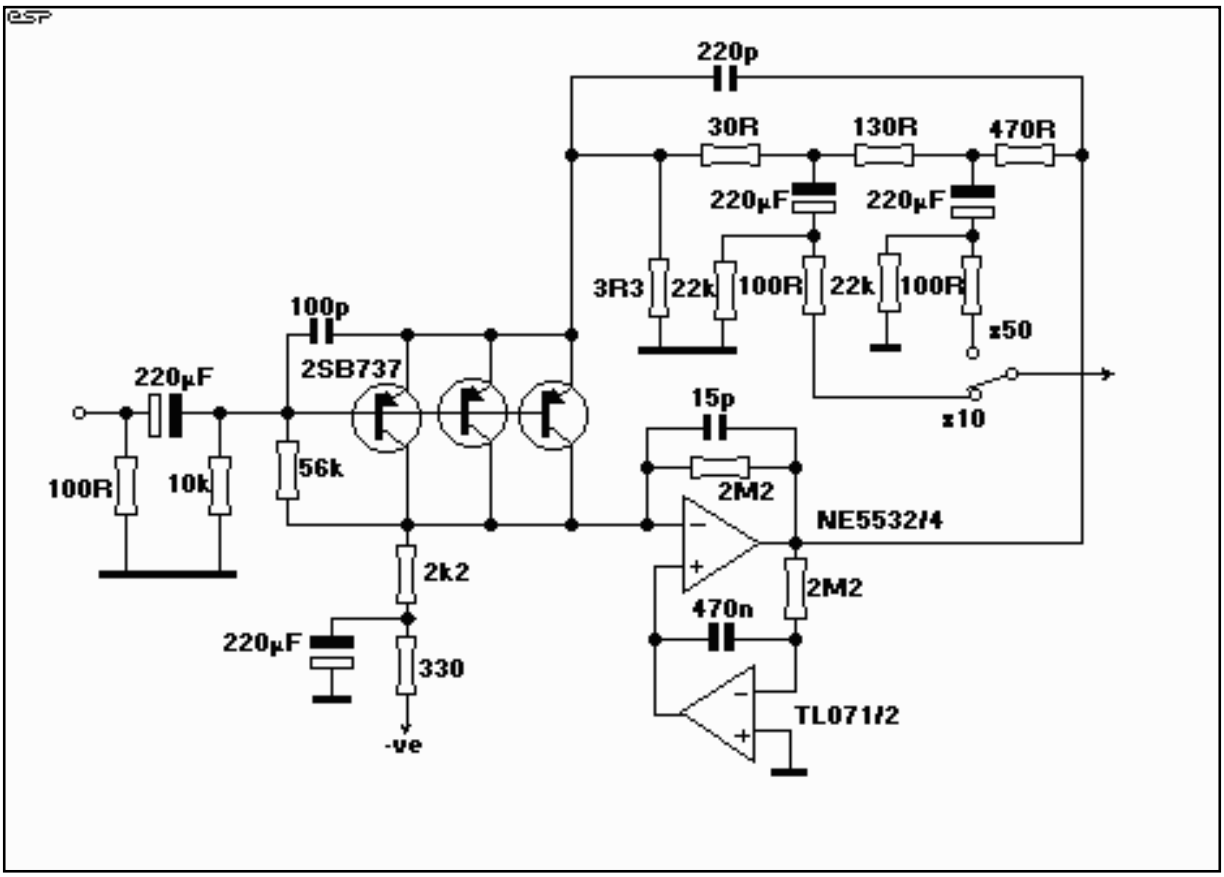

Figure 1 - Moving Coil Preamplifier (After Douglas Self)

This design uses multiple transistors as the initial amplifying stage. The transistors chosen have very low noise, and this is reduced even further by the parallel technique.

As can be seen from the diagram, the circuit gain can be changed to suit high and low output cartridges with a single switch. The gains as shown are x10 and x50 (20 dB and 34 dB respectively), but could be modified if desired. I will leave this up to the reader to experiment with.

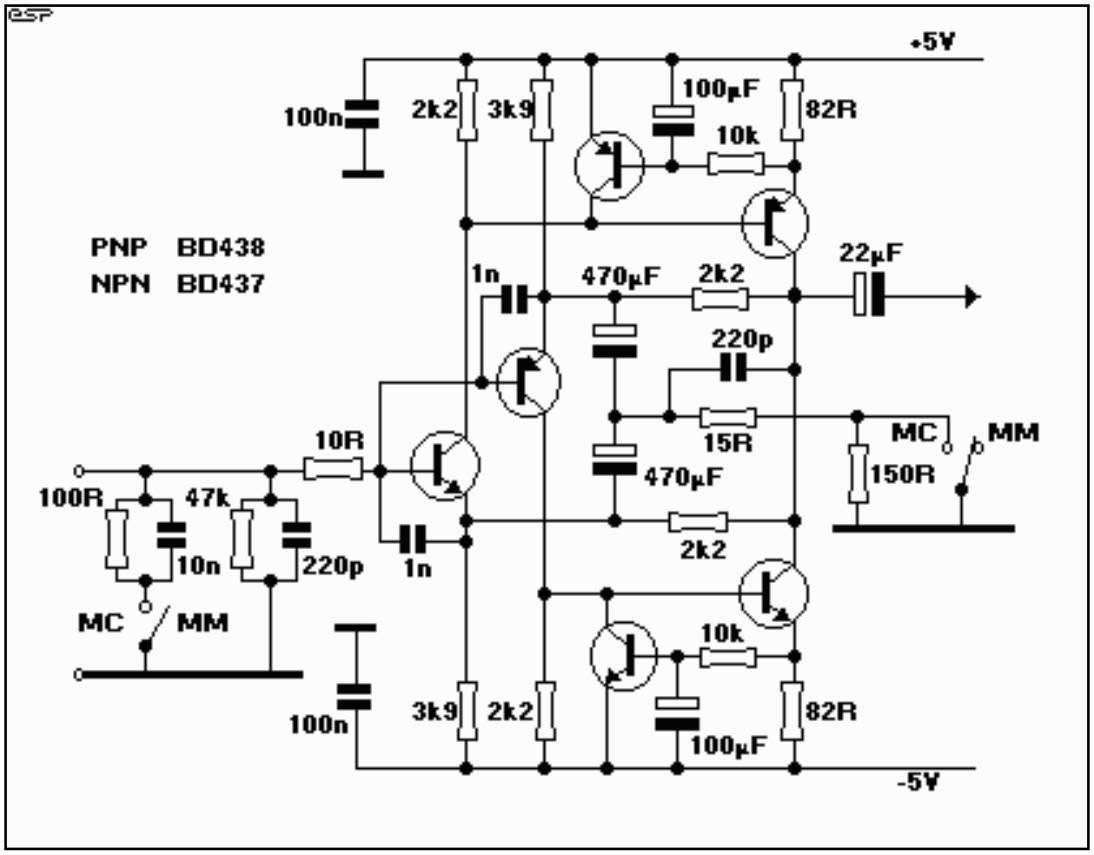
As I look at the circuit, I'm not sure why the gain resistors were set up as they are. With the values shown, the circuit actually has a gain of 192 (set the feedback resistors in series and the 3.3 Ohm emitter resistor), and this is then attenuated to provide the gains of 50 and 10 as shown. I'm sure there was an excellent reason for this arrangement, but I cannot see it.

The second opamp (TLO71/72) acts as a bias servo device, and ensures that the inverting input of the NE5532 is at the same voltage as its non-inverting input. With this arrangement, output offset voltage can be expected to be very low - typically no more that a couple of millivolts.

MC Preamp #2

This next design is based on the work of John Linsley-Hood, and again can be expected to give

good results. As can be seen, there are no opamps used, and the circuit is completely symmetrical. This offers a reduction in noise over a single circuit, since the two complete mirror image halves are in parallel. Distortion is probably reduced as well, but at the signal levels produced by a moving coil pickup, this is not likely to be significant.



Moving Coil Preamp (After John Linsley-Hood)

The circuit is (more or less) conventional, using a common emitter stage modulating a constant-current source. As the circuit is mirrored, these are reproduced for both positive and negative supplies. The net output voltage will again have a low DC offset, but probably somewhat higher than the previous design due to the lack of a bias "servo" to maintain an exact 0V DC output.

Gain is set by the 2.2k resistors from the collectors of the output devices (in parallel, so 1.1k) and the 15 Ohm resistor (MC or Moving Coil position) optionally in series with the 150 Ohm (MM or Moving Magnet position).

These give a theoretical gain of 74 (37 dB) in the MC position, or 7.6 (17.6 dB) for the MM setting. In practice, one can expect the gain to be very slightly less than these figures, especially for the MC setting.

I cannot comment on the relative noise performance of these two preamps, but as they are both based on designs by well respected audio designers, I would expect that noise would not be an issue with either circuit.

Phono Equalisers

With two different circuits and several additional EQ networks to choose from (plus my own version, published as Project 06), there has to be one for you!

I do not know the origin of these circuits (other than from Richard), so cannot be too specific about them. They are both reasonably conventional, as can be seen.

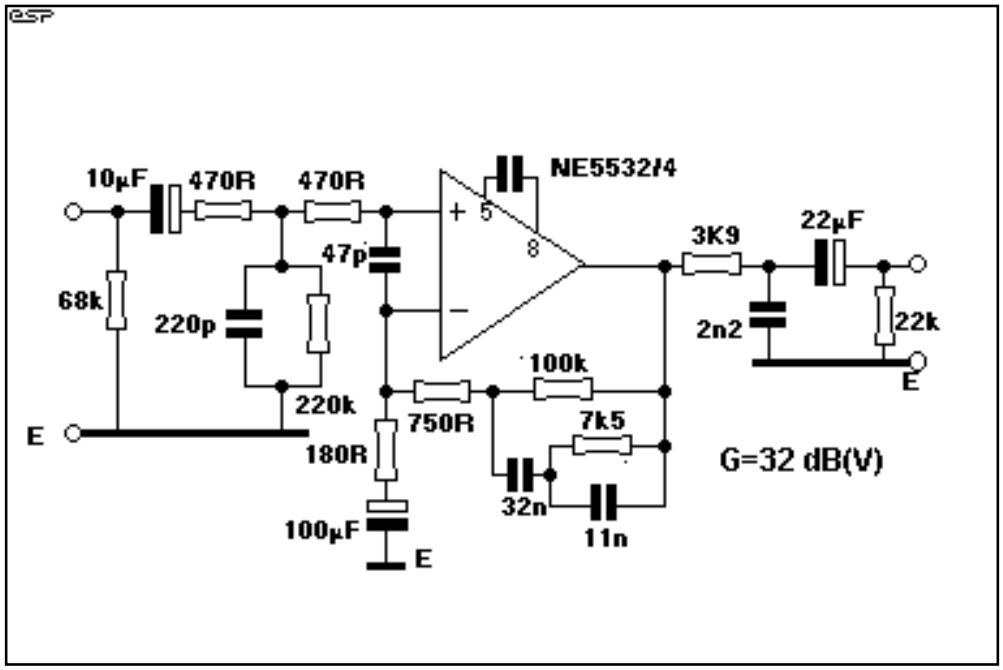


Figure 3 - Phono Preamp #1

This is a simple, one opamp phono preamp, but has a few added features. These are mainly for radio frequency (RF) suppression, and with the input circuit shown can be expected to be highly resistant to even high levels of RF interference.

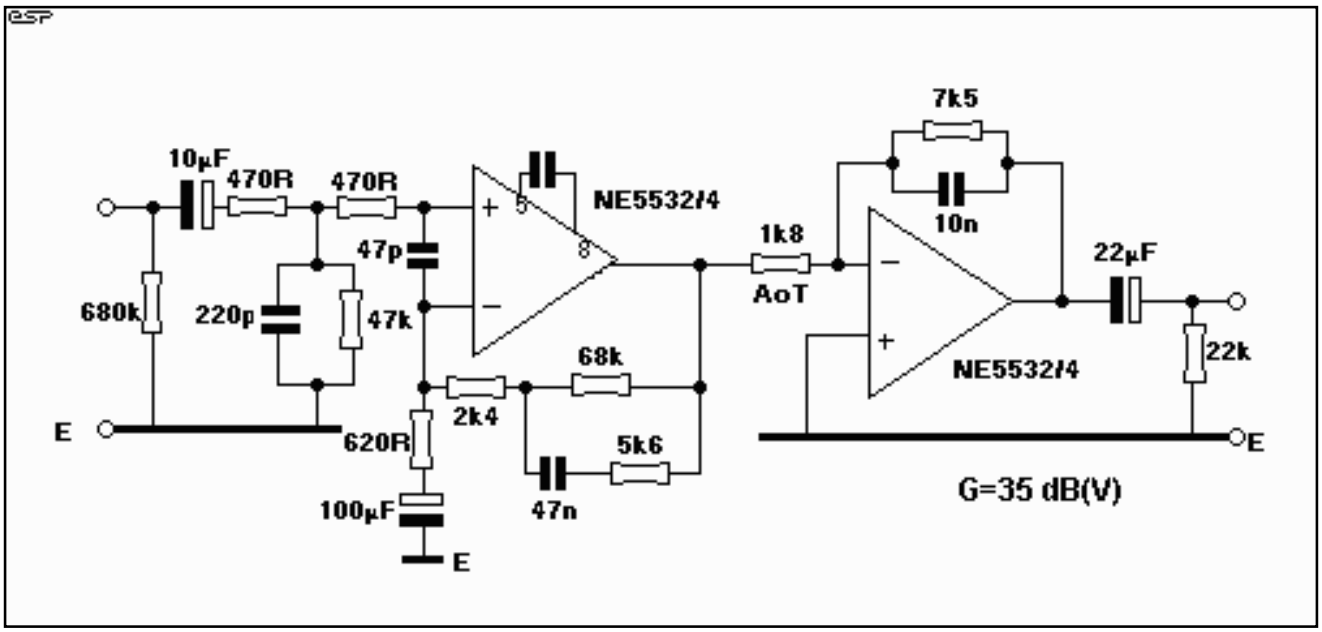

Figure 4 - Phono Preamp #2

This preamp splits the equalisation into two stages - the first stage provides the low frequency boost required by the RIAA specification, and the second reduces the high frequency component (again, to the RIAA spec.).

The advantage of this approach is that the two filter sections have less interaction, and much of the circuit noise produced by the first (and second) stage is attenuated by the top-cut circuit.

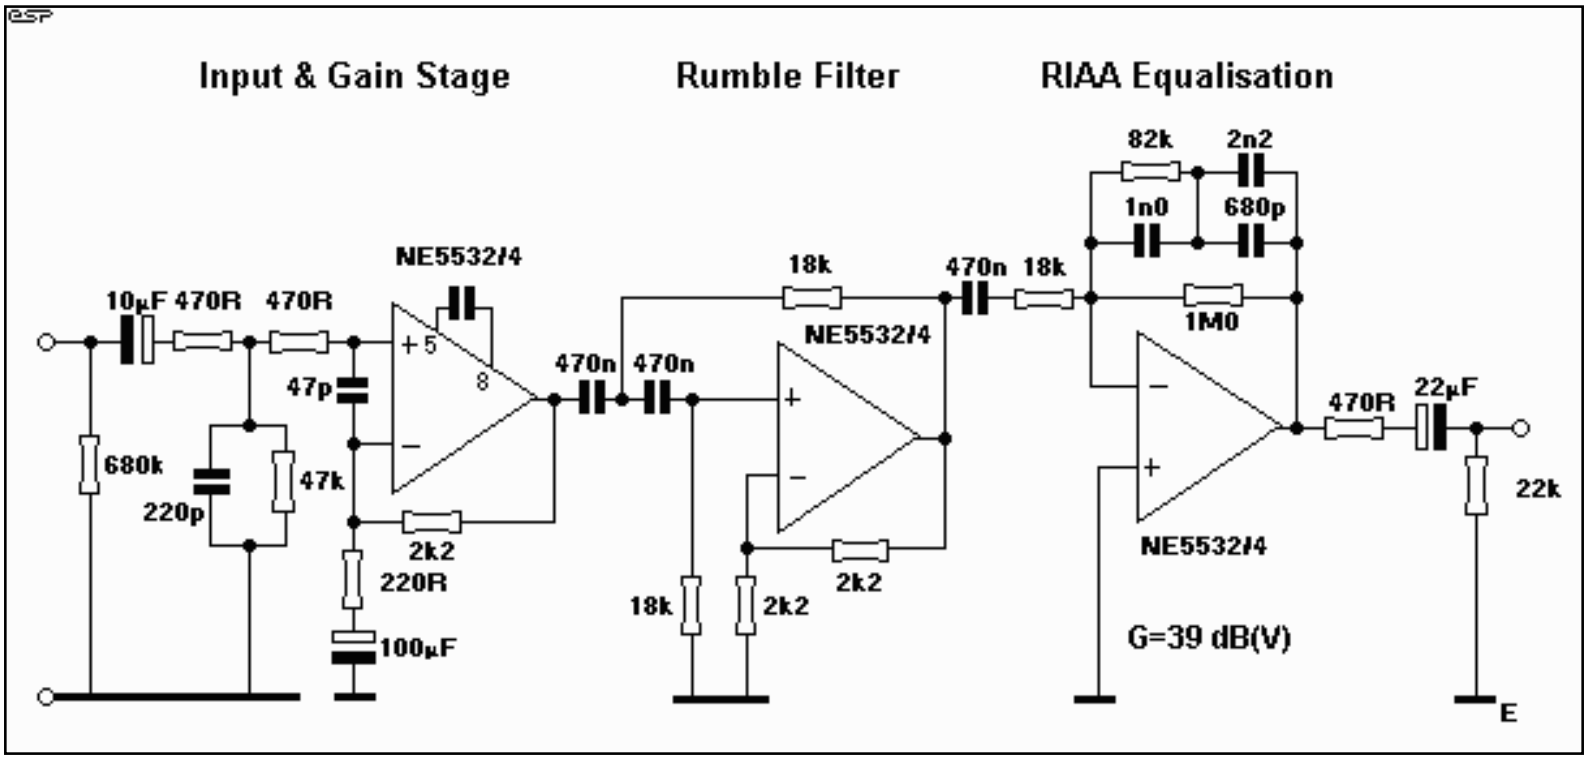

Figure 5 - Phono Preamp #3

As can be seen, this preamp is considerably more complicated than the first two, but includes a

3rd order rumble filter with a cutoff frequency of about 18 Hz.

The first stage is a simple amplifier, again with complete RF interference protection. This is followed by the rumble (infra-sonic) filter, and finally the equalisation stage. Note that in this circuit arrangement, the opamp is operating as an inverting amplifier, which has no bearing on the final result, but is (very) slightly noisier than the non-inverting configuration. This is unlikely to be audible in practice, since the gain contributed by the final stage is much lower than normal.

Total gain is 39 dB, of which 17.5 dB is contributed by the input stage, 6 dB by the filter, leaving only 15.5 dB gain in the final stage. All preceeding high frequency opamp noise is attenuated by the RIAA equalisation, leading to a design which should have an excellent overall noise figure.

Equalisation Networks

These EQ networks can be used around any opamp, and will provide RIAA equalisation to an accuracy as shown next to each diagram. Some care must be used to ensure that the feedback resistor (to ground) is selected to give the required gain.

This is specified at 1 kHz for all phono preamps, because of the frequency characteristics of the filter network.

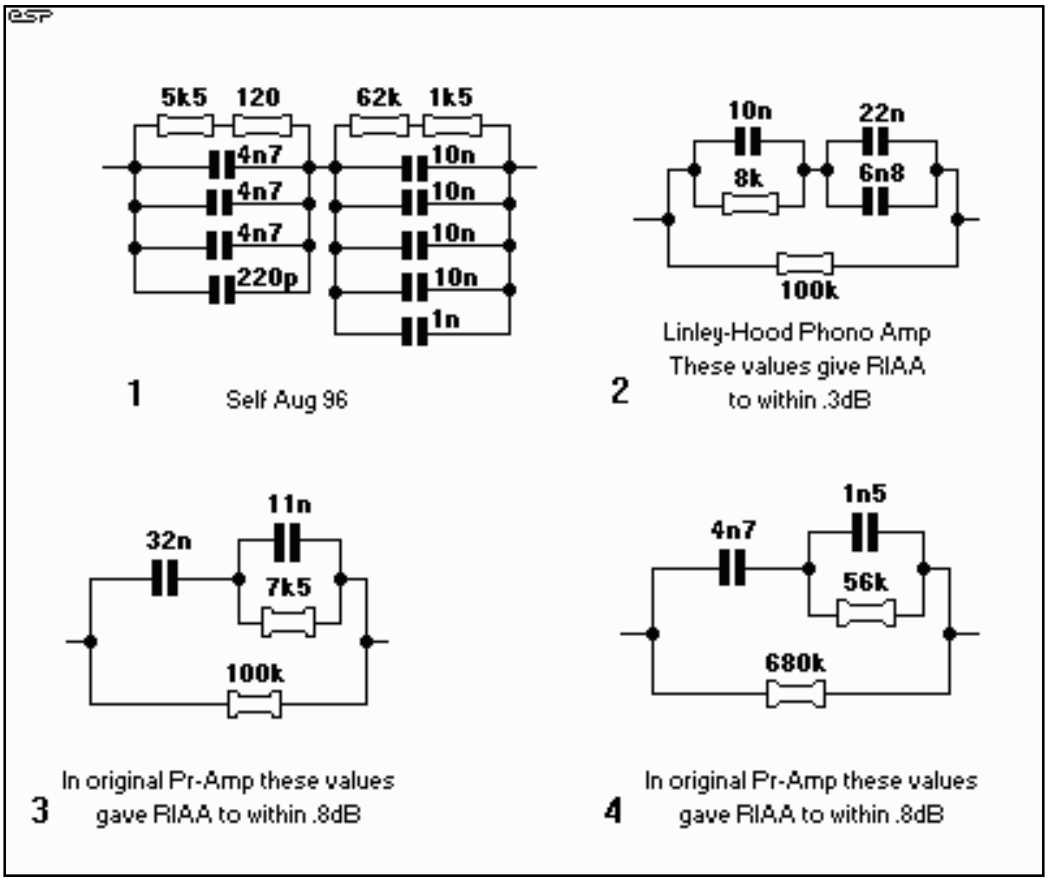

Figure 6 - Various RIAA Phono EQ Networks

Note - I have been advised by a reader that the 1nF capacitor in Figure 6-1 should be 10nF. I do not have the original circuit diagram for this preamp, so cannot be sure, but it is worth bearing in mind if you use the EQ network. A calculation reveals that there should be 50nF in parallel with 63,500 ohms to obtain 50Hz, so I expect that the 1nF cap is indeed incorrect.

The 1 kHz impedance of each network is quite different, so the required feedback resistor has been calculated for a nominal gain of 35 dB (x 56) . These work out to (approximately)

Circuit Nbr.	Network Z	Feedback Res.	Actual Gain
1	7.75 k Ohms	138 Ohms	56.6
2	10 k Ohms	180 Ohms	57.0
3	9.43 k Ohms	168 Ohms	56.6
4	67 k Ohms	1.2 k Ohms	56.8

With this in mind, the 1 kHz gain resistor can be calculated. For example, using (1) above, for a gain of 35 dB (a gain of 56 for ease of calculation), this will need a resistor to ground from the -ve input of the opamp of 138 Ohms.

RIAA Equalisation Response

For the sake of reference, the table below shows the response curves for both RIAA equalisation, and the IEC modified version. The latter was not very popular, because it represented a loss of bass (-3 dB ref RIAA at 20 Hz). For anyone wanting to know a little more about how and why the equalisation was done in this way, read on.....

Hz	*RIAA*	*IEC*	*Hz*	*RIAA*	*IEC*	*Hz*	*RIAA*	*IEC*

190	8.67	8.62						
210	7.97	7.93						

RIAA Time Constants

The time constants (**2 π f**) that provide RIAA equalisation are

- High Frequency = 75us (2122 Hz)
- Mid Frequency = 318us (500.5 Hz)
- Low Frequency = 3180us (50.05 Hz)

The basic principle behind the equalisation curve was quite simple, and was designed to reduce the grove modulation to a manageable level (both for the cutter and the reproducer), and provide some basic high frequency noise reduction.

With this in mind, frequencies below 500 Hz were "cut" using constant amplitude, which means that the signal from the cartridge will increase at 6 dB / Octave, since if the amplitude remains constant, the velocity must increase with the frequency. Because the output of a magnetic cartridge is dependent upon the velocity, bass boost must be applied to bring the levels back to normal.

It is this rather large amount of bass boost that accentuates the mechanical noise of a turntable, producing what is commonly known as "rumble". There is also the risk of low frequency feedback if the turntable is not capable of isolating the platter and tone-arm from the listening room environment. Timber floors and rigid suspension increase the risk of feedback, and many manufacturers went to extreme lengths to provide isolation and very low levels of low frequency noise.

Above 500Hz, the cutter mode changed to constant velocity, so the output of the cartridge will now be independent of frequency. Vinyl (or any other material for that matter) will collect dust, and will also have minor surface imperfections, so all signals above 2100 Hz are boosted (again at 6 dB / Octave), so the equalisation curve now applies treble "cut". This brings the signal level back where it should be, and reduces disc surface noise as well.

'A' Weighting Filter For Audio Measurements

Rod Elliott - ESP (Design based on an old Ampex circuit)

(Updated with improved filter - 29 Aug 2003)

Introduction

I have to say from the outset that I do not agree with the use of weighting filters, since they are not (despite the claims to the contrary) an accurate representation of human hearing.

In fact, the standard "A" weighting curve is accurate at only one SPL (Sound Pressure Level), assuming that the listener has British Standard Ears. I have no idea what SPL this filter is meant to be accurate at, and I doubt that anyone else does either (although at a rough guess I would suggest somewhere around 50dB and below).

When the police measure the noise from a car exhaust or a party, they happily use A-weighting (it's probably in the legislation - that has to be scary - politicians thinking that they know about SPL? Next thing they will tell us that they understand fiscal policy. But I digress .....

The purpose is supposedly to account for the fact that human hearing is less sensitive at low and high frequencies than in the upper midrange, and that this variation is dependent upon the sound intensity (SPL). The Fletcher-Munson curve (as it is commonly known, and reproduced below) shows the variation, and it is clear that any loss of sensitivity is highly dependent upon the actual SPL. The idea that a single filter can represent this at all levels is clearly wrong, but it is a standard nonetheless. (Interestingly, being wrong has never stopped a standard from being imposed, and this is probably truer in the audio industry than almost any other I can think of.)

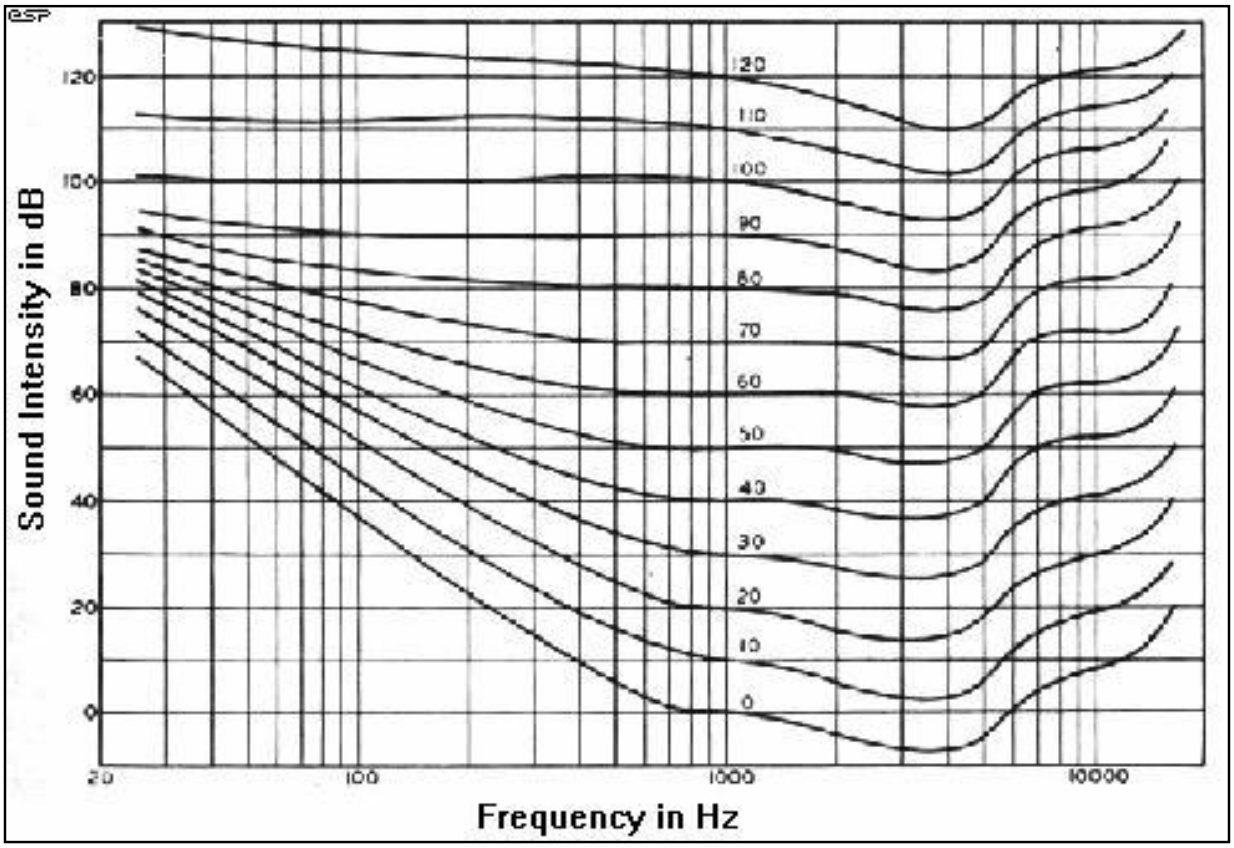

Figure 1 - Equal Loudness Curves (After Fletcher and Munson)

The premise behind all this is that as the SPL is reduced, our ability to detect low or high frequency noise is reduced, so measurements should reflect this phenomenon. While it is undeniable that the chart above represents reality in terms of human hearing [1], I remain unconvinced that A-weighting is a valid test methodology unless the absolute sound intensity is specified.

Ok, I agree that there just might be some validity hiding in there somewhere for noise measurements of amplifiers and the like, but just because the meter tells me that I should not be able to hear the harmonics of the 50/60Hz mains, does not mean that I cannot. There are some sounds that seem (at a casual glance) to defy all measurement standards, and remain audible (albeit at very low level) despite all the "evidence" that this should not be so. As with all such things, experience and practical application are more important than the absolute indication on a meter.

A piece of equipment that is essentially "noise-free" for all intents and purposes is in reality a waste of time, since the ambient noise level in most urban or suburban areas is likely to be far higher than the residual noise of most audio equipment. How useless is 100dB signal to noise ratio for a car hi-fi system, for example? Even the most expensive luxury cars generate far more noise than any tuner/cassette/CD system (and this is apart from all the other external noise generated by other vehicles on the road).

Description

Since it is unlikely that I shall be able to convince the entire industry that it is using flawed reasoning, I shall describe an A-weighting filter so that we can at least make some meaningful comparisons with other systems where this has been used. Note that A-weighting is generally applied only to noise measurements, so *might* have some validity in this respect (as long as the noise we are measuring is of very low amplitude - the neighbour's party is unlikely to fit this mould, but will be measured with A-weighting anyway - oh dear - so much for getting some sleep! (And yet again I digress ....))

The curve of the described filter is shown in Figure 2, and it can be seen that it is essentially a tailored bandpass filter, having a defined rolloff above and below the centre frequency. The reference point is at 1kHz, where the gain is 0dB. The filter response is supposed to be the inverse of one of the curves of the equal loudness graph shown in Figure 1 - it is a little hard to tell which one, but this is a standard, so we shall leave it at that.

As can be seen from Figure 3, the circuit is very simple, but even with this frequency response it is not particularly hard to calibrate accurately so that it really does account for our perception of noise level - especially if an accurate sinewave tone is used as the reference.

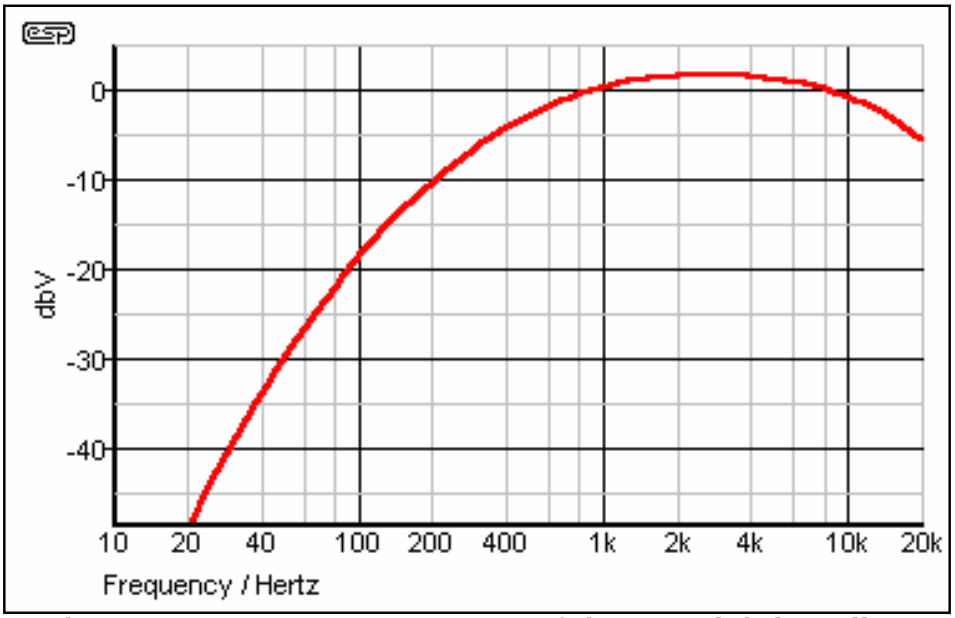

Figure 2 - Frequency Response of the A-Weighting Filter

The filter itself is passive, and the opamps are there only to buffer the input and output, and to adjust the gain so there is some correlation with reality (however slight). Note that the input impedance is quite low, and the output impedance is high, so the unit should be well shielded to prevent noise pickup from the outside world.

As always, I suggest the use of 1% metal film resistors, and the capacitors should be measured and selected, or close tolerance types used. If "ordinary" capacitors are used, their

tolerance will adversely affect the accuracy, but for normal use (i.e. non-certified laboratory), it should be close enough even if 10% caps are used. After all, the noise level of any semiconductor amp is likely to be somewhat variable anyway, so extreme precision is not normally warranted.

The circuit can be operated from a pair of 9 Volt batteries, or a regulated supply of up to +/- 15V. There is no need to use premium opamps unless extremely low noise levels are to be measured, and even then are not needed if there is a gain stage at the front end.

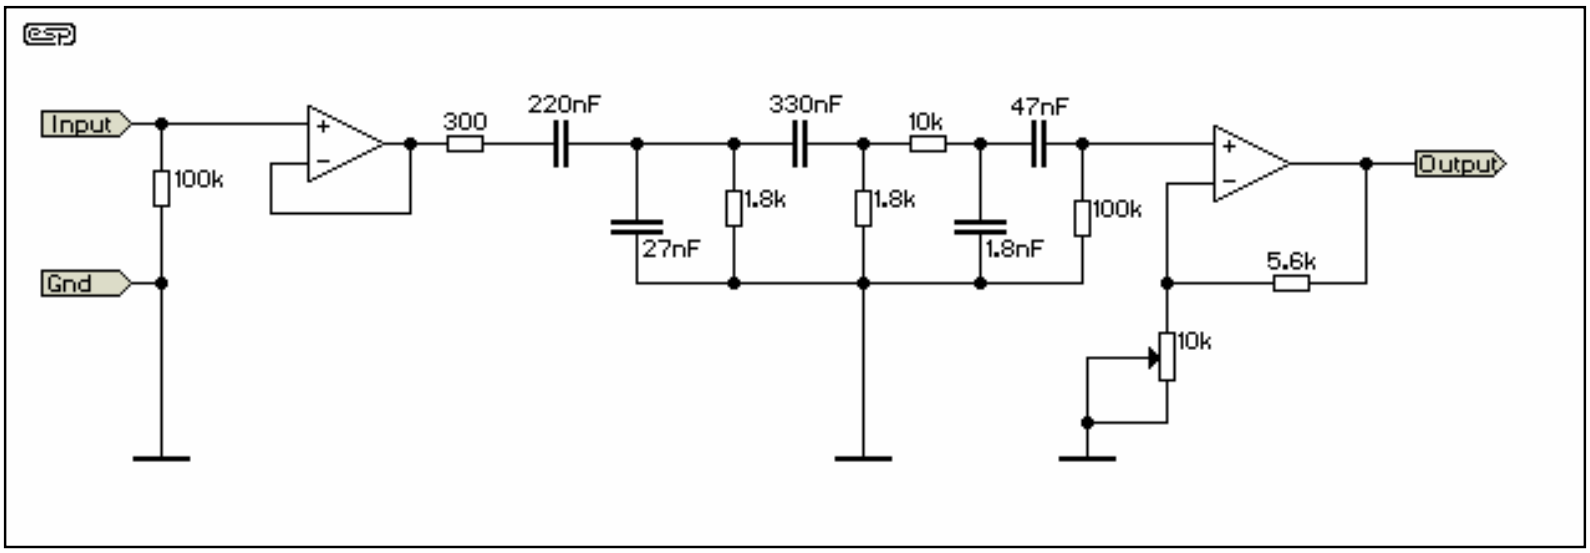

Figure 3 - The A-Weighting Filter Schematic

I will leave it up to the reader to decide on the opamps - I suggest a TL072 dual FET device or similar, which should be ok for most applications (they are not too bad for general purpose work). No opamp pinouts have been included, these are available on any manufacturers' data sheet if you don't know them.

Please note that the filter circuit has a very low impedance at high frequencies. This is liable to stress many opamps, and if a voltage in excess of a few hundred millivolts is expected at high frequencies, I suggest that the driving opamp either be cabable of reasonable current (for example the NE5534) or use two opamps in parallel. At 10kHz and 1V, the opamp will be expected to supply about 8mA.

Basic calibration is not hard - the overall gain at 2,700Hz is supposed to be about 1.3dB, so if the input is set to 1V RMS, the output at 2.7kHz should be 1.162V. Alternatively, at 1kHz, the gain (or insertion loss) should be 0dB - I would suggest that it is checked at both frequencies if possible, and if necessary, average the error between the two frequencies.

Use the 10k trimpot to adjust the level (you need to be accurate with your measurements if true A-weighting is to be obtained). Note that the trimpot should be a quality multi-turn "Cermet" (Ceramic-Metal Film) type to enable accurate setting and long-term stability. Alternatively the trimpot may be replaced with a 5.6k resistor, and accuracy will be quite

acceptable for most applications (the error is less than 0.2dB).

So, there you have it. This project will enable you to make "industry standard" measurements of amplifier noise levels, it is up to you to decide which particular standard you want to make comparisons against. Life would be so much easier if all noise measurements were made "flat" - with no filters of any kind, but this is not to be.

Update - 29 Aug 2002

The filter as originally shown was a little off at 2.7kHz relative to 1kHz (it should be 1.3dB higher at the higher frequency), and this has been corrected. The version shown should be accurate to within about 0.1dB.

It was pointed out (May 2000) that the curve of the original filter shown is not a very good fit to more modern measurement sets, and a small modification will cure this. The low frequency response of the original was not quite what it should be, and at high frequencies the rolloff was too slow. The circuit now shows the final version which is more accurate than the original.

Topic No. 2

Loudspeaker Diffraction Loss and Compensation

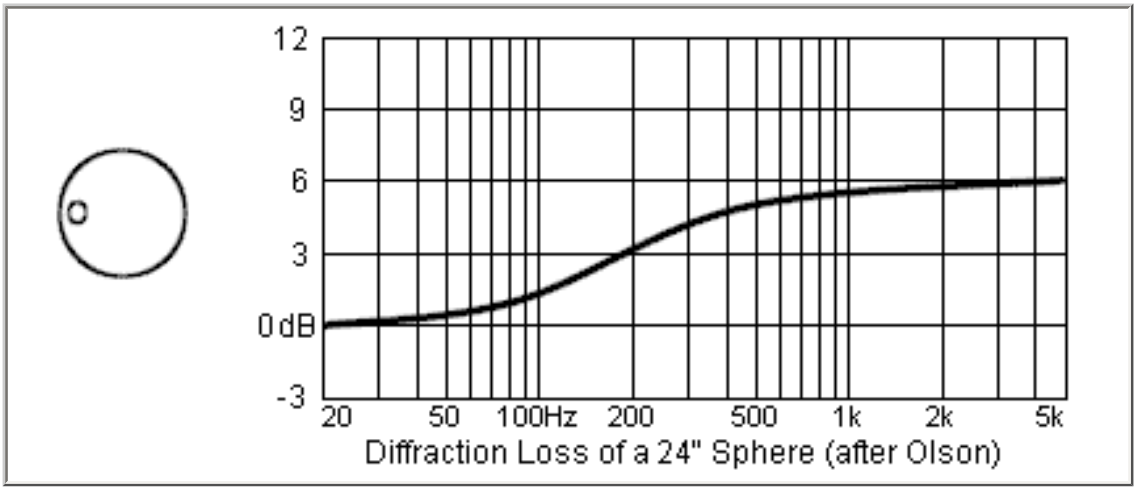
by
John L. Murphy
Physicist/Audio Engineer

Loudspeaker enclosure "diffraction loss" occurs in the low frequency range of loudspeakers in enclosures that are located in the open, away from walls or other surfaces. The essence of it is this: At high frequencies the speaker is radiating into "half space" i.e. it is only radiating into the forward hemisphere. No significant energy is radiated to the rear of the speaker. At low frequencies the speaker is radiating into both the forward hemisphere and the rear hemisphere. That is, at low frequencies the speaker radiates into "full space". Because the "energy density" at low frequencies is reduced there is a loss of bass. In short, speaker systems designed for radiation into half space (mounted flush on an infinite plane) exhibit a loss of bass when implemented in typical speaker enclosures. Fortunately, this bass loss can be accurately modeled and subsequently compensated.

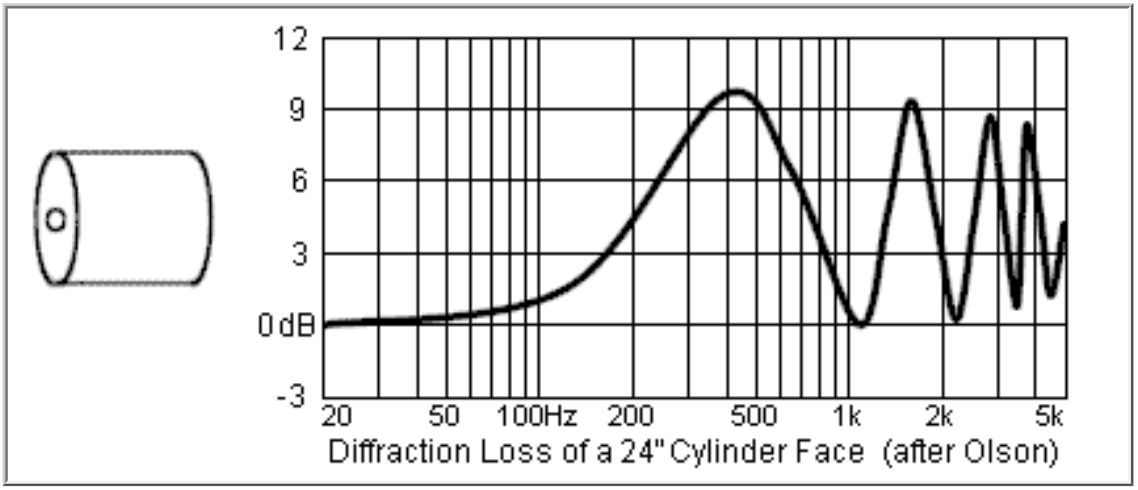
Most loudspeaker modeling is performed based on the assumption of radiation into half space. A speaker radiating into half space plays 6 dB louder than the same speaker radiating into full space. This is the crux of the diffraction loss. A full range speaker finds itself radiating into half space at the upper frequencies but radiating into full space at lower frequencies. As a result, there is a gradual shift of -6dB from the highs to the lows. This is what is called the "6 dB baffle step" or the enclosure's "diffraction loss". The center frequency of the transition is dependent on the dimensions of the baffle. The smaller the baffle the higher the transition frequency.

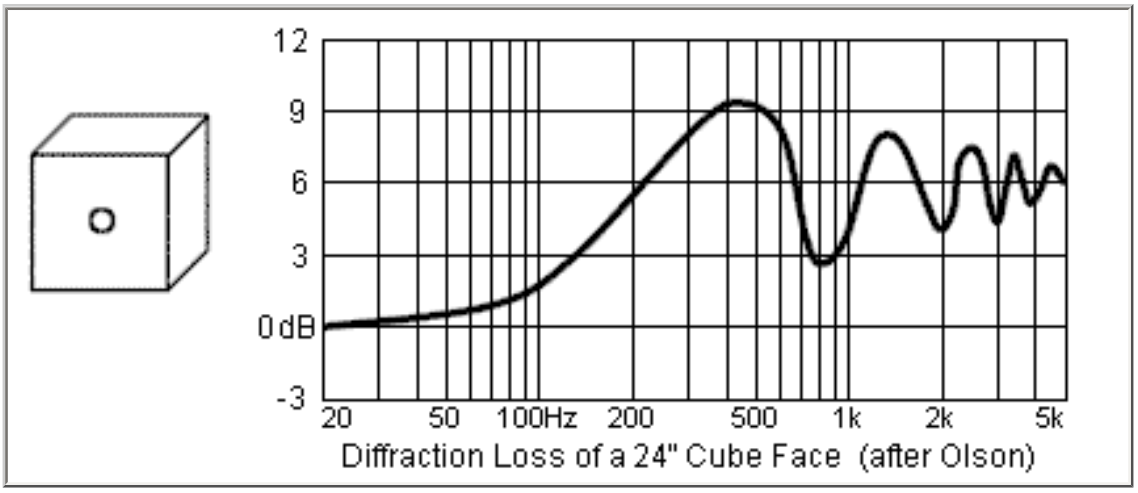
The shape of the diffraction loss frequency response curve depends on the size and shape of the enclosure. Olson has carefully documented the diffraction loss of enclosures of various shapes (see

references below). All enclosure shapes exhibit a basic 6 dB transition (or "step") in the response with the bass ending up 6 dB below the treble. A spherical enclosure exhibits this transition clearly with a very smooth diffraction loss curve. In the curves below I have taken the liberty of extending the frequency range of Olson's original graphs from 100 Hz to 20 Hz at the low end and from 4kHz to 5 kHz at the high end. The low frequency response was extended to more clearly reveal the "stepped" nature of the response. I wanted it to be clear that the response levels off at the low end. Olson's own reproductions of the measured diffraction loss of a sphere by Muller, Black, and Davis tend to confirm that my extensions to the responses are correct.

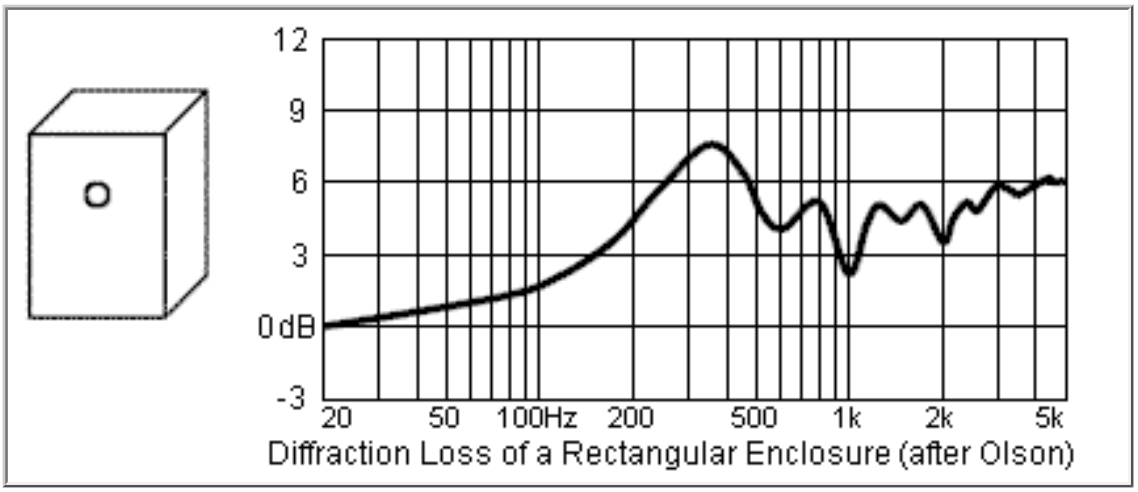


More "angular" enclosures exhibit the underlying 6 dB step along with a series of response ripples that are dependent on the placement of the speaker with respect to the baffle edges. The worst case appears to be placing the driver at the center of a circular baffle so that it is the same distance from all diffracting edges.



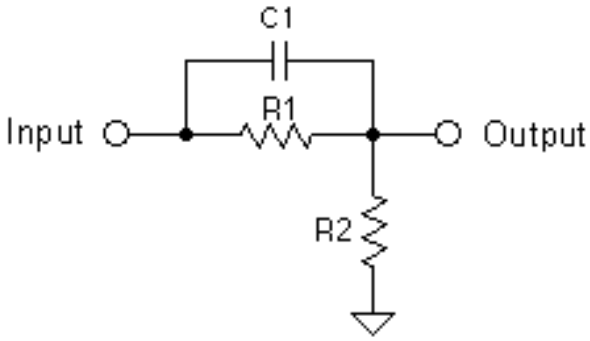


Placing the driver on the baffle so that it is a different distance from each edge tends to minimize the response ripples and make the diffraction loss look more like the smooth loss of the sphere. Olson's rectangular enclosure is an improvement over the cube and the cylinder face but the driver is still equidistant from three edges. Other authors report further reduction in the ripples with careful driver placement and edge rounding.



Because the spherical diffraction loss is a common element for the diffraction of all enclosures and the response ripples are much more difficult to predict (and can be minimized anyway) it makes sense to approximate the diffraction loss of a loudspeaker as the diffraction loss of the equivalent sphere.

One simple electrical circuit which produces a 6 dB step reduction in the bass response is shown below.

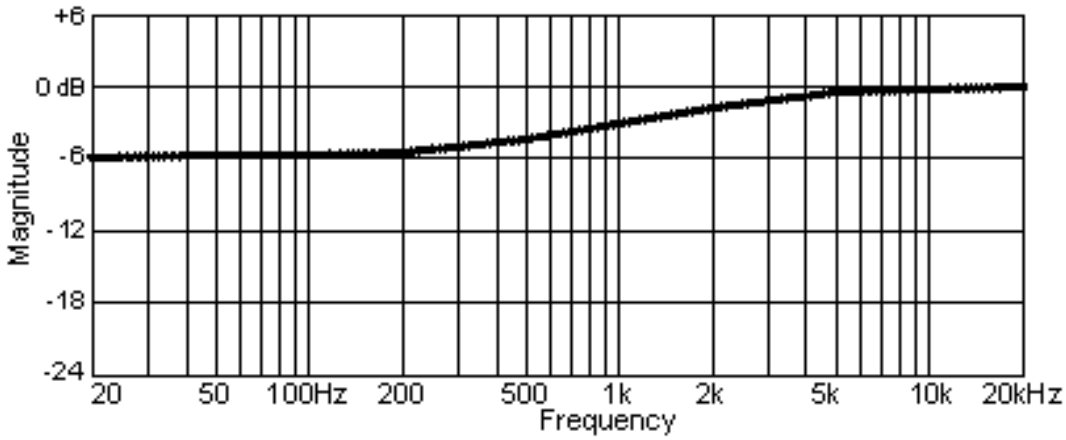


If we let R1 = R2 = R then a 6 dB attenuation results at low frequencies. At higher frequencies (where C1 becomes a low impedance) the attenuator is effectively bypassed and the signal is passed without attenuation.

It can be shown that the 3 dB "center" frequency for the above network is given by:

$$f_3 = \frac{\sqrt{2}}{2\pi RC}$$

The frequency response of diffraction modeling network typically looks like this:



Careful inspection of Olson's spherical diffraction loss curve reveals a -3dB frequency of about 190 Hz for the 24" sphere. Assuming that the 3 dB frequency is inversely proportional to the baffle diameter I have arrived at the following approximation for calculating the -3dB frequency as a function of baffle diameter.

f(3) = 115/W(B)
(where W(B) is the baffle width in **meters**)

or

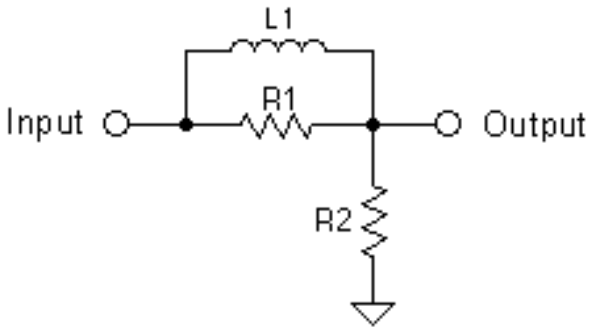
f(3) = 380/W(B)

(where W(B) is the baffle width in **feet**)

Sanity Check: for Olson's 24" (2 feet) baffle we calculate f(3) = 380/2 = 190 Hz . . .**OK!**

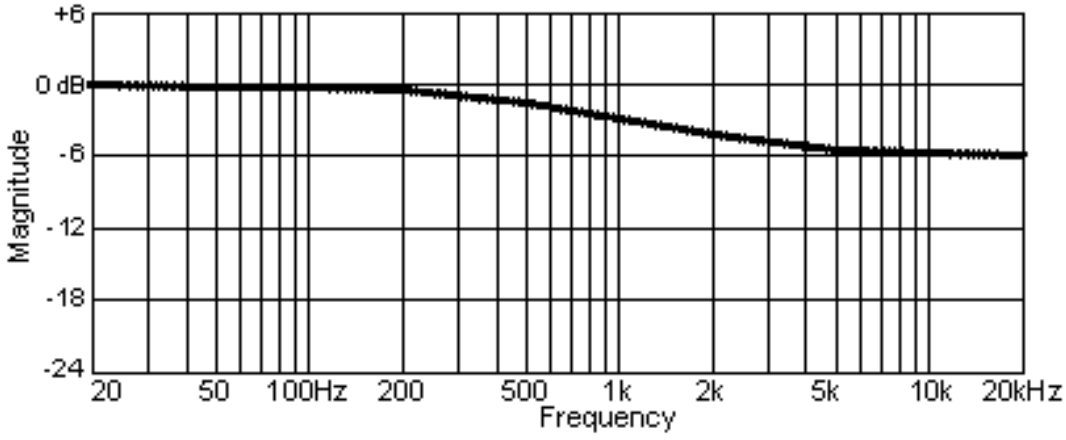
Once the diffraction loss is known it is possible to design a simple electrical network that will exactly mirror the spherical diffraction loss and restore the lost bass to a speaker system. Loudspeaker designers have traditionally compensated for the diffraction loss by reducing the level of the tweeter and making other adjustments in the crossover. The method I propose is to design for half space but then do a precise mirror image compensation for the diffraction loss by way of an R-L network wired in series with the (impedance compensated) speaker. Alternately, the diffraction loss can be compensated at line level with a simple R-R-C network. Line level correction would reduce the requirement for the large inductors typically needed for a speaker level compensation network.

A simple electrical network which produces a 6 dB step reduction in the treble response is shown below.



Here R2 represents the loudspeaker load impedance. If we let R1 = R2 = R then a 6 dB attenuation results at high frequencies. At lower frequencies (where L1 becomes a low impedance) the attenuator is effectively bypassed and the signal is passed to the driver (R2 here) without attenuation.

The frequency response of 6 dB diffraction compensation network looks like this:



To design an RL network which will compensate for diffraction loss of a particular system we start by setting:

R1 = R2 = R =Nominal System Impedance (8 Ohms for example)

Next, you can use my empirically derived equation to calculate the value of the inductor L1:

$$L1 = \frac{W_B R}{1.021}$$

Where W(B) is the baffle width in meters, R is in Ohms, and L1 in millihenrys.

I arrived at this equation for L1 by forcing the 3 dB frequency of the compensating network to match the 3 dB frequency for the diffraction loss of the baffle.

The resulting RL network should be wired in series with the speaker system it is compensating. The correction will be most accurate if the loudspeaker itself approximates a resistive load.

Example:

Find the network required to compensate the spherical diffraction loss of a 4 Ohm speaker system with a 0.25 meter wide baffle.

R = 4 (the nominal impedance of the system)
(this resistor should have a power rating something like a quarter of the **system** power rating)

L1 = .25 x 4 / 1.021 = 1 / 1.021

L1 = .979 mH
(1 mH will be close enough)

To **build** this network, start by connecting a 4 Ohm resistor in parallel with a 1 mH inductor. Then connect this RL network in series with the speaker. You should hear reduced treble when the diffraction loss compensator is used.

WinSpeakerz models the diffraction loss of the enclosure as a simple spherical diffraction loss. Provided the driver is located "irregularly" on the baffle this gives very good approximation to the actual diffraction loss of the enclosure. The frequency of the transition is controlled by the "Baffle Width" parameter at the System Editor page 1. The response of the speaker can be viewed with or without the diffraction loss and the diffraction loss can also be viewed separately.

25Jun99 A follow-up post on this topic:

Question:

> I've been researching the idea of adding a baffle step compensation circuit
> to my Marchand XM9 active crossover. The only thing that seems hard to do
> is calculate the amount of boost actually needed as this is room dependent.
> The theory, see John Murphy's article at www.trueaudio.com, suggests 6db
> boost. An article at the TL web page suggests 3db is more likely with room
> reinforcement. Has anyone looked at this.

The 6 dB loss is correct for a speaker enclosure in free space. When the enclosure is placed in a room it will encounter various effects due to the room (reverb, standing waves, boundary effect, cavity effect . . .)

Diffraction loss and room effects are independent and completely different effects. The diffraction loss is nicely predictable whereas the effects of the room are highly variable, not only from room to room but also with speaker placement and room furnishing. This typically means that each listening environment will be unique and will require unique compensation.

I suggest the 6 dB diffraction loss correction as a correction for the diffraction loss alone. I don't suggest that it will neutralize all the effects due to a unique listening environment. Others suggest you "deal with diffraction" in the crossover, usually by just lowering the tweeter level a bit.

In some situations 3 or 4 dB of diffraction loss correction may result in an overall response that is closer to neutral (flat). But the most correct way to compensate the room would be to do it separately from any diffraction loss correction. Room compensation might take the form of several notch filters tuned to the worst peaks resulting from room modes. Next you might want to tilt the treble up a smidge to compensate for reverberation that has significant treble loss. Dark room reverb will make the playback sound a little darker. Bright reverb . . . bright. Next, depending on the size of the room and speaker response, you might need to compensate for the cavity effect. In larger rooms cavity effect can be ignored but in vehicle cabins it is a major effect.

Diffraction loss compensation is only part of the job of precisely compensating for the difference between a theoretical half-space acoustic load and what happens when we place an enclosure in a real world listening room. Reducing the degree of diffraction loss compensation MAY reduce the coloration from the room effects as these effects largely tend to "boost the bass" but such an adjustment is imprecise at best.

If we can systematically identify each source of color between our half space model and our particular listening room then we can then take steps to precisely neutralize the response in our own listening room. Spherical diffraction compensation is one effect we can correct with a high degree of precision. As we move toward a better understanding and modeling of our listening rooms I'm sure we will work out more practical and precise ways to compensate our rooms.

Comments and critique are welcome. :-)

Regards,

John

Issues in loudspeaker design - 1

When it comes to the practical requirements for accurate sound reproduction, then there are a surprising number of issues that are not fully understood. Sound reproduction is about creating illusions in our mind, in that amazing information processor between our two ears. Sound reproduction involves physical processes to generate air vibrations that move our eardrums and in turn stimulate mental processes, that have evolved over millions of years for the purpose of survival and for communication, processes that lead to perception of the sound source and its environment. While we can measure many different physical parameters involved in the generation and propagation of a sound field, it becomes exceedingly difficult to assess their relative importance to what we hear and how it helps or detracts from the illusion. The published scientific material on the psychology of hearing (psychoacoustics) is extensive and sometimes helpful in explaining phenomena in two-channel and surround sound reproduction.

In the following I describe what I see as frontiers, if not in yours, then at least in my understanding of what matters for accurate sound reproduction. While I strive as an engineer to find answers and explanations based on the physics of the situation, I try to be honest to my listening observations as ultimate arbiter. I use my memory of un-amplified sound as reference for judging accuracy of the illusion. What I see as frontiers may be settled areas to others, or clear separations between opposing camps, that hold on to cherished convictions. I would hope that the exposé stimulates a few readers to research a subject further and share their insights.

structures to extend the steady-state low frequency response of the speaker. In general, the energy leads to very high sound pressures inside the box. A small amount of the energy is lost as heat in the stuffing material, some in the process of flexing the cabinet walls. Much of it reappears outside the box, because the thin cone presents a weak sound barrier. Just how much is difficult to measure, but it is a contributor to the frequency response. I am of the opinion that the effect is most notable in the low hundreds of Hz region, where stuffing materials are ineffective and the internal dimensions not small enough for the internal air volume to act as a pure compliance. Consequently, enclosures should be either very small (less than 1/16th of a wavelength) or extremely large, both of which are not very practical for different reasons.

To make progress with box speakers an acoustic resistor is needed that can more effectively dissipate energy in the 80 Hz to 800 Hz frequency range at high volume velocities. Such device would not only be useful for closed box speakers, but also for speakers that use the rear radiation from the driver to form a specific polar radiation pattern, such as a cardioid.
A cardioid speaker can be made with two opposite polarity monopole sources separated by a distance D, and with the signal to one of the sources delayed by a time T = D/c. An implementation of this concept could be a driver in a box of depth D where the rear wall is an acoustic resistor R. At long wavelengths the box internal air volume behaves as a compliance or acoustic capacitor C. The acoustic output from the rear of the box is low-passed by the RC filter and delayed relative to the front output by T = RC.

The acoustic resistor should be purely dissipative, with vanishing reactive component, and be independent of frequency. It also should be linear over the range of volume velocities encountered for high SPL. Traditionally cloth type materials have been used for cardioid speakers. Long fiber wool, synthetic fibers or fiber glass matting have been used to attenuate sound inside enclosures. The properties of these materials are neither frequency independent nor linear.

It may not be widely known that filter media for the filtration of liquids and gases in the chemical and other industries can have applications in acoustics. Such filters may be thin sheets (<1 mm thick) of a non-woven, sintered, stainless steel fibre matrix for filtration levels from 5 to 50 micron. Airflow at a constant velocity v through the filter material causes a pressure drop Δp between input and output sides corresponding to a flow resistance $R_f = \Delta p/v$ [Ns/m^3].

It is common in this industry to specify an inverse quantity which is Permeability P [l/dm^3/min] at 200 Pa pressure drop. Flow resistance and permeability are related by $R_f = 1200/P$ in this case.

Resistance values between 150 and 3500 Ns/m^3, or 15 to 350 rayl in the older cgs system of units (1 rayl = 10 Ns/m^3), are obtainable from a single filter sheet. For comparison the free-space acoustic field impedance $p/v = \rho c$ is resistive and has a value of 414 Ns/m^3 = 41.4 rayl. Materials are available with greater structural rigidity such as Feltmetal with thickness up to 6 mm and resistance between 6 and 50 rayl. The impedance is resistive and constant over the 20 Hz to 2 kHz range that I tested. Linearity should also be quite good, but I have not measured it.

The challenge remains to build an acoustic termination for the inside of a box. Feltmetal and filters should be readily useable for a cardioid speaker, but for a woofer application their linearity at high volume velocities needs investigation.
Top

B - Frequency response of open baffles

At this point in time the design of an open baffle speaker using cone type drivers is highly empirical. The baffle shape which determines the on-axis and off-axis frequency response must be optimized by experiment. This is how the dimensions of the PHOENIX main panel were determined (Ref.2), because no modeling software was available. Some guidance for baffle size can be derived from the response of a flat,

thin circular disk baffle of radius D with the driver in its center. This shape is less than optimum for use at frequencies above f = 0.5 c/D, where comb filtering occurs. The peaks and dips in response are smoothed by a flat rectangular baffle. As the driver itself becomes more directional the outline of the baffle has less effect.

For size, appearance and structural reasons the baffle may be folded back into a shallow U-shape. At low frequencies the H-shape and W-shape baffles lead to space savings. All of theses structures are considerably more difficult to analyze, because lumped and distributed acoustic elements have been added in the process of folding.

The radiation of the driver itself to front and rear is not symmetrical. The basket structure adds a complicated acoustic lowpass filter. This affects not only the output to the rear of an open baffle, but also the response in front due to additional phase shift and change in amplitude.

While it is not too difficult to estimate the response of H and W baffle structures at long wavelengths, it would be highly desirable to have modeling software for flat and U-shaped baffles for the whole frequency range. To be of usefulness the software would have to account for the measured frequency response of the driver in an 'infinite' size baffle, for radiation in front and rear and at different angles.
Top

C - Dipoles below the Schroeder frequency of a room

The Schroeder frequency describes the approximate border between the frequency range of discrete, sparse room mode distribution below it and high mode density above it.

$$f_s = 2000 \left(T_{60} / V \right)^{1/2} \quad [\text{Hz, s, m}^3]$$

For typical domestic listening rooms f_s is in the order of 100 - 200 Hz.

Above f_s a dipole source is in the reverberant field and has the following behavior:

- 1/3rd or -4.8 dB of the radiated acoustic power compared to a monopole for the same direct sound pressure level, due to the cos (angle) free-space polar pattern.
- A 4.8 dB higher level of direct to reverberant sound compared to a monopole.
- Rotation of the source affects the direct sound level, but this is strongly masked, because of the typically higher reverberant sound level.
- Room placement and rotation have little practical effect upon the reverberant sound field level. The number of possible modes is so high, that reducing the excitation of some increases it for others.
- Reflections are affected by placement and rotation.

Below f_s in the sparse mode region:

- Fewer modes are excited compared to a monopole, because of the cos(angle) directivity.
- A monopole and a dipole source in the same location will excite a given mode to a different degree, because their source impedances are very different. Consequently, the match to the acoustic field impedance of the mode is different.
- Monopole and dipole source in the same location will excite a given mode to a different degree for an additional reason. For maximum

excitation by a dipole source the direction of mode propagation has to coincide with the free-space direction of maximum source radiation.

The observed audible difference between monopole and dipole for bass below f_s is:

- Less boom and droning of specific notes with a dipole,
- A higher degree of articulation and resolution of complex musical bass lines,
- A sense of air, spaciousness, and very natural reproduction of acoustic bass,
- Less physical impact,
- Less absolute bottom foundation below the lowest room mode frequency.

To my knowledge these and similar subjective observations have not been explained satisfactorily by theory and only partially by measurement. In Ref.1 I have investigated dipole behavior on the basis of:

- Steady-state frequency response of the transfer function between source and listener for a simple 2-dimensional model and measurements in a very small office room and a living room,
- Cumulative spectral decay measurements,
- Energy-time curve of the low frequency impulse response,
- Modulation transfer function for low frequencies,
- Frequency response to shaped tonebursts,
- Frequency and time response to a multi-burst signal and its correlation to listening impression.

The best physical evidence for dipole benefits, that I have found, comes from multi-burst tests. A CD with such test signals is available.
The steady-state frequency response has been used for arguments pro and con dipole low frequency sources. While the transfer functions for dipole and monopole are clearly different I would not dare to make sound quality judgments based either on the data that I have seen or the ones I have taken myself. The exception to this is the very low frequency region, below the first mode, where the monopole response gains consistently from pressure buildup compared to a dipole.

I suspect that the perceived low frequency benefits of dipoles are related to the psychology of hearing and involve much more complex processes than a simple steady-state response analysis. Our mind is geared towards analyzing time, frequency and amplitude variant sound pressure between two ears and selectively draws information from it.

My hypothesis is that three effects contribute to the subjectively more accurate reproduction of bass:
1 - The open baffle, dipole woofer has a figure-of-eight radiation pattern and therefore excites fewer room modes.
2 - Its total radiated power is 4.8 dB less than that of a monopole woofer for the same on-axis SPL. Thus the strength of the excited modes is less.
3 - A 4.8 dB difference in SPL at low frequencies is quite significant, due to the bunching of the equal loudness contours at low frequencies, and corresponds to a 10 dB difference in loudness at 1 kHz.
Thus, bass reproduced by a dipole would be less masked by the room, since a dipole excites fewer modes, and to a lesser degree, and since the perceived difference between direct sound and room contribution is magnified by a psychoacoustic effect.
Top

D - Room and baffle reflections

Reflections are part of everyday life. If you have been inside an anechoic chamber and experienced the eerie silence and feeling of disorientation, then you know what I mean. In more common surroundings, every sound we make generates a set of reflections. If the sound is sustained, then its amplitude and phase at a given location are affected by the surroundings. This is what happens in a listening room. To quote:
"The acoustics of a room resemble either a linear filter or a hall of mirrors, depending upon the time scale of interest. As a filter, a room causes linear distortion in the amplitudes and phases of steady-state tones received by the listener's ears. As a hall of mirrors, a room appears to be a collection of spatially distributed reflecting surfaces that create multiple versions of each transient sound. The reflected transients ultimately reach the listener from diverse directions, almost none of which agree with the direction of the source. Thus, both the steady-state and the transient response of a room result in the listener receiving misleading cues about the location of a source of sound in the room." [1]

Modeling and understanding of how we manage to cope with this situation, and actually localize real and virtual sources surprisingly well in most instances, is subject of ongoing scientific investigation [2]. Inter-aural time delay (ITD), and intensity differences (IID), spectral envelope cues, and the "precedence effect", all play their part in recognizing the location of sources when room reflections are present. In addition to affecting localization: "The lagging sounds can contribute markedly to perceived timbre and to the sense of a room's acoustics. If the acoustical features of the lagging sounds are consistent with them being echoes of the leading sound, then the lagging sounds are perceptually suppressed, and are not heard as separate auditory events. On the other hand, if the lagging sounds cannot be plausibly interpreted as echoes, or if insufficient information is available to decide whether they are echoes or not, then they will tend to be heard as separate auditory events." [2]

Most of the research into audibility of reflections has been performed under anechoic conditions. Detection thresholds and phantom image shifts for a single reflection versus delay time and amplitude have been studied extensively. But, the results cannot necessarily be translated to binaural listening in reverberant spaces. Nevertheless, the prevailing school of thought amongst audiophiles holds all reflections to be detrimental. The prescription is to either absorb or diffuse reflections as much as possible. A room with only hard reflective surfaces and with no furnishings, having echoes and long reverberation time, is clearly not an ideal playback environment, but nor is an overstuffed room, full of absorbing materials and resembling an anechoic chamber. The ideal room may be a function of the type of speaker used.
The typical, conventional box speaker has a power response that decreases over 10 dB from low to high frequencies, assuming a flat on-axis response. It is omni-directional up to a few hundred Hz and becomes ever more forward radiating with increasing frequency. An open baffle, dipole speaker has at least 5 dB less power response variation between low and high frequencies. While box speakers seem to perform best in relatively dead rooms, I have found that dipole speakers show their qualities better in a rather live room.

In general, the more a room resembles an anechoic chamber, the less the off-axis radiation contributes to the sound at the listening place. The type of dipole speakers I have worked on, all try to duplicate the on-axis response for off-axis horizontal angles up to +/-60 degrees, albeit at decreasing levels and up to about 5 kHz. This has two effects. The level of the reflected sound is angle dependent and can be reduced by speaker orientation. The acoustic features of the reflected sound are consistent with the direct sound. Both of these help in suppressing a perception of timbre change and decrease a sense of the room's acoustics. Consequently, you hear more of the speaker and less of the room.

Much has been made about the wall behind an open baffle speaker, the front wall from the listeners perspective. The wall reflects the rearwards radiated sound which is 180 degrees out-of-phase with the forward radiated sound. The interference between the two leads to progressive cancellation at low frequencies and comb filtering at higher frequencies for steady-state sounds. A corresponding effect occurs with a box speaker, at least up to several hundred Hz, only the comb filter frequencies are different and the low frequencies are boosted. All of this is controlled by the distance between speaker and wall. If the speaker is at least 1 m (3 ft) in front of the wall, then the reflected sound

is delayed by about 6 ms, which is sufficient not to be perceptually summed with the direct sound. The cognitive process disassociates it from the speaker and attributes it to the room with a sense of space.
Panel type open baffle speakers can have specific problems with the back wall. The radiation impedance seen by the panel goes to extreme values at frequencies where the distance is a multiple of a quarter wavelength. The motion amplitude of the very low mass panel may change due to the change in air load, causing a change in frequency response. Also, a large panel area creates a lobing polar response at higher frequencies and the reflection can become colored in timbre, shift angle and cause unstable imaging.

I have observed that a certain amount of lateral reflection is necessary for creating a believable illusion of the space in which the recording took place or to give a satisfyingly rich musical experience [3,4,5]. Flush (soffit) mounted speakers strike me as producing a sound that is two-dimensional, analytical, but ultimately lifeless. Highly directional horn speakers create a similar negative impression. In the tweeter range, wide horizontal dispersion removes harshness and adds airy-ness in my experience. This only makes sense if the reflected sound intensity has been increased. It might also explain why ribbon tweeters, which can be very narrow sources leading to wide dispersion, are so highly regarded, despite their poor vertical polar response.

RT60 for my listening room is around 550 ms and pleasantly lively for conversation and socializing. I do not like a muffled cocktail lounge ambience. The two side walls are mostly double pane glass. The room is very long. A large brick fire place is 1.5 m (5 ft) behind the speakers. Imaging is very precise, given a good recording, with a smooth spread of the venue acoustics between the speakers and slightly beyond. The images are placed behind the plane of the speakers, never in front. The speakers disappear completely.

Sound diffraction at the edge of a box speaker baffle is claimed to degrade stereo imaging. I have not experienced this myself for speakers with typical flat baffles for drivers up to 8" (20 cm), nor have I seen scientific evidence. The low amplitude diffracted sound wave occurs so early after the direct sound (<500 us), that the precedence effect does not come into play and summing localization occurs [6]. What is significant, is that the "baffle step", the transition from 4π to 2π-space radiation, occurs at higher frequency for a narrower baffle. This keeps the power response more uniform over a wider frequency range and the spectral signature of any reflection more like the on-axis response. Large radius or wide chamfered edges smooth the high frequency response on-axis and off-axis.

The question remains: When is room treatment necessary and for what purpose?
Specular reflections [7] can be diffused with quadratic residue diffusor panels, but this will not change the reverberant sound energy in the room. Diffusors become very large for frequencies below 500 Hz. Reflections can also be absorbed. This too works best above 500 Hz. Treatment for lower frequencies becomes exceedingly more space consuming and below 100 Hz requires custom solutions.

E - Line sources

As a line source I define a speaker with a very narrow and long radiating surface, which is used at frequencies above f = c/2L, where its length L is greater than 1/2 wavelengths. Often such line source consists of a vertical array of a large number of identical drivers on a narrow baffle. In other cases it might be a ribbon like, narrow and long conductor in a magnetic field, or a narrow and tall electrostatic source. Specifically, I am referring to lines that are at least 1.5 m (5ft) long.

Under free-field conditions such lines will have a wide and fairly uniform horizontal radiation pattern The vertical polar response will be very irregular and highly distance dependent, because of the finite length of the source [1]. In a room, though, the images of the source in floor and ceiling will make it appear as infinitely long, the more so, the less the gaps between the ends of the source and the reflecting floor and ceiling surfaces. Consequently, the line launches a cylindrical wave and illuminates the room very uniformly. The acoustics of the room, therefore, are of similar importance as for an omni-directional point source. At sufficient distance the direct SPL falls off with the square root of distance, which improves the direct-to-reverberant sound ratio over that of a point source.

It surprises me that in a reverberant environment, such as a typical living room, these radiators give little indication of poor vertical polar behavior, even when the line does not fully extend to floor and ceiling. Clearly, the reverberant field in the room fills in any perceptual notches in the polar response. Standing close to the line and moving with one's ears up and down, the acoustic image does not change and follows the ear over the active length of the line, almost to its ends. Imaging is very precise, when standing or seated in the near-field of the line, which is closer than the typical listening distance given by the apex of an equilateral triangle. At greater distances the images grow in height. This can be impressive on big orchestral pieces, as if looking through a large window onto the sound stage. Small acoustic sources, like a vocalist or a cello, though, become overblown in size. Line source speakers are at their best when listened to close-up like giant headphones. This preserves proper size imaging and gives the illusion of a large sound stage.

Vertical height of the sound stage adds to its realism. I find small 2-way speakers very unsatisfactory in this respect, even when they are correctly positioned at ear level height. Line sources provide this height, as do single tweeter symmetric driver layouts like LM-UM-T-UM-LM. In the latter case separate frequency ranges are assigned to each symmetrical set of drivers LM-LM and UM-UM, such that any free-space vertical lobing is minimized. This type of source suffers considerably less from the image size distortion of a uniform line.

An added advantage of tall sources is their relatively large radiating surface area, which means small excursions and, therefore, progressively lower non-linear distortion for a given maximum sound level. The low distortion aspect is even more important, than sound stage height, wide angle horizontal dispersion and uniform power response. Low distortion means increased dynamics and clarity, and the ability to play back at near live levels without listener strain. It brings the naturally occurring distortion mechanisms of the ear into play, which are necessary elements for creating an illusion of reality.
Sensitivity can be high. A line with 25 identical drivers connected in series-parallel to obtain the same combined impedance as that of a single driver, will have 14 dB higher SPL for the same voltage applied.
Stored energy is not necessarily low because of the many cabinet and driver chassis cavities.

I would encourage more investigation of line sources for use in very large venues, as for public address or entertainment speakers. For typical domestic environments they are unnecessarily large. Today, the same low distortion sound pressure levels can be obtained from far fewer drivers and without the image distortion.

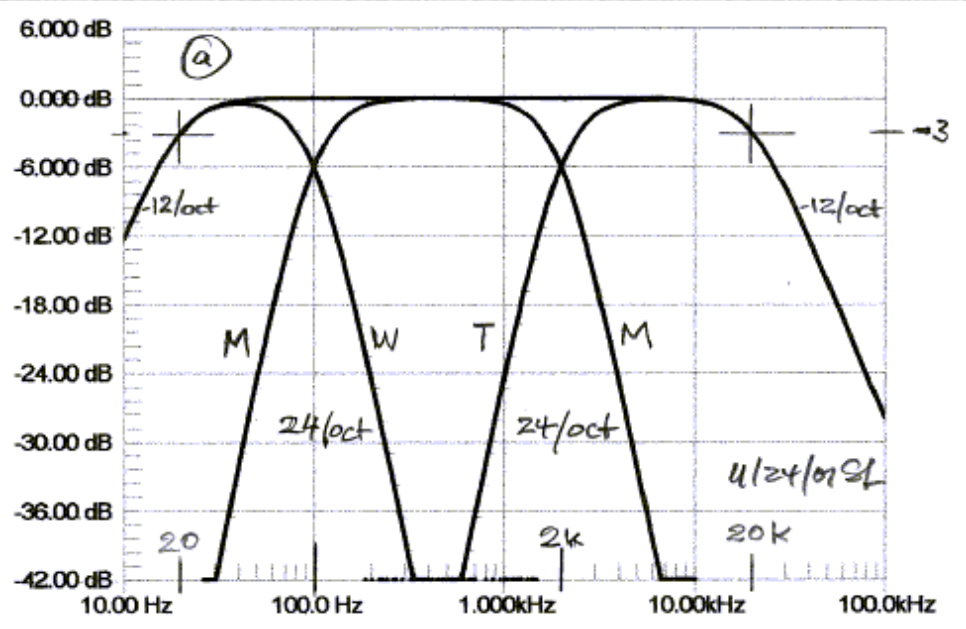
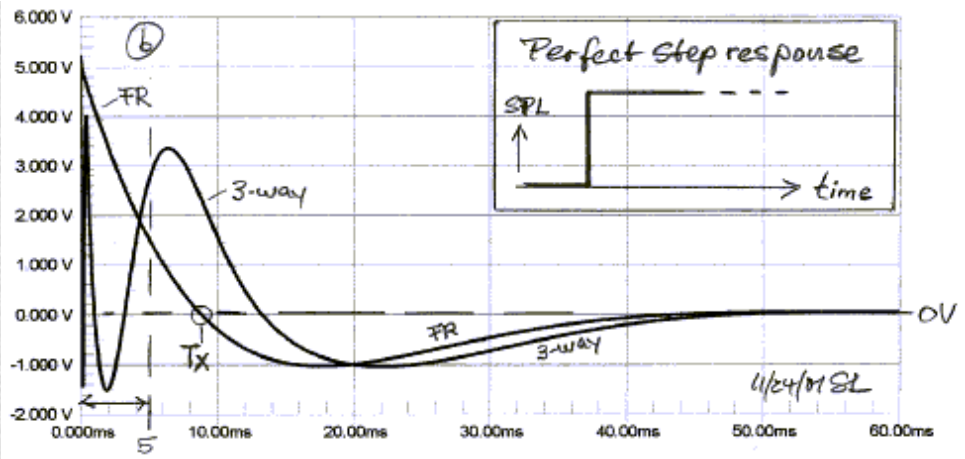
F - Group delay and transient response

Few studies have been made about the audibility of linear distortion of the time waveform for an acoustic signal. Some people have great expectations about the improvements that DSP technology can bring to loudspeakers and crossovers through linearizing their phase response, which should result in a perfect transient response. The step response fidelity is often taken as a measure of performance. The step response is the integral of the impulse response over time, and belongs to a frequency response, that has been rolled off at 6 dB/oct towards high frequencies, starting from zero frequency.

It is instructive to review the step response of a practical 3-way speaker and to compare it to a full-range speaker. Both speakers are assumed to have a flat frequency response that is 3 dB down at 20 Hz and 20 kHz, rolling off at 12 dB/oct like a filter with Q = 0.7. The 3-way speaker has LR4 crossovers at 100 Hz and 2 kHz as in graph (a).

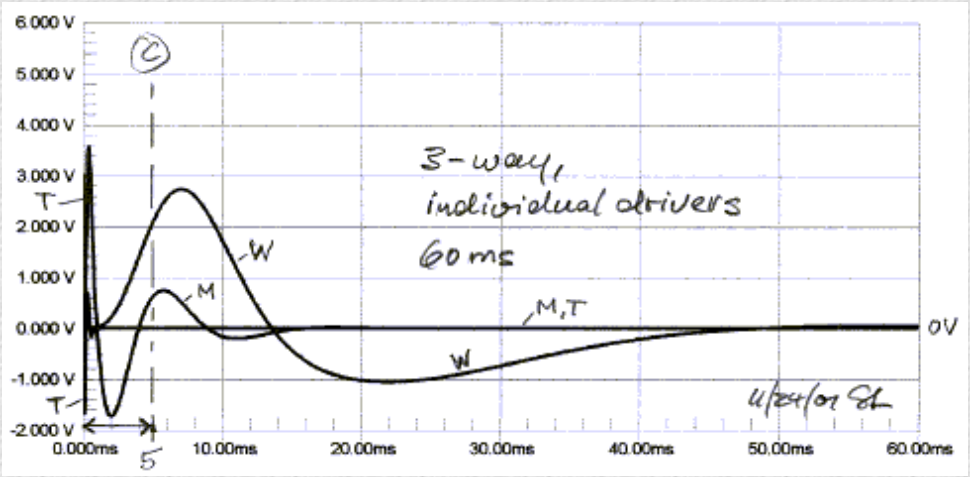


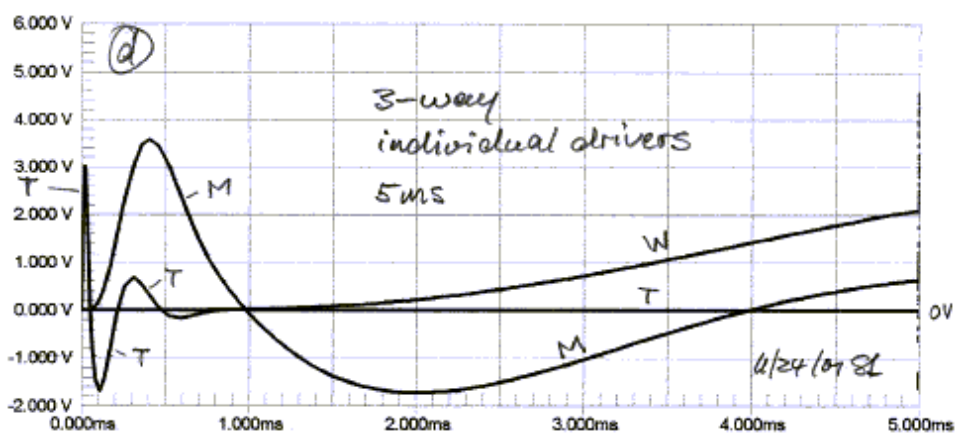
The step response of the full-range speaker FR is far from perfect, because the loudspeaker is a bandpass and in this view (b), over a 60 ms time window, the low frequency highpass dominates the shape of the curve. At time Tx the response crosses the zero axis. The positive area under the curve between zero and Tx equals the negative area between Tx and very large time, because a bandpass system cannot pass dc. Equivalently, a speaker cannot set up a permanent pressure increase, as would be required for perfect step response.



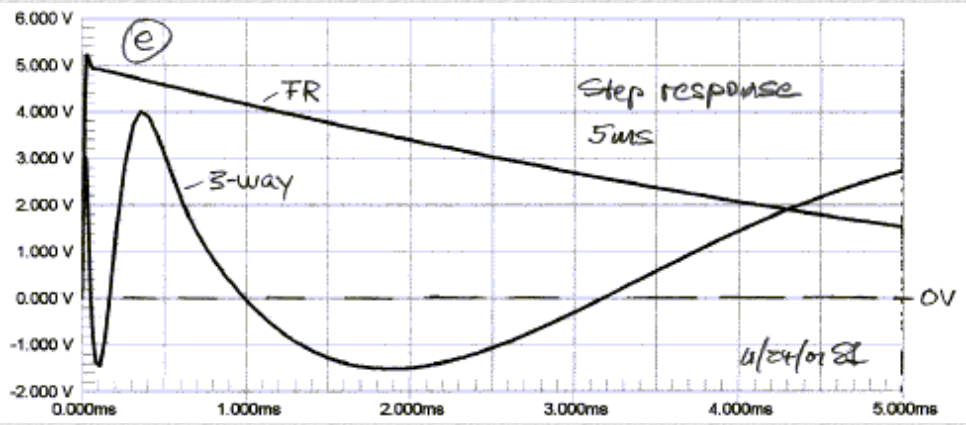
DSP based equalization can move Tx out in time, but how far is enough needs to be established. The aural integration time window is about 50 ms, before echoes are noted.

The step response of the 3-way looks even further removed from the ideal and it is easy to understand why people like to think this should be accompanied by audible defects. The response is the sum of woofer, midrange and tweeter outputs (c). The tweeter response, barely visible on the 60 ms time scale, really shows up in a display of the first 5 ms (d).



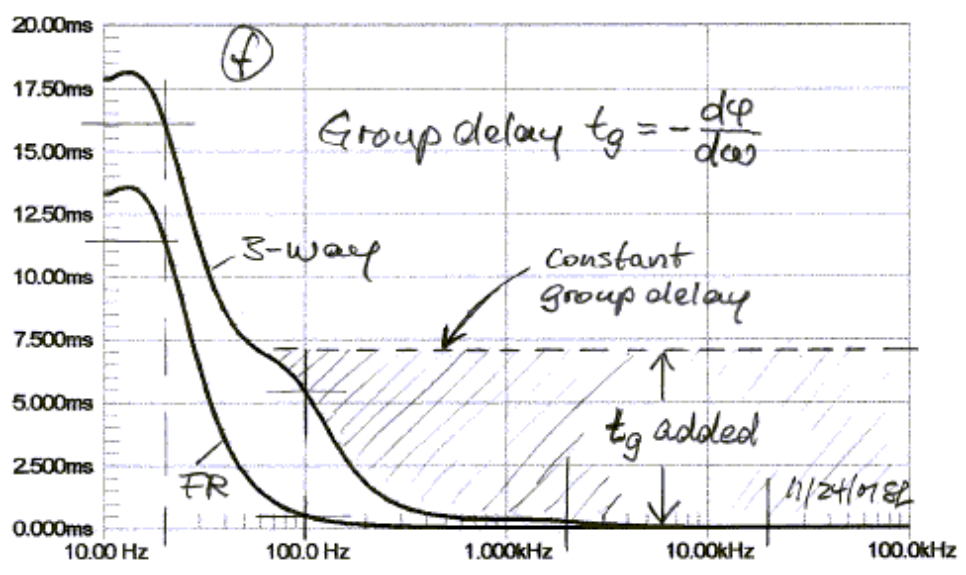


Note that the tweeter response has settled in 1 ms. The midrange has its second zero crossing at 4 ms. The woofer has barely started to move after 2 ms. A time window of 5 ms or less is frequently used in speaker reviews to comment about driver polarities and waveform preservation (e). This covers less than 10% of the transient response time for many speakers.



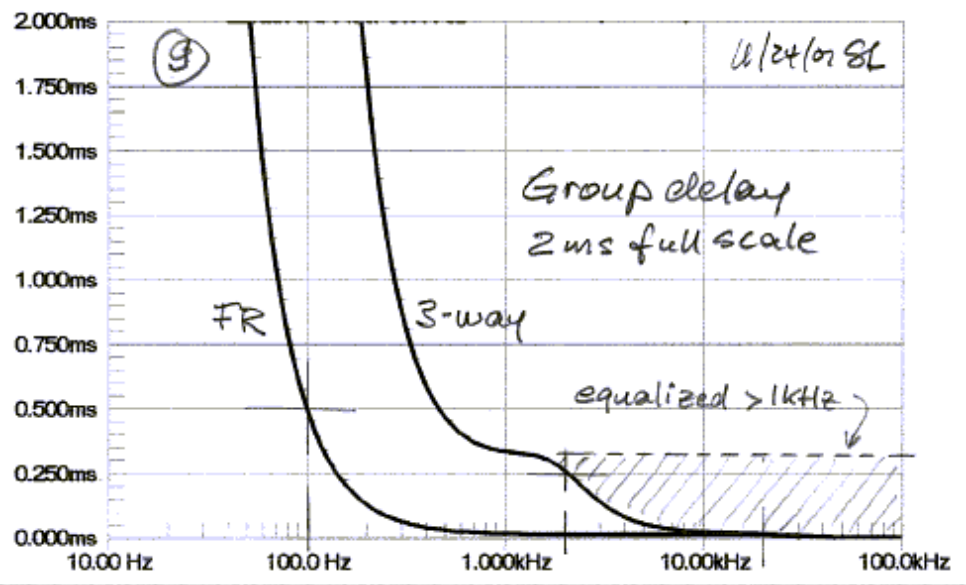
A recent audiophile magazine review of a 3-way speaker, with response similar to (e) above claimed: "... The step response indicates that the tweeter and midrange unit are connected with positive acoustic polarity (the sharp up/down spike at 0 ms and the lazier triangle 0.4 ms later), while the woofer is connected with negative polarity (the broad, negative-going hump centered between 1.5 and 2.5 ms). The actual drive-unit polarity doesn't matter except when it comes to waveform preservation -- and the jury is out on that subject."
More understanding of the subject matter is obviously needed.

The phase of a speaker's frequency response has to change linearly with frequency in order to preserve waveform fidelity. This is equivalent to saying, the group delay has to be constant (f).



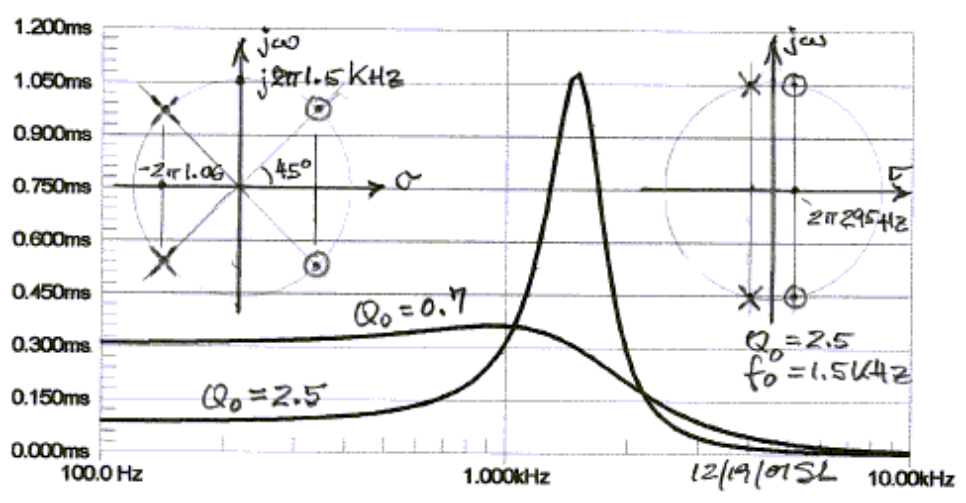
Group delay increases dramatically at low frequencies, even for the full-range speaker. To equalize the 3-way speaker down to 50 Hz a great amount of delay would have to be added to the higher frequency portion of the spectrum. This is practically impossible to accomplish with analog means and not completely trivial with DSP either.

If delay equalization is restricted to higher frequencies, where digital processing becomes easier because of shorter time record lengths, then large portions of the spectrum remain distorted (g). Such solution may improve the first few milliseconds of the step response, but it remains to be shown unambiguously that if this is audibly noticeable. It will enable fairly accurate reproduction of square-waves with frequencies above 1 kHz though.

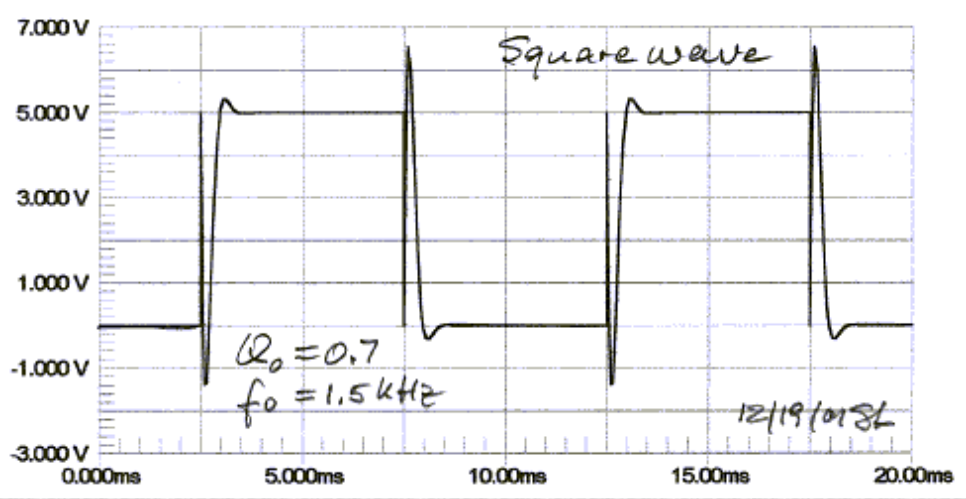


With similar effort a 2-way speaker could be delay equalized over a wider frequency range. A 2-way loudspeaker is either marginal in frequency coverage or in dynamic range and improvements in its transient response might be easily masked by other shortcomings. A full-range or single driver speaker is even more limited and not a contender, except in the form of headphones.

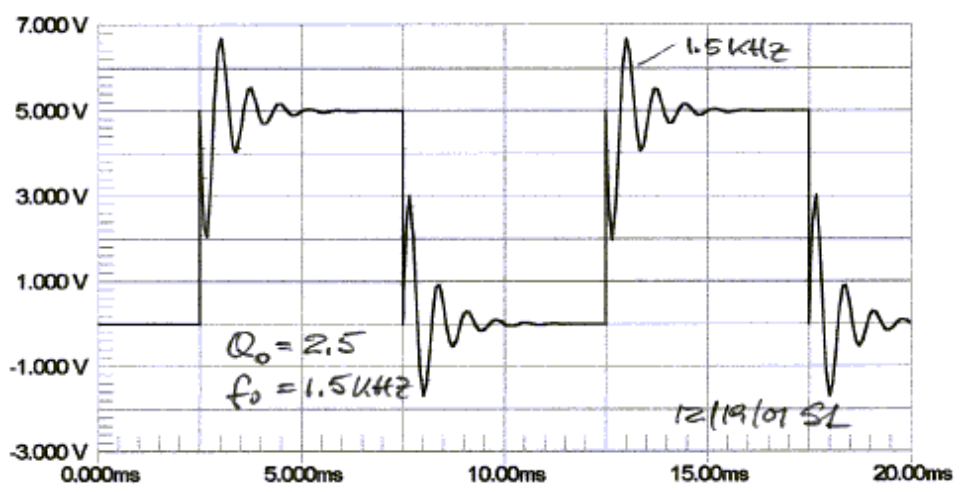
I have used headphones to convince myself that the phase distortion introduced by LR4 crossovers around 2 kHz and at 100 Hz are not audible. For example, a 1.5 kHz LR4 crossover with 24 dB/oct slopes forms a second order allpass filter with Q0 = 0.7 for its pole and zero locations.



Its non-linear phase shift and non-constant group delay in the crossover region cause waveform distortion which is not audible, though.



If the allpass Q0 is significantly higher, like Q0 = 2.5, then the phase distortion does become audible. In the case of the 100 Hz square-wave a high pitched sound is added. The frequency response, though, is completely flat.



I am not certain what happens in the range below 100 Hz and I have strong suspicions that this is the region where delay distortion is audible. It is also the region where delay really accumulates via vented and bandpass woofers, and the great numbers of dc blocking capacitors in the signal chain from microphone to speaker terminal.

Further experiments might be performed with a high quality 3-way speaker system, whose phase response or group delay have been carefully measured or modeled. Knowing the phase distortion, which the speaker will introduce, use digital signal processing with the appropriate software to pre-distort various music files on a PC, such that the overall playback phase response will be linearized. Burn the newly created files to CD-R. For comparison take the same music files and add a constant delay to them, so that pre-distorted and un-distorted material have undergone the same process and any artifacts are common to both. In this way one could switch directly between nearly identical tracks of a CD-R and listen for differences that can only be the result of phase response differences.

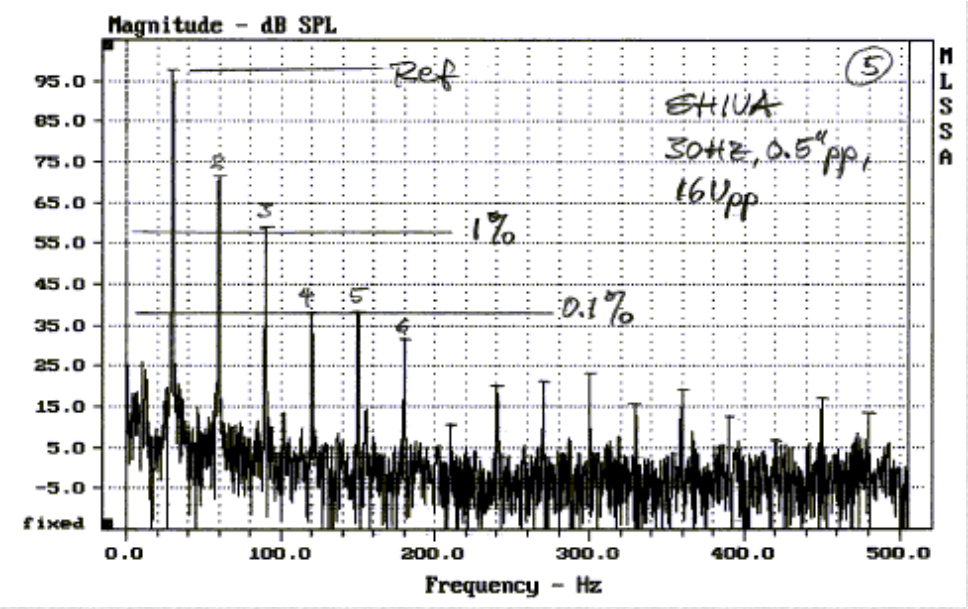
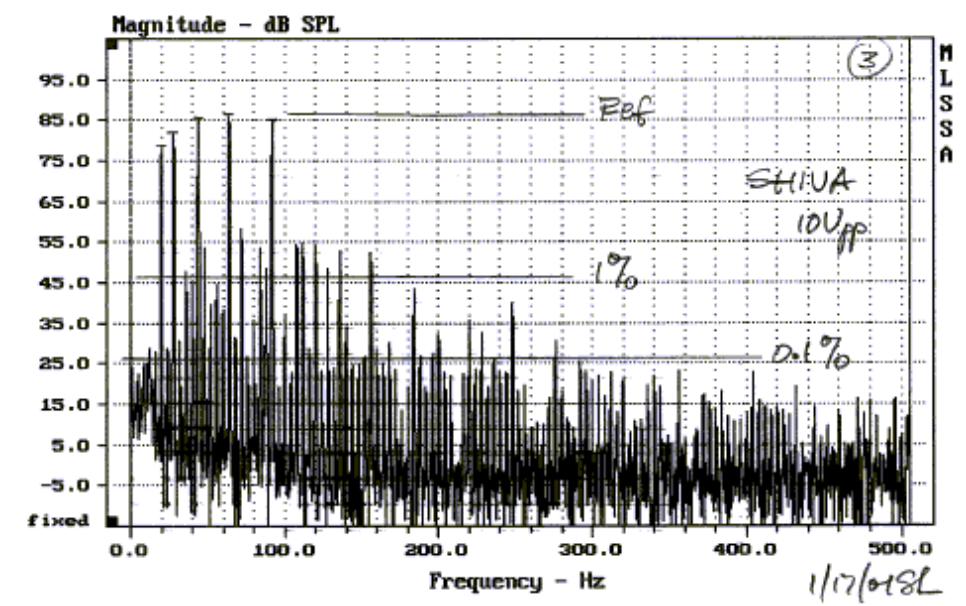
G - Multitone distortion

The measurement of harmonic distortion gives an incomplete description of the non-linear behavior of a loudspeaker, even when the exciting sinewave is swept to generate a continuous display of distortion products. Still, it is very useful data for comparing devices.

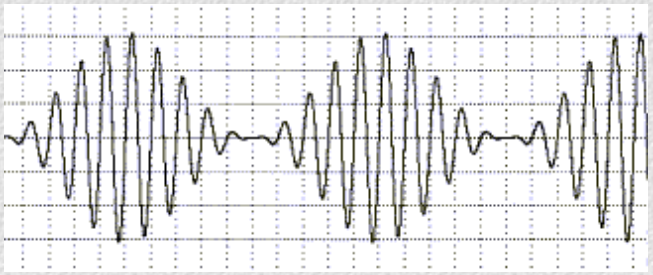


More information is obtained when two tones are used, because now also the various sum and difference products of the two stimuli and their harmonics can be measured with a spectrum analyzer. These intermodulation products are usually higher in amplitude than the related harmonic distortion products. I cannot emphasize enough, that anytime when a device introduces harmonic distortion, it will generate intermodulation distortion, when more than one tone is involved. Some seem to think that a little bit of 2nd harmonic distortion, as often generated by tube equipment, has a pleasing effect, because it enriches the natural even harmonics of acoustic instruments. It will also generate non-harmonic intermodulation, and has little to do with accurate sound reproduction or even generating the illusion of a real sound. Instead it imparts a euphonic sameness to all sounds.

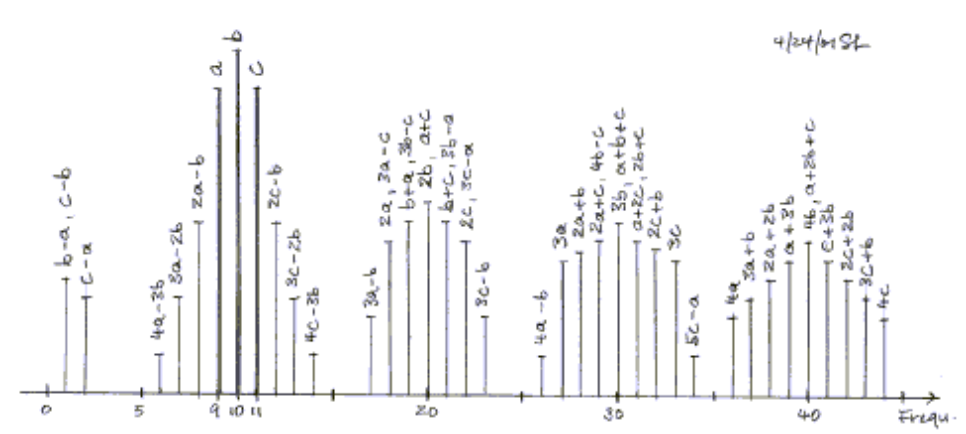
Real sounds contain many tones. A woofer might be tested with a set of 5 tones that are not harmonically related, such as 20, 28, 44, 64, and 92 Hz, but which cover the woofer's intended operating range. Each of the tones is a multiple of 4 Hz, with factors 5, 7, 11, 16, 23, and the resulting distortion products will occur at 4 Hz intervals.



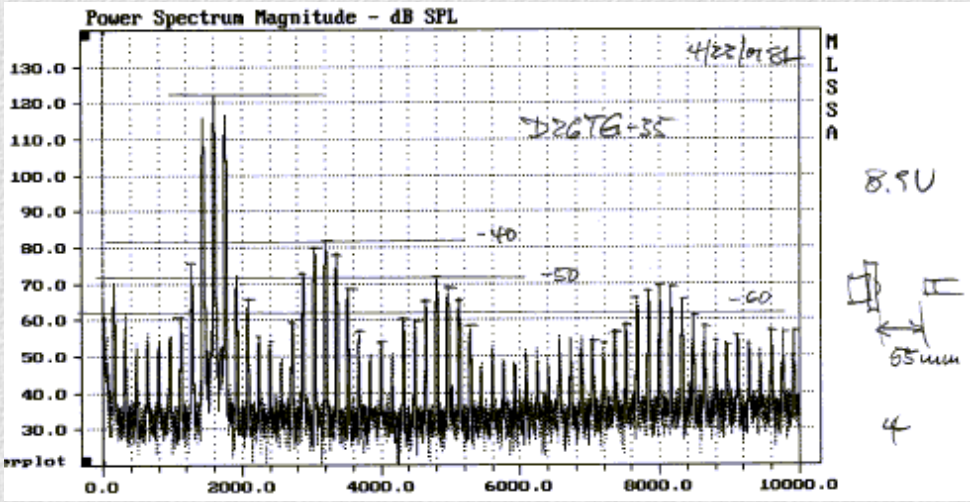
The richer distortion spectrum makes comparison between devices easier than relying on the few data points that harmonic distortion provides. The time waveform for the sum of the 5 tones looks very erratic but is, of course, periodic. A very simple looking, but highly effective test signal is a sinewave that is 100% amplitude modulated at 1/10th its frequency. This type of stimulus is especially useful for stressing vibrating systems and audibly detecting the onset of distortion as its amplitude is increased. To avoid permanent damage only bursts of this signal should be used.



The undistorted spectrum consists of the carrier b and two sidebands a, c, which are 6 dB down and offset by b/10. The potential distortion spectrum contains harmonic and intermodulation products. A few of those are shown below. They occur at intervals b/10.



The close-up measurement of a tweeter reveals the dense sound spectrum generated by the cluster of 3 tones at 1.6 kHz.



I have found these and other types of multitone test signals useful for sorting and relative ranking of drivers. Their subjective evaluation when part of a complete speaker correlates closely with the measurements. It should be understood that distortion has audible effects long before it is perceived as distortion. For example, it might enhance sonic detail, analogous to contrast enhancement in a photo.

I think a recent experience while attending a San Francisco Symphony performance gave me further insight into why we are able to tell a loudspeaker from a live instrument. Loudspeakers reproduced pre-recorded material, interspersed with the musicians' playing, during the performance of several modern pieces of music. It seemed, that coming out of the loudspeaker a sound carried a comet like trail of newly created sounds with it, that formed a continuum of background sounds, which was completely absent from the live instruments and made the speaker immediately recognizable as such. Live instruments had a space between tones, like a black background, and even en mass always remained articulate. I believe the observation had nothing to do with recorded ambience, which was present occasionally, or with hall reverberance. It reminded me of other incidences, where I had easily recognized live instruments, though there was no reflection free path between the source and my ears, and where I then struggled to describe to myself what would have been different, if a loudspeaker was playing instead. It seems to me that the ongoing-ness of sound is one of the major problems with speakers. It shows less with recordings of a

single voice with small accompaniment, so often favored by audiophiles, but in complex passages of classical orchestral music and choral works.

Much work remains to be done before firm predictions of sound character can be made from distortion measurements. Wolfgang Klippel has developed a practical methodology for characterizing and auralizing the effects of various distortion parameters in woofers at large excursions. Researchers at Cerwin Vega have done extensive theoretical work [1]. They concluded amongst other things: "... With an increase in the number of tones, the multitone provides increasingly detailed information about the nonlinear behavior of a DUT. An ultimate increase in the number of tones leads to a noise-like signal that may hypothetically provide complete information about a nonlinearity-impaired DUT, but demands an enormous amount of calculation, if a high-order nonlinearity is to be assessed."

H - Suggestions and hearing

It is common practice in promoting audio products to tell a customer what to pay attention to in what he is going to hear, then to follow that with a demonstration, and afterwards to tell him again what he heard. It is the same process, whether it is a manufacturer's representative speaking with a store sales person, or the sales person talking to a prospective buyer. It is almost impossible for the target person not to hear, what has been suggested they will hear.

The power of suggestion has been used to perform major surgery without anesthesia, where the patient experiences no pain. It has been shown with CAT scans of the brain that in such cases an information disconnect occurs between the region that responds to pain, and the region of the brain that gives the patient the perception of pain. Thus, the normal perception process has been altered through the verbal, non-physical preparation that the patient received beforehand.

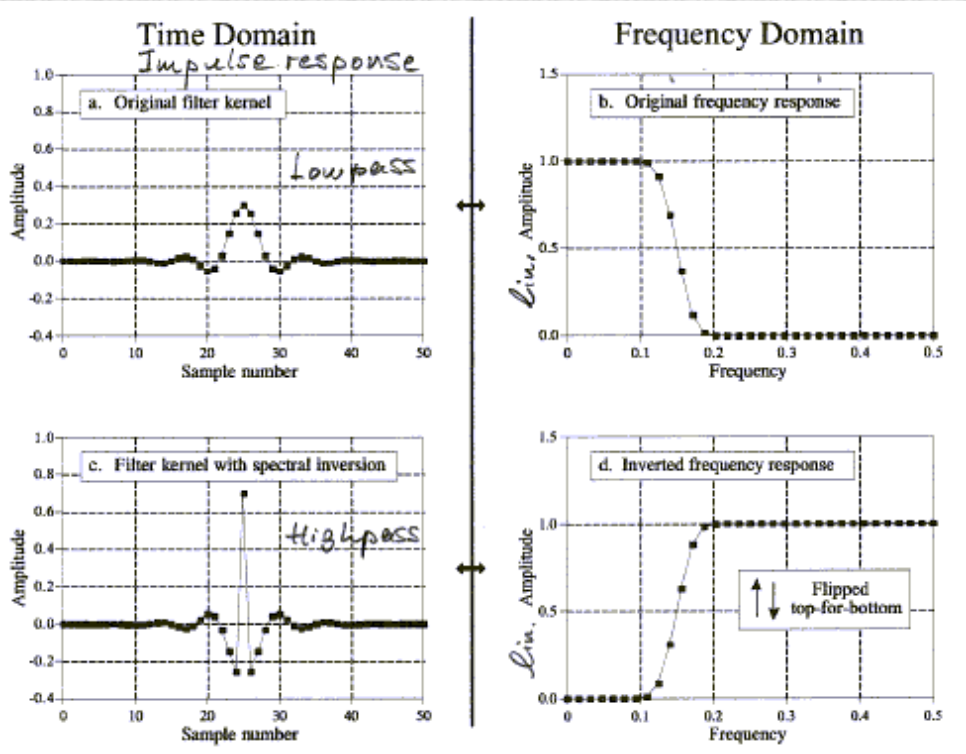
The influence of suggestion, especially when frequently repeated, should not be underestimated in the field of hearing. Many listeners have not acquired an auditory reference that is based on un-amplified sounds and are thus easily misled in matters of accuracy. Double-blind and ABX product comparison tests are frowned upon in some audio circles, though they remove any influence of suggestion, self or other generated.

I have no problem, if people enjoy their music more, because it has passed through a certain interconnect, has been transformer balanced, amplified without feedback, processed through a reissued WW2 transmitter tube and sent to their speakers on litz wires of specific arrangement and purity, except that the money for these suggestions could have been spent on better speakers, for real improvements in accuracy of dynamic range and resolution. After all, the loudspeakers are by far the weakest link in the chain of components that are needed for sound reproduction.
Top

I - Digital crossovers

Some people think that digital crossovers will replace analog ones, because digital filters can be designed with desirable characteristics that are impossible to realize with analog circuitry. In particular, lowpass and highpass filters with extremely steep slopes and linear phase shift are possible. Steep slopes reduce the overlap region between drivers. Linear phase shift eliminates waveform distortion and merely causes a delay of the signal. Such characteristics can be obtained from the digital equivalent of tapped delay line filters, which have a finite impulse response (FIR) duration that depends upon the number of taps used. Digital FIR filters can have almost any desired frequency response, if the number of weighted taps is made sufficiently high. [1]

The linear phase shift comes at a price. The impulse response rings. The more so, the steeper the filter slopes. Both lowpass and highpass sections of the crossover ring, but when the outputs are combined, as for a crossover, then the two impulse responses add to a non-ringing, delayed pulse.



All would be fine, if we listened only in anechoic spaces or to speakers with coincident drivers. In reality we use speakers in rooms with reflections and reverberation and the the drivers are separated from each other due to their sizes. As a consequence the off-axis response of the speaker matters and contributes to what we hear. With the drivers non-coincident, the lowpass and highpass outputs are delayed different amounts at points off-axis, and the ringing is no longer canceled in the addition. In the best case the drivers might be coaxial, but this has another set of problems. Very steep crossovers can also cause a very abrupt change in the polar pattern of the speaker, when transitioning from a large diameter driver to a small one. Under reverberant conditions and/or listening off-axis this may have audible consequences.

A different type of digital filter has an infinite impulse response (IIR), from using recursive or feedback topologies. IIR filters can closely simulate all the known analog filter functions, but also have their associated non-linear phase shifts. The frequency response of a given IIR

filter, such as a biquad, can be easily changed by reprogramming its coefficients. They are readily adapted to different needs.

Digital filters have high accuracy and are very repeatable. They require high performance ADC, DAC and DSP. Analog anti-aliasing and reconstruction filters are part of their design. Dynamic range, clipping and noise must be dealt with in the digital domain of numbers. In particular, the effects of numeric round-off upon filter shapes and distortion must be analyzed. For reasons of limited linear digital range the volume control must be located after the DSP to maximize bit resolution. Non-linear distortion in all its forms between input and analog output has to be considered and minimized. Loudspeaker drivers have their own inherent acoustic highpass amplitude and phase response, which must be accounted for in the digital crossover filter design. Electromagnetic compatibility (EMC) should be designed in and tested for.

Top

J - Doppler distortion

Drivers are now available that generate very low intermodulation distortion, because their motor behavior is very linear. This may bring Doppler distortion to the foreground under certain conditions. Doppler distortion occurs when two tones of largely different frequency are radiated from the same membrane. It is a linear form of distortion, at least to the first order, which means its magnitude is independent of the amplitude of the higher frequency tone and distortion increases linearly with the amplitude of the lower frequency tone..

For example, a 18 cm (6.5 inch) driver with 126 cm^2 cone area like the Seas W18E001 may radiate a 50 Hz low frequency tone at 5 mm peak excursion, which produces 86 dB SPL at 1 m. The sinusoidal cone displacement has a peak velocity of:

$$V_p = 2 \pi f_L X_p = 1.57 \text{ m/s}$$

A 2000 Hz tone which is radiated simultaneously will have its wavelength shortened and lengthened at a 50 Hz rate as the cone velocity is added to and subtracted from the speed of the sound's propagation (c = 343 m/s). Based on a relatively simple analysis this results in a frequency modulation of the 2000 Hz tone with a peak deviation of:

$$\Delta f_H = 2 \pi f_L f_H X_p / c = 9.2 \text{ Hz}$$

The modulation distortion can be reduced to 5.5 Hz for the same 50 Hz SPL by using a W22EX001 driver with 220 cm^2 cone area.

The audibility of Doppler distortion depends upon three criteria:

1. the FM threshold of hearing,
2. masking by the low frequency tone,
3. FM to AM conversion due to room resonance.

The FM threshold is typically determined at a low modulation rate of 4 Hz and is about 0.35% for frequencies above 500 Hz, corresponding to 7 Hz deviation at 2000 Hz. Higher modulation rates around 70 Hz may be perceived as roughness of the tone.
Masking is dependent upon the relative levels and frequency separation of the two tones.

A room with a reverberation time T_{60} = 500 ms has resonances with a 3 dB bandwidth of BW = 2.2 / T_{60} = 4.4 Hz. The slope of the filter curves is about 3 dB per BW/2 or 1.4 dB/Hz. Thus, a 9.2 Hz deviation of the 2000 Hz tone could generate up to 12.9 dB change in its amplitude, if the rate was slow enough so that the sidebands of the FM signal are not significantly attenuated by the filter.

Doppler distortion of a driver can be measured with a spectrum analyzer by observing the amplitude of the frequency or phase modulation sidebands A_s relative to the carrier A_H. The relative amplitude for the first pair of sidebands is approximately

$$A_s / A_H = 0.5 \Delta f_H / f_L = \pi f_H X_p / c = 0.09$$

or 20.7 dB below the 2000 Hz carrier A_H, regardless of f_L as long as X_p = 5 mm. This corresponds to a phase modulation with a maximum phase deviation of $2 A_s / A_H = 2 \times 0.09$ rad = 0.18 x 180 / π = 10.3 degree.

The sidebands occur at the same frequencies $f_H - f_L$ and $f_H + f_L$ as the 2nd order intermodulation products of the two tones. They can be differentiated by changing the applied signal levels. Doppler sidebands decrease 3 dB for a 3 dB reduction in signal levels, whereas 2nd order intermodulation sidebands decrease 6 dB. The two sidebands may be of different amplitude when both forms of distortion are present, because the intermodulation products are in-phase with each other, the FM sidebands are out-of-phase. This fact allows a decomposition of unequal sidebands into their two constituent odd and even parts.

I have experimentally verified the results of the above analysis by measuring the relative amplitude of the sidebands in the frequency spectrum. The Doppler effect is very difficult to measure in the time domain, though, because of the small amount of phase shift (e.g. 10.3 degree) that it causes for the higher frequency tone. Rod Elliott claims to have been able to measure the shift in the time waveform. An analysis of his observation confirms that the maximum phase shift occurs when the cone is at its maximum excursion, where its velocity is zero. The Doppler analysis usually mentions only the maximum frequency shift, which occurs when the cone has its highest velocity, or when going through zero excursion for a sinusoidal low frequency tone. Both results are correct and are a consequence of the fact that the radian frequency ω = d(phase) / dt . This leads to a 90 degree phase shift between time varying frequency and phase for a sinusoidal signal. Either way of looking at the situation results in identical magnitudes of the spectral components. It all is the Doppler effect, though I have not seen the associated phase modulation pointed out in text books.

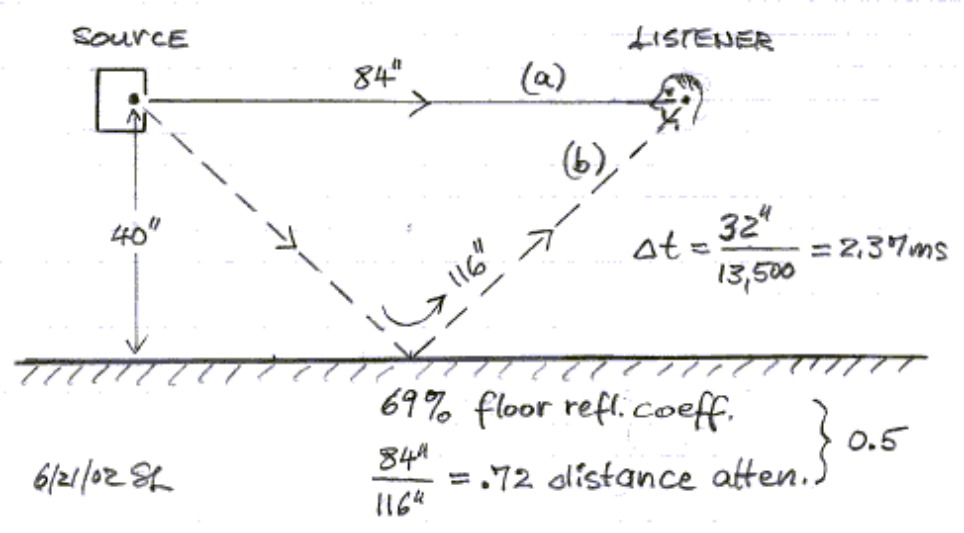
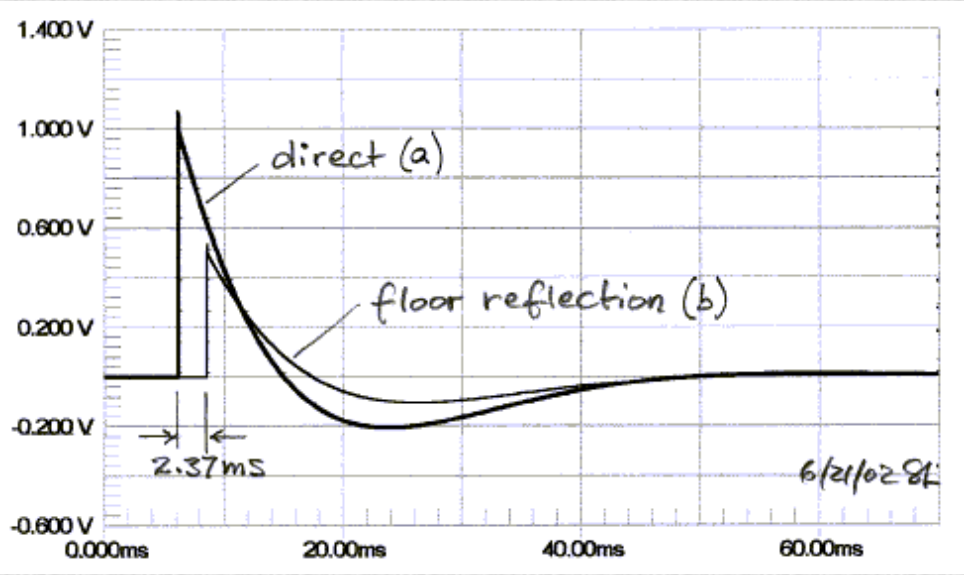
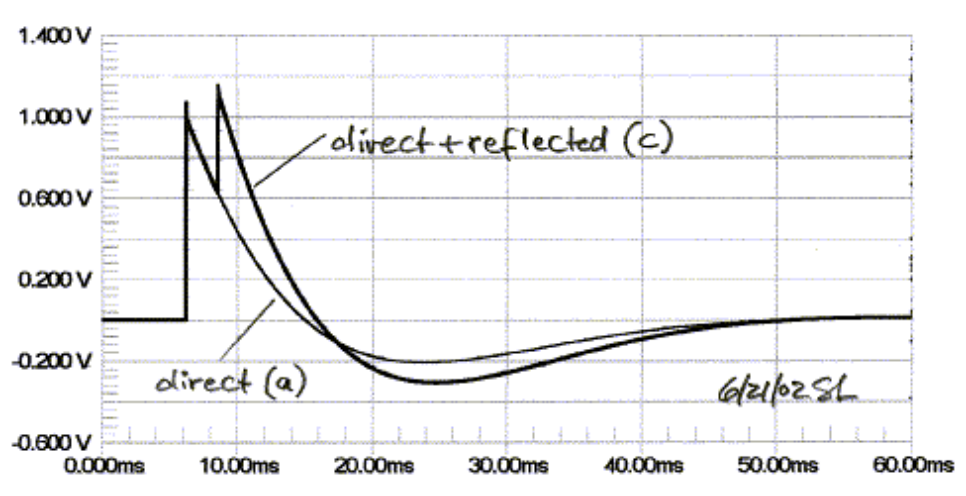
K - Room response equalization

In theory, digital signal processing allows to remove completely the effect of the room upon the frequency response of a loudspeaker at the listening position, but only over a very small region in space. The principle is illustrated by correcting the output signal from a loudspeaker in order to cancel the effect of the inevitable floor reflection upon the response at the listener's place.

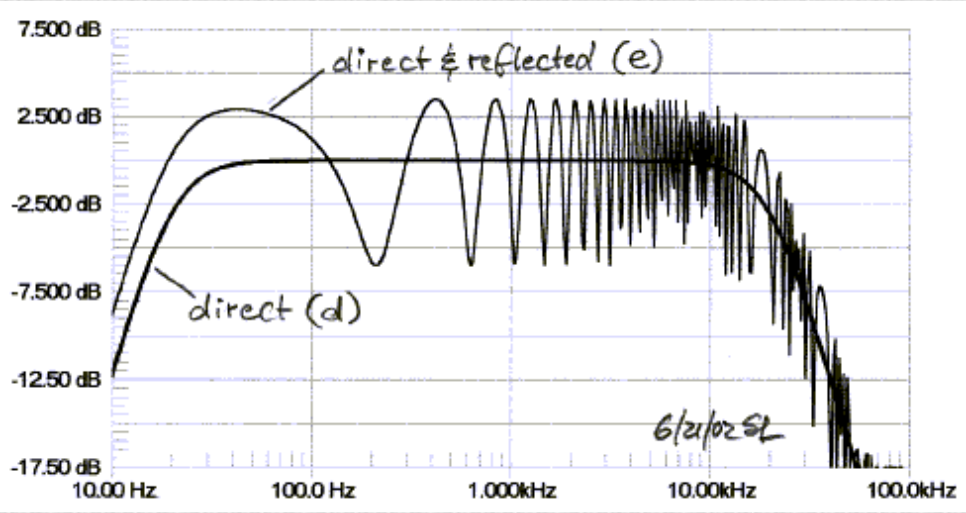


The model assumes a speaker with 20 Hz to 20 kHz response. The floor is not perfectly reflecting and together with the attenuation, due to a 32" (0.81 m) longer path length for the reflected signal (b) than the direct signal (a), the amplitude of the reflected signal at the listener will be half that of the direct signal. The floor reflection is delayed by 2.37 ms. The step response at the listener position is the sum of direct and reflected signals (c).

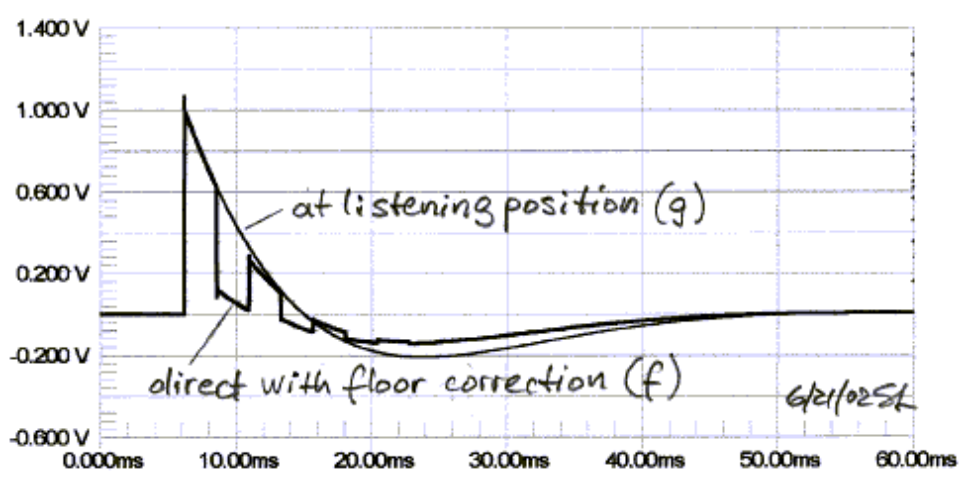




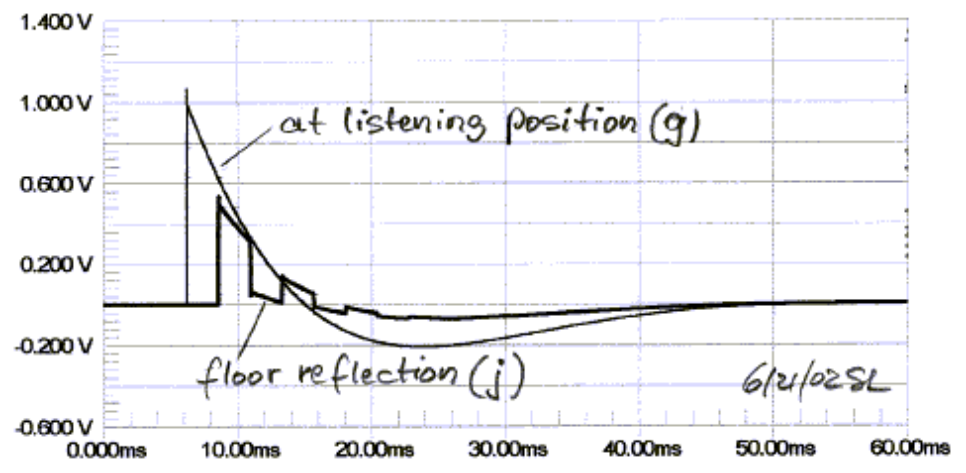
The frequency response at the listener position shows the typical comb filter behavior (e). At low frequencies the floor reflection adds to the direct sound (d). The first minimum in the response occurs when the 32" path length difference corresponds to 1/2 wavelength and causes 180 degrees of phase shift, which is at 211 Hz. The next peak is at 422 Hz, followed by a minimum at 633 Hz, and so on. The response is non-minimum phase and can be corrected with a minimum phase parametric equalizer to some degree, but only at the very low frequencies.



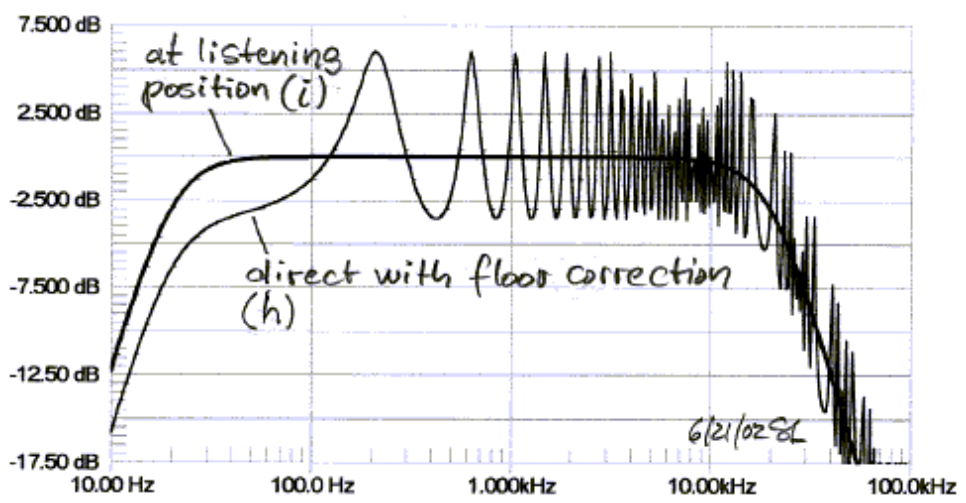
The effect of the floor reflection can be cancelled by pre-distorting the direct signal from the speaker. After 2.37 ms from the start the direct signal has to have a negative step to cancel the first reflected signal which arrives at the listener. The negative step in turn causes a floor reflection which must be cancelled by a positive step 4.74 ms later, and so on. Since the floor reflection is attenuated, consecutive correction steps will decrease in amplitude (f).



Direct (f) and reflected (j) signals combine at the listener position for a perfect step response (g), identical to the anechoic response (a).



The frequency response of the pre-distorted direct signal (h) may have large peaks to correct for the notches in the room response (e).



It should be obvious that this form of room correction is a delicate balancing act, particularly to maintain equalization at higher frequencies. Small deviations in listener position from the point for which the speaker was equalized, cause large changes in room response. In real rooms there is not only the floor reflection, but all the many other reflections from walls, ceiling, furniture, etc. that enter the correction of the speaker. Since the correction can at best be valid only for a single sweet spot, it will necessarily send a distorted signal to every place else. Even at the sweet spot the system performance does not degrade gracefully, when the correction is less than perfect. Gross spectral distortion is introduced at higher frequencies and may become aurally distractive.

Room equalization with DSP will require a new understanding of what should be corrected, and what should be left alone, to meet a specific overall objective for sound reproduction. For example, the comb filter response due to floor reflection is intimately familiar to us, since most sounds we hear, have at least a floor reflection. As we grew up and became taller the comb spectrum shifted towards lower frequencies. How do we use the information conveyed by it? How important is it to correct for it in a speaker setup? The issue with room equalization is not about sufficient computing horse power, but how and where to apply it.

The following two references are highly recommended reading before embarking on any digital room equalization project.

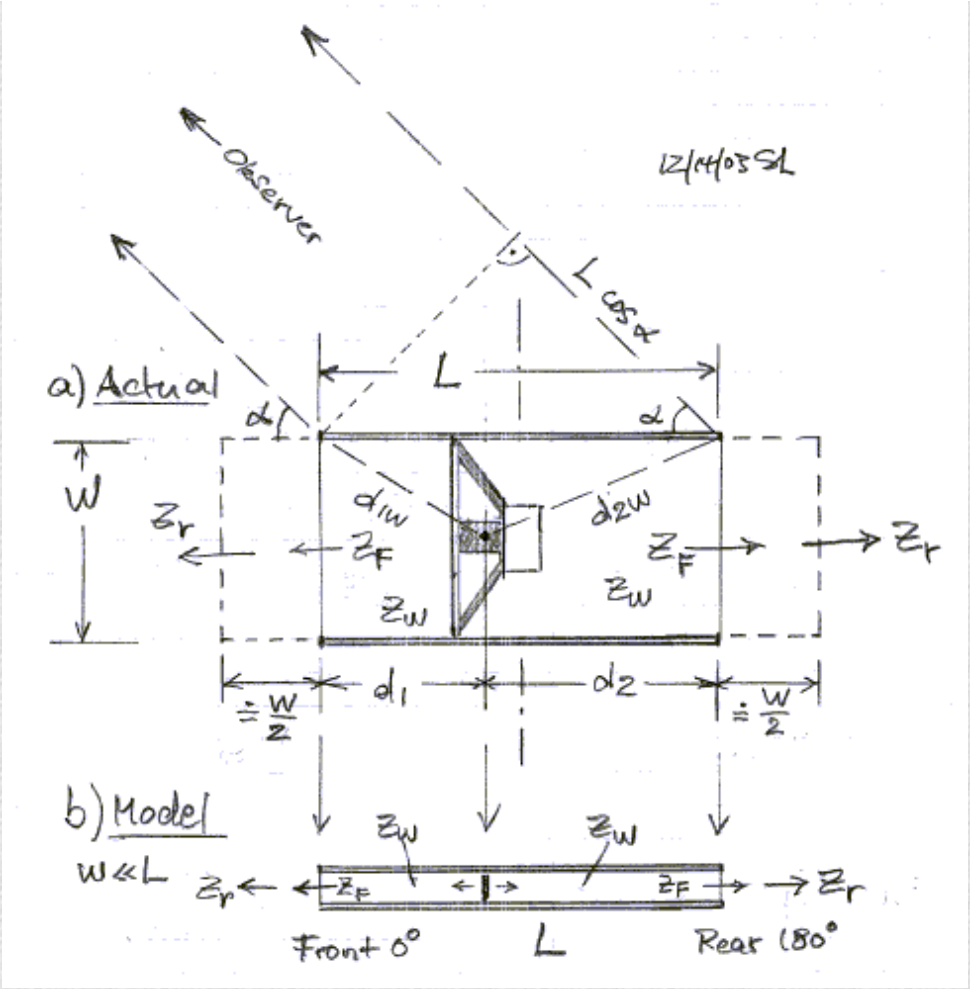
L - H-frame and U-frame open-baffle woofers

The analysis of a H-frame dipole woofer is rather simple due to the symmetry of the mechanical structure combined with the fact that front and rear acoustic outputs are of reversed polarity. The influence of a number of important parameters upon the radiated field can be ignored, since their effect is equal in magnitude on both sides of the baffle and cancels because of the 180 degree phase difference. The analysis becomes more complicated when the frame is no longer symmetrical and the driver is moved closer to one of the openings of the frame.

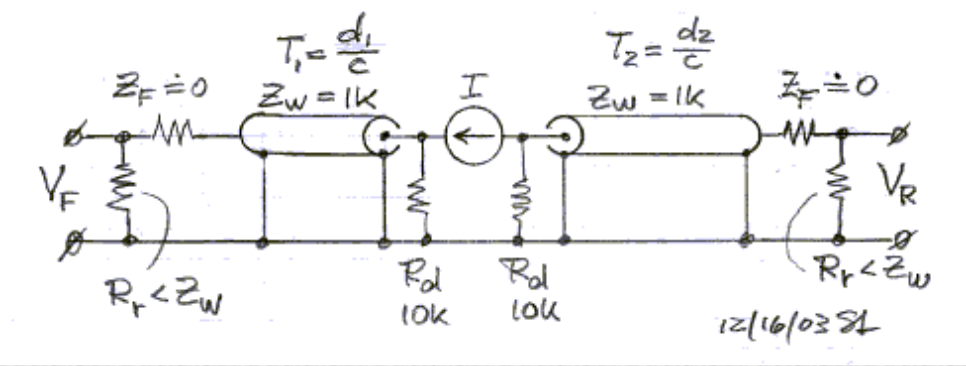


The baffle structure has a physical length L = d1 + d2 and width and height W. The acoustic length is larger by about W/2 on each end, similar to the end correction of the vent of a Helmholtz resonator. For determining the polar pattern I will assume the case where W << L, and work only with the physical length L. Any calculated 1/4 wavelength resonance frequency will be higher than in actuality, but that does not invalidate the relative performance at different driver positions d1. The observation point is far enough away so that the outputs from front and rear are seen at the same angle α. The two propagation paths then differ in length by Lcos(α).
I assume that the driver is operated in its mass controlled region and acts as a volume source or like an electrical current generator. Using an actual driver model would complicate the analysis and only be beneficial if we needed to know absolute numbers. I will also assume that the source is fully symmetrical, as would be the case with two drivers having their magnets pointed in opposite directions. A single driver would introduce additional phase shift on its backside due to the acoustic elements associated with the cavities around the basket and magnet structure.

Looking from the driver cone towards the rear of the baffle the displaced volume propagates through a waveguide of acoustic impedance Z_W.

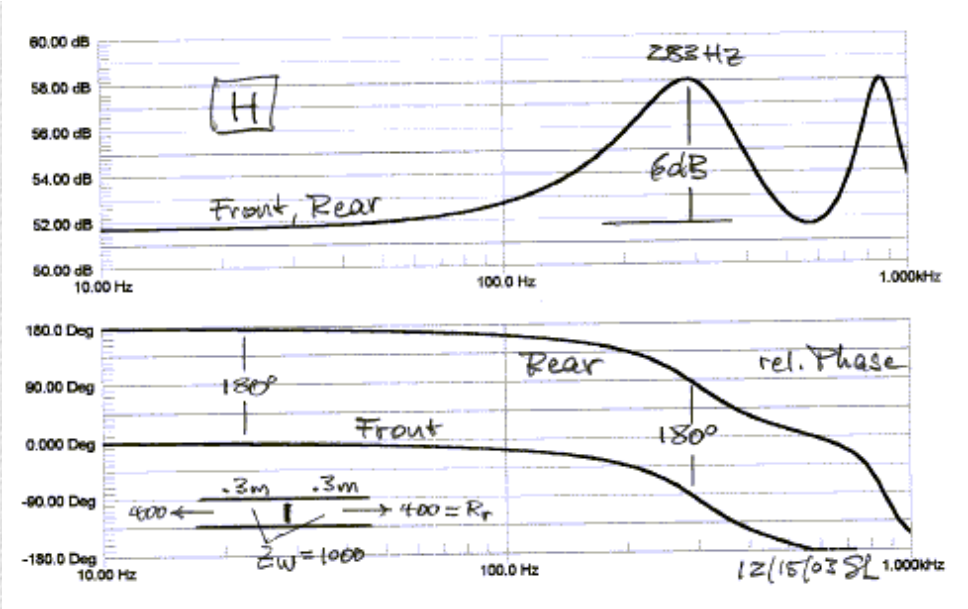
If the waveguide were closed off at its end by a wall, then the volume flow would come to a stop as it reaches the wall and be reflected back to the source. The wall can be described by an infinite flow impedance Z_F. When the the waveguide is open ended the corresponding flow

impedance Z_F is nearly zero. In reality, Z_F is an acoustic mass or, electrically, an inductive element. A small percentage of the flow is reflected back from the opening towards the source. When the wave hits the cone it is reflected back towards the opening, where again a small fraction of it bounces back to the cone. This back and forth travel sets up a resonance at the frequency where d2 equals a quarter wavelength. The major percentage of the volume flow exits the opening and expands into the larger free space. Consequently, its pressure drops relative to what it was inside the waveguide. This can be described by an impedance Z_r which is less than Z_w. The impedance mismatch exists at all frequencies. The pressure developed across the real part R_r of this radiation impedance Z_r is the quantity of interest.

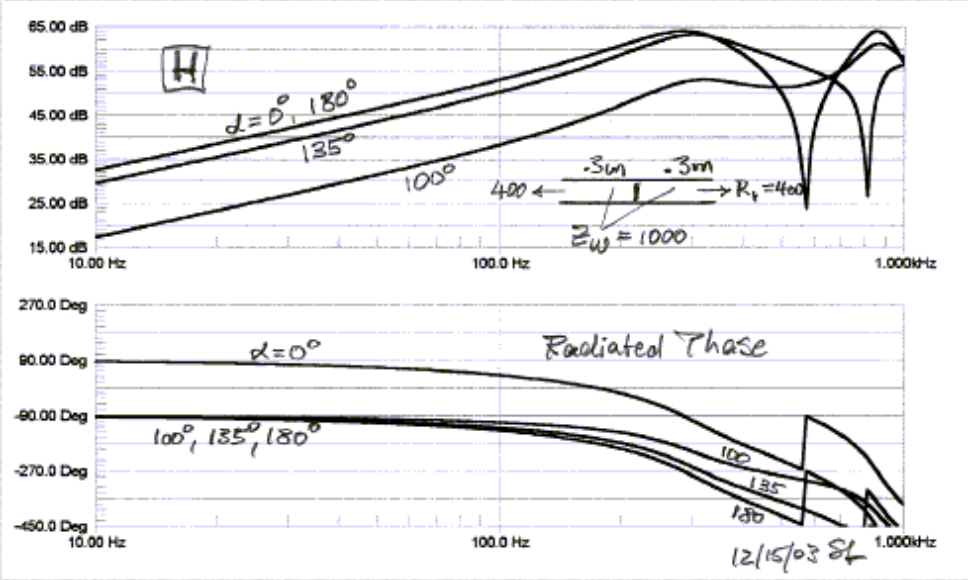


The circuit above describes the acoustic behavior in electrical terms. The two loss-less transmission lines are specified by their impedance Z_w and propagation delay T as function of their length d. The current generator has a finite impedance $R_d >> Z_w$. The flow impedance Z_F is assumed to be zero for the moment. The voltages V_F and V_R across the radiation resistors R_r are summed vectorially using the path length difference L cos(α) to determine the phase shift between front and rear outputs. The summed signal is proportional to the SPL at observation angle α.

It is important to work with representative values of R_r in the electrical model. Assuming R_r = 400 and Z_w = 1000 leads to a 1/4 wave resonance peak of about 6 dB. This is in the range of peak magnitudes that I have measured in the opening plane of H-frame woofers. All modeling is done for L = 0.6 m (24"), thus for the symmetrical H-frame the resonance occurs at 340m/s / (4 x 0.3m) = 283 Hz. The graph below shows magnitude and phase of front and rear radiation.

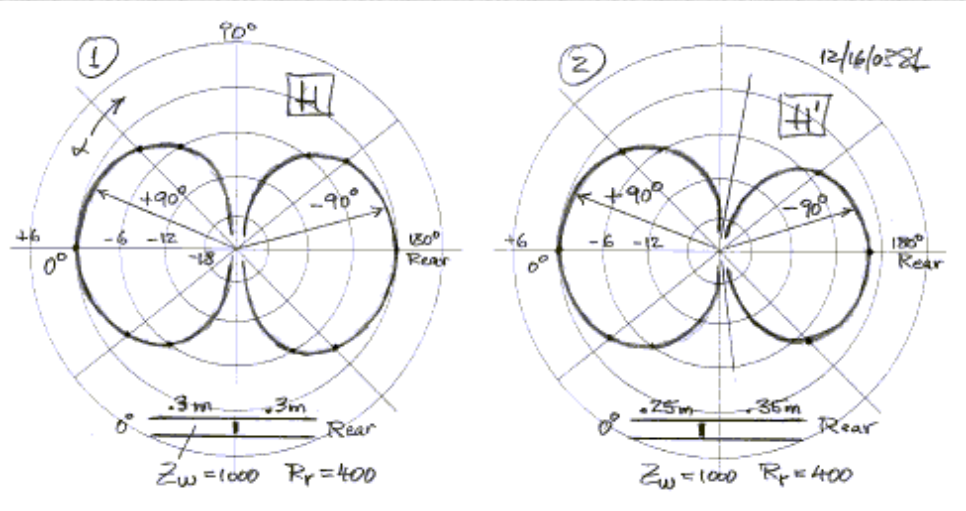


The frequency response at different observation angles α is obtained by adding the front and rear outputs vectorially. The analysis was carried out using CircuitMaker which is a SPICE program. Notice the slight amount of peaking near the resonance. The outputs sum to zero at 90 degrees. This would be off the graph. Instead, the 100 degree response is shown.

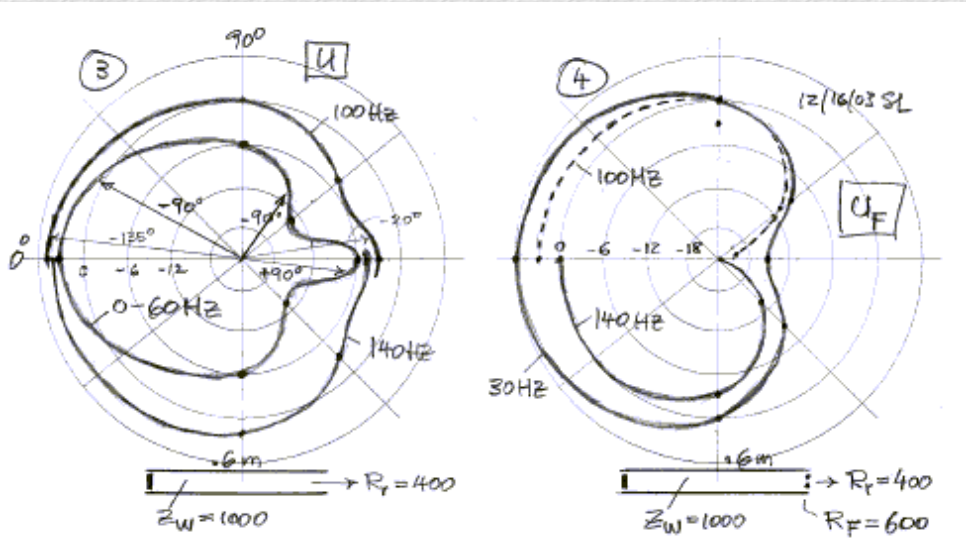


The polar plot (1) below is drawn on a dB scale with 6 dB increments between circles. Note that the phase of the acoustic wave to the left of α = 90 degrees is at +90 degrees, to the right at -90 degrees relative to the volume source excitation.
When the source is shifted slightly towards the front of the H-frame, then the null occurs at an angle α that is greater than 90 degrees. Also,

the rear lobe decreases slightly in magnitude (2).



This trend continues and leads to the polar pattern (3) where the driver has been fully moved to the front of the waveguide. It is the U-frame configuration. The magnitude of the polar response has increased over that of the H-frame in the left half of the polar graph. On-axis and below 60 Hz by 3.4 dB, and at 90 degrees there is no longer any null. The right half of the graph takes on different shape that are quite frequency dependent. There is no null, but there is a small region where the phase of radiation is +90 degrees as compared to -90 degrees for the major portion of direction angles α.



The shape of the polar pattern is strongly influenced by the impedance that the wave sees at the rear opening. By inserting a flow resistor R_F = 600, so that the waveguide is terminated reflection free, the response begins to look more like a cardioid. The on-axis response is 6 dB higher than that of the H-frame of same length L.

A cardioid polar response is obtained by the summation of a monopole response with magnitude 0.5 in all directions of radiation, M = 0.5, and a dipole with magnitude 0.5 on-axis, D = 0.5 cos(α), such that C = 0.5 + 0.5 cos(α) . A monopole, such as a closed box woofer, is a pure pressure source. A dipole, like a H-frame woofer, is a pure velocity source. A cardioid or U-frame woofer would exhibit characteristics of both monopole and dipole. It is not clear what the room acoustic benefits might be. Unlike the H-frame with its 90 degree nulls, these types of mixed radiators can excite room modes at ALL angles. Even the null towards the rear of a pure cardioid woofer does not prevent the excitation of the room mode along the 0 degree to 180 degree axis.

I have heard a rock band that used big Meyer Sound cardioid woofers in a very open setting. Walking around the stage there was a clearly audible reduction of low frequencies in the back. More slam for the audience, less for the neighborhood.
In a normal living room there could be an application for a cardioid above 1 kHz to reduce reflections from objects behind the speaker, if that were an issue.
It's a different story for microphones where the cardioid pattern can provide a clear benefit by reducing unwanted sound pickup.

If you have any interested in further analysis of the U-frame woofer, then go to Appendix L .

Doppler shifts in loudspeaker. Fact or fiction?

Updated Novermber 24, 2004

The document below presents a brief analysis of wave form distortion in loudspeaker dynamic drivers when reproducing both a single tone as well as 2 arbitrary tones such that the different frequencies are related as Fh = n Fl, where n is any number greater than 1.0. The single tone analysis shows that when a driver is subject to a single sine wave input, the acoustic output will under go a distortion of the wave form. The level of this distortion is dependent on the driver displacement. In the two tone case, it is shown that in addition to the wave form distortion present for a single tone, there is also a frequency shift in the higher frequency. The amount of frequency shift is primarily dependent on the excursion of the driver associated with the lower of the 2 frequencies, and completely independent of the excursion related to the higher frequency. If the frequency shift is give by df, then it is shown that the higher frequency tone oscillates about the input frequency Fh as F = Fh + df sin(2*Pi*Fl*T). It is also shown that the magnitude of df asymptotes to a limiting value as the ratio of the frequencies, n, gets large. The frequency shift is shown to result in the creation of intermodulation sidebands, thus rsulting in IM distortion of the input signal. The document is in MS Word format in compressed zip form, about 73k and down loads quickly.

On the next page I present experimental data supporting the results predicted by the analysis.

(Written Feb. 2001)

As of Noverber 24, 2004 I have added a second paper where I revisit wave form distortion arising from Doppler effects. This new paper, which parallels the analysis below, is much simpler and easier to follow than the previous paper and yields similar results. This new paper is available for download at the link below. The paper is in MS Work format in compressed zip form, about 29k.

Download New Article
(Written Nov. 2004)

In a recent article By Rod Elliott on Doppler distortion in loudspeakers Mr. Elliott examines the frequency shifts associated with the higher frequency in loudspeakers radiating two different frequencies and concludes that the observed frequency shifts are not a result of Doppler effects. He bases this conclusion on the premise that, "If the shift observed is indeed in frequency,and caused by the Doppler effect, then it must occur at the point where the cone velocity is at its peak - at the zero crossoing point of the wave form. However, if the shift is simply one of phase, then the peak shift will occur at the extremes of excursion, where the cone velocity is effectively stationary." Mr. Elliott also states, " Papers such as that by John Kreskovsky are very convincing, but unfortunately work from the wrong premise in the first place." He then goes on to develop his conclusion that the shifts are a result of phase shifts due to the relative position of the driver's cone with respect to the listener. While it is certainly valid to pursue the problem from the perspective of phase shifts rather than Doppler related changes in wave lengths, as I proceeded, a very simple analysis is all that is required to demonstrate the phase based argument is nothing more than a restatement of the Doppler Effect.

In light of these ststements I have prepared the following rebuttal.

Consider the signal

$$S(t) = \sin(\omega_h t + \Phi)$$

Φ is the phase shift and is related to ω_h as,

$$\Phi = \omega_h \Delta t$$

where Δt is incremental the time delay to listener due to the changing position of the cone.

$$\Delta t = (x_o - x) / c$$

Here c is the sound speed and x_o is the distance from cone to driver when the cone is at rest. If the cone velocity due to some low frequency motion is U_l then

$$x = x_o - \text{Integral}(U_l\, dt)$$

and

$$\Delta t = \text{Integral}(U_l\, dt)/c$$

Thus,

$$S(t) = \sin(\omega_h t + \omega_h \text{Integral}(U_l\, dt)/c)$$

If we consider the case where U_l is constant,

$$S(t) = \sin(\omega_h t\, (1 + U_l/c))$$

and we find

$$\omega_h' = \omega_h (1 + U_l/c) = \omega_h + \Delta\omega_h$$

where $\Delta\omega_h$ is the Doppler related frequency shift.

If $U_l = Um \cos(\omega t)$

$$\Delta t = U_m/(\omega_l c) \sin(\omega t)$$

and

and

$\Phi = U_m \omega_h /(\omega_l c) \sin(\omega_l t)$

Thus,

$S(t) = \sin(\omega_h t + ((\omega_h U_m /c)/ \omega_l) \sin(\omega_l t))$

It is evident from the equation for ω_h' above that $(\omega_h U_m /c)$ is nothing more than the maximum Doppler related frequency shift, $\Delta\omega_h$, which will occur over a low frequency cycle and

$S(t) = \sin(\omega_h t + \Delta\omega_h /\omega_l \sin(\omega_l t))$.

This is the same result obtained in my paper where $\Delta\omega_h /\omega_l$ is the modulation index and shows that whether the analysis begins with consideration of wave length compression/expansion or phase variation the result is identical and lead to the generation of intermodulation sidebands due to Doppler related effects.

Finally note that

$(\omega_h t + \Delta\omega_h /\omega_l \sin(\omega_l t))$

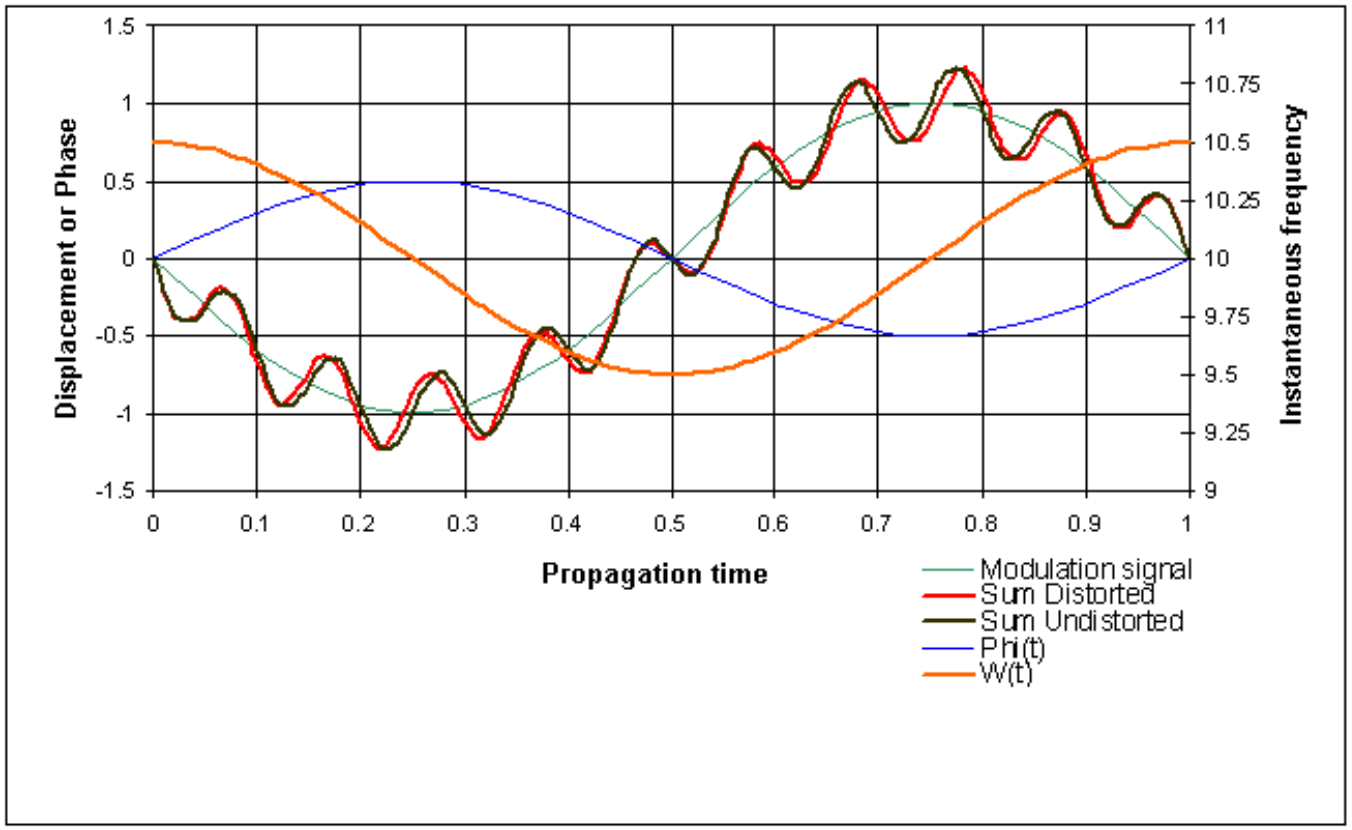
can be considered the instantaneous phase of the signal,

$\Phi(t)$, and the instantaneous frequency is given by

$d\Phi /dt = \omega_h'(t) = \omega_h + \Delta\omega_h \cos(\omega_l t)$

and we note the 90 degree difference between where the phase shift is maximum and where the frequency shift is maximum. Since, as Mr. Elliot measured, the maximum phase shift occured at the the point of maximum excursion, it follows that the point of maximum frequency shift does indeed occur at the point of zero crossoing where the cone velocity is at a maximum as would be expected if it were a result of Doppler effects.

The figure to the left shows the results of the analysis above for a modulation frequency of 1, a frequency ratio of 10 and a modulation index of 0.5. The thin green line is the displacement due to the modulation signal. The black line is the sum sin(T) + sin(10xT). The red line is the sum of sin(T) + the distorted signal. The orange line is the instantaneous frequency of the distorted signal. Note that the frequency is a maximum at the zero crossing of the modulation signal



(green line). The blue line is the time dependent phase of the distorted signal. Note that it is a maximum at the peak displacement of the modulation signal and is consistent with the measured data of Rod Elliott. However, Mr. Elliot's conclusion that this indicates the shift is not a result of Doppler effects is incorrect as the maximum frequency shift does occur at the poit of zero crossoing where the velocity due to the modulation signal is a maximum, a Doppler result.

Doppler Effect

You hear the high pitch of the siren of the approaching ambulance, and notice that its pitch drops suddenly as the ambulance passes you. That is called the Doppler effect.

Doppler Effect

When a vehicle with a siren passes you, a noticeable drop in the pitch of the sound of the siren will be observed as the vehicle passes. This is an example of the Doppler effect. An approaching source moves closer during period of the sound wave so the effective wavelength is shortened, giving a higher pitch since the velocity of the wave is unchanged. Similarly the pitch of a receding sound source will be lowered.

Source receding:

$$f_{observed} = \left[\frac{v}{v + v_{source}}\right] f_{source}$$

Source approaching:

$$f_{observed} = \left[\frac{v}{v - v_{source}}\right] f_{source}$$

Doppler Wavelength Change

The speed of sound is determined by the medium in which it is traveling, and therefore is the same for a moving source. But the frequency and wavelength are changed. The wavelengths for a moving source are given by the relationships below. It is sometimes convenient to express the change in wavelength as a fraction of the source wavelength for a stationary source:

Source receding, wavelength increase.

$$\lambda' = (v + v_s)T = (v + v_s)\frac{\lambda_s}{v} = (1 + \frac{v_s}{v})\lambda_s$$

$$\frac{\Delta\lambda}{\lambda} = \frac{(1 + \frac{v_s}{v})\lambda_s - \lambda_s}{\lambda_s} = \frac{v_s}{v}$$

Source approaching, wavelength decrease.

$$\lambda" = (v - v_s)T = (v - v_s)\frac{\lambda_s}{v} = (1 - \frac{v_s}{v})\lambda_s$$

$$\frac{\Delta\lambda}{\lambda} = \frac{(1 - \frac{v_s}{v})\lambda_s - \lambda_s}{\lambda_s} = \frac{-v_s}{v}$$

Doppler Effect Frequency Calculation

At temperature [ ] C = [ ] F

the sound speed in air is [ ] m/s.

If the source frequency is [ ] Hz

and the velocity of the source is [ ] m/s = [ ] mi/hr

then for an approaching source the frequency is [ ] Hz

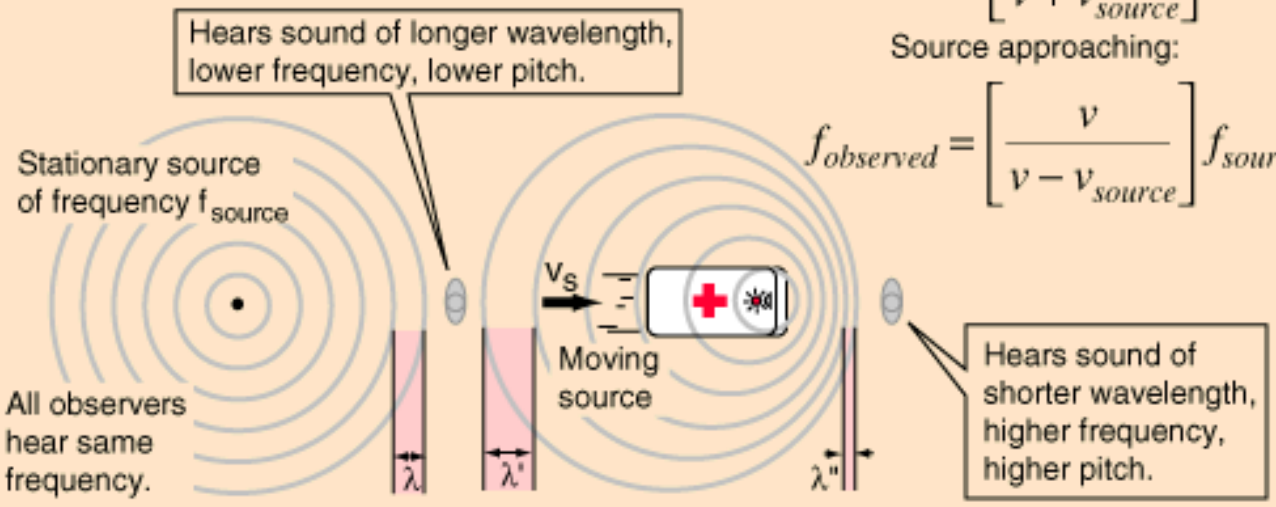
and for a receding source the frequency is [ ] Hz.

Source receding:

$$f_{observed} = \left[\frac{v}{v + v_{source}}\right] f_{source}$$

Source approaching:

$$f_{observed} = \left[\frac{v}{v - v_{source}}\right] f_{source}$$



Note: The frequency will default to A4 (440 Hz) and the temperature will default to 20 C if those values are not entered. Any parameters can be changed.

Pitch

Pitch = frequency of sound

For example, middle C in equal temperament = 261.6 Hz

Sounds may be generally characterized by pitch, loudness, and quality. The perceived pitch of a sound is just the ear's response to frequency, i.e., for most practical purposes the pitch is just the frequency. The pitch perception of the human ear is understood to operate basically by the place theory, with some sharpening mechanism necessary to explain the remarkably high resolution of human pitch perception.

The place theory and its refinements provide plausible models for the perception of the relative pitch of two tones, but do not explain the phenomenon of perfect pitch.

The just noticeable difference in pitch is conveniently expressed in cents, and the standard figure for the human ear is 5 cents.

More detail

Place theory concepts

Details About Pitch

Although for most practical purposes, the pitch of a sound can be said to be simply a measure of its frequency, there are circumstances in which a constant frequency sound can be perceived to be changing in pitch.

One of most consistently observed "psychoacoustic" effects is that a sustained high frequency sound (>2kHz) which is increased steadily in intensity will be perceived to be rising in pitch, whereas a low frequency sound (<2kHz) will be perceived to be dropping in pitch. (More detail)

The perception of the pitch of short pulses differs from that of sustained sounds of the

Index

Hearing concepts

same measured frequency. If a short pulse of a pure tone is decaying in amplitude, it will be perceived to be higher in pitch than an identical pulse which has steady amplitude. Interfering tones or noise can cause an apparent pitch shift.

Further discussion of these and other perceptual aspects of pitch may be found in Chapter 7 of Rossing, The Science of Sound, 2nd. Ed.

HyperPhysics***** Sound *R Nave* Go Back

Effect of Loudness Changes on Perceived Pitch

A high pitch (>2kHz) will be perceived to be getting higher if its loudness is increased, whereas a low pitch (<2kHz) will be perceived to be going lower with increased loudness. Sometimes called "Stevens's rule" after an early investigator, this psychoacoustic effect has been extensively investigated.

With an increase of sound intensity from 60 to 90 decibels, Terhardt found that the pitch of a 6kHz pure tone was perceived to rise over 30 cents. A 200 Hz tone was found to drop about 20 cents in perceived pitch over the same intensity change.

Studies with the sounds of musical instruments show less perceived pitch change with increasing intensity. Rossing reports a perceived pitch change of around 17 cents for a change from 65 dB to 95 dB. This perceived change can be upward or downward, depending upon which harmonics are predominant. For example, if the majority of the intensity comes from harmonics which are above 2 kHz, the perceived pitch shift will be upward.

Perfect Pitch

"Perfect pitch" or "absolute pitch" refers to the ability of some persons to recognize the pitch of a musical note without any discernable pitch standard, as if the person can recognize a pitch like the eye discerns the color of an object. Most persons apparently have only a sense of relative pitch and can recognize a musical interval, but not an isolated pitch.

Rossing suggests that less than 0.01% of the population appear to be able to recognize absolute pitches, whereas over 98% of the population can do the corresponding visual task of recognizing colors with no color standard present.

Types of Modulation

Amplitude Modulation (AM)

In Amplitude modulation (AM), the information signal is mixed with the carrier signal in such a way as to cause the AMPLITUDE of the carrier to vary at the frequency of the information signal.

Figure 6: Amplitude Modulation

Frequency Modulation (FM)

With frequency modulation, the modulating signal and the carrier are combined in such a way that

causes the carrier FREQUENCY(fc) to vary above and below its normal(idling) frequency. The amplitude of the carrier remains constant as shown in figure below.

Figure 7: Frequency Modulation

As the voltage of the modulating signal increases in the positive direction from A to B, the frequency of the carrier is increased in proportion to the to the modulating voltage. As the voltage reduces from B to C, the frequency of the carrier decreases until it is back to the original value at C. the modulating voltage increases in the negative direction from C to , hence the carrier frequency decreases to a minimum value at D. It will start increasing again from D to E until it reaches its original value again. Thus in one cycle, the frequency has gone up and down (i.e. above and below the idling frequency) as mentioned earlier.

Throughout this process the amplitude of the carrier is not affected. The carrier frequency change above and below that of the unmodulated condition is proportional to sign and amplitude of the modulating signal.

Phase Modulation (PM or Indirect FM)

Phase modulation is a type of frequency modulation. Here, the amount of the carrier frequency shift is proportional to both the amplitude and frequency of the modulating signal.

The phase of the carrier is changed by the change in amplitude of the modulating signal as shown in Figure 8 below.

Figure 8: Phase Modulation

The modulated carrier wave is lagging the carrier wave when the modulating frequency is positive. This can be clearly seen if we concentrate on the peak amplitude along line AB (previous slide). When the modulating frequency is negative, the modulated carrier wave is leading the carrier wave. This can be seen clearly by looking at the peak amplitude along line CD (previous slide).

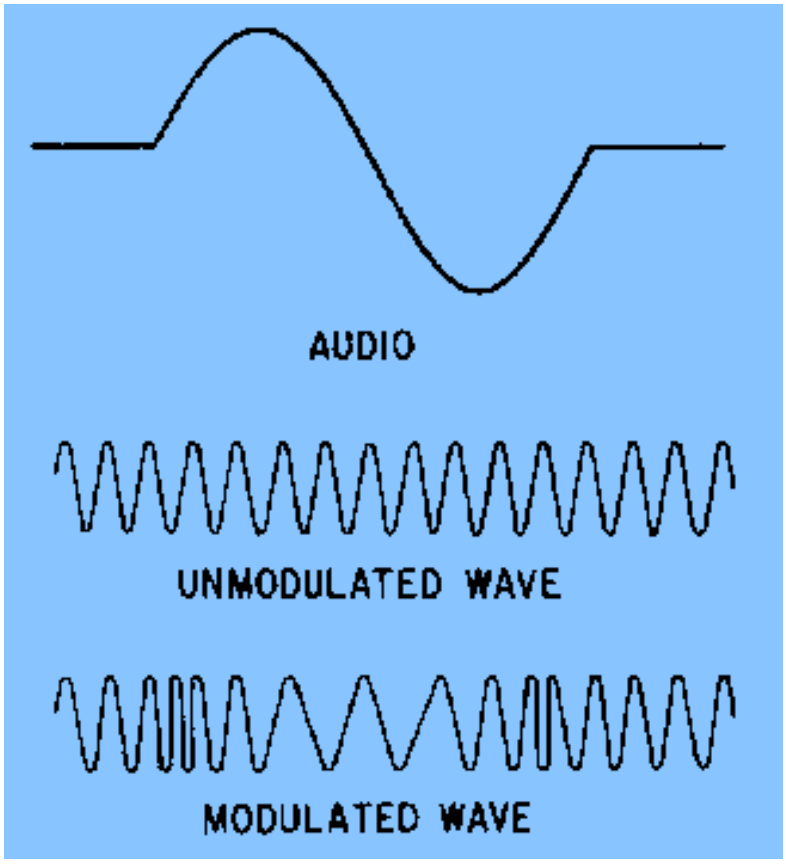
PHASE MODULATION

Frequency modulation requires the oscillator frequency to deviate both above and below the carrier frequency. During the process of frequency modulation, the peaks of each successive cycle in the modulated waveform occur at times other than they would if the carrier were unmodulated. This is actually an incidental phase shift that takes place along with the frequency shift in fm. Just the opposite action takes place in phase modulation. The af signal is applied to a PHASE MODULATOR in pm. The resultant wave from the phase modulator shifts in phase, as illustrated in figure 2-17. Notice that the time period of each successive cycle varies in the modulated wave according to the audio-wave variation. Since frequency is a function of time period per cycle, we can see that such a phase shift in the carrier will cause its frequency to change. The frequency change in fm is vital, but in pm it is merely incidental. The amount of frequency change has nothing to do with the resultant modulated wave shape in pm. At this point the comparison of fm to pm may seem a little hazy, but it will clear up as we progress.

Figure 2-17. - Phase modulation.



Let's review some voltage phase relationships. Look at figure 2-18 and compare the three voltages (**A**, **B**, and **C**). Since voltage **A** begins its cycle and reaches its peak before voltage **B**, it is said to *lead* voltage **B**. Voltage **C**, on the other hand, *lags* voltage **B** by 30 degrees. In phase modulation the phase of the carrier is caused to shift at the rate of the af modulating signal. In figure 2-19, note that the unmodulated carrier has constant phase, amplitude, and frequency. The dotted wave shape represents the modulated carrier. Notice that the phase on the second peak leads the phase of the unmodulated carrier. On the third peak the shift is even greater; however, on-the fourth peak, the peaks begin to realign phase with each other. These relationships represent the effect of 1/2 cycle of an af modulating signal. On the negative alternation of the af intelligence, the phase of the carrier would lag and the peaks would occur at times later than they would in the unmodulated carrier.

Figure 2-18. - Phase relationships.

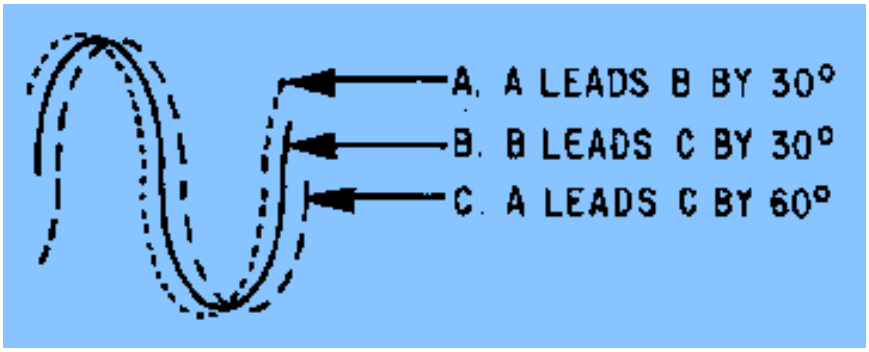


Figure 2-19. - Carrier with and without modulation.

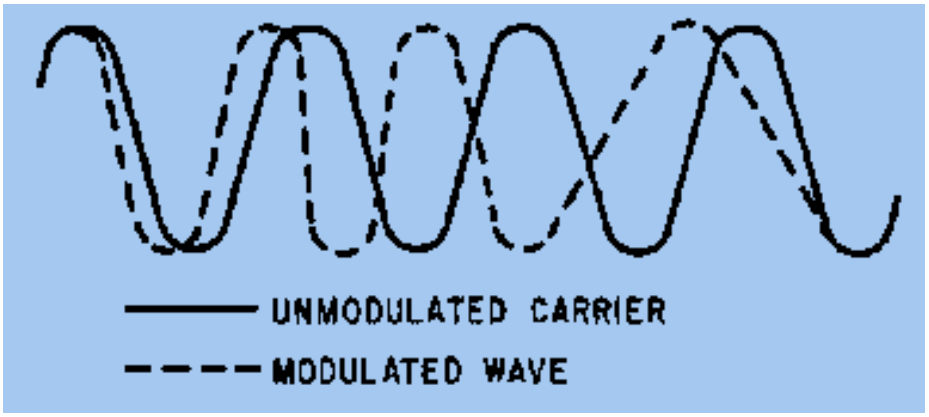
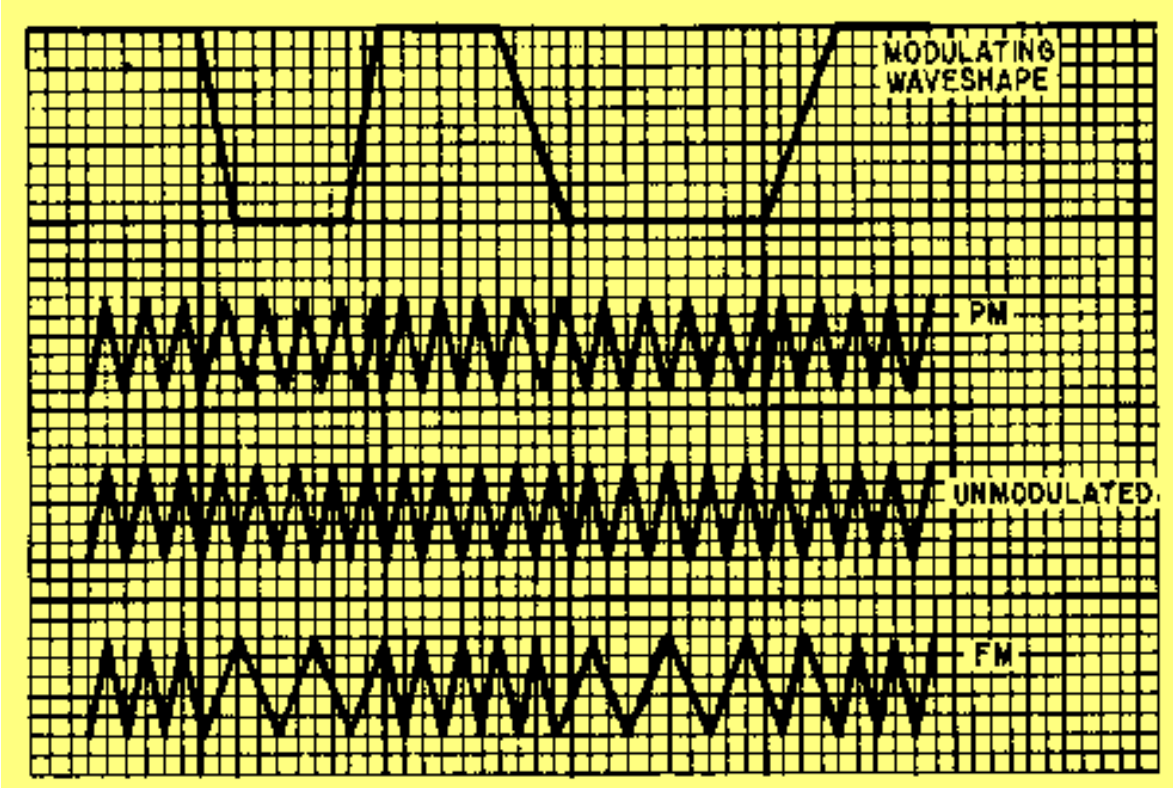


The presentation of these two waves together does not mean that we transmit a modulated wave together with an unmodulated carrier. The two waveforms were drawn together only to show how a modulated wave looks when compared to an unmodulated wave.

Now that you have seen the phase and frequency shifts in both fm and pm, let's find out exactly how they differ. First, only the phase shift is important in pm. It is proportional to the af modulating signal. To visualize this relationship, refer to the wave shapes shown in figure 2-20. Study the composition of the fm and pm waves carefully as they are modulated with the modulating wave shape. Notice that in fm, the carrier frequency deviates when the modulating wave changes polarity. With each alternation of the modulating wave, the carrier advances or retards in frequency and remains at the new frequency for the duration of that cycle. In pm you can see that between one alternation and the next, the carrier phase must change, and the frequency shift that occurs does so *only* during the transition time; the frequency then returns to its normal rate. Note in the pm wave that the frequency shift occurs only when the modulating wave is changing polarity. The frequency during the constant amplitude portion of each alternation is the REST FREQUENCY.

Figure 2-20. - Pm versus fm.



The relationship, in pm, of the modulating af to the change in the phase shift is easy to see once you understand AM and fm principles. Again, we can establish two clear-cut rules of phase modulation:

AMOUNT OF PHASE SHIFT IS PROPORTIONAL TO THE AMPLITUDE OF THE MODULATING SIGNAL.

(If a 10-volt signal causes a phase shift of 20 degrees, then a 20-volt signal causes a phase shift of 40 degrees.)

RATE OF PHASE SHIFT IS PROPORTIONAL TO THE FREQUENCY OF THE MODULATING SIGNAL.

(If the carrier were modulated with a 1-kilohertz tone, the carrier would advance and retard in phase 1,000 times each second.)

Phase modulation is also similar to frequency modulation in the number of sidebands that exist within the modulated wave and the spacing between sidebands. Phase modulation will also produce an infinite number of sideband frequencies. The spacing between these sidebands will be equal to the frequency of the modulating signal. However, one factor is very different in phase modulation; that is, the distribution of power in pm sidebands is not similar to that in fm sidebands, as will be explained in the next section.

Modulation Index

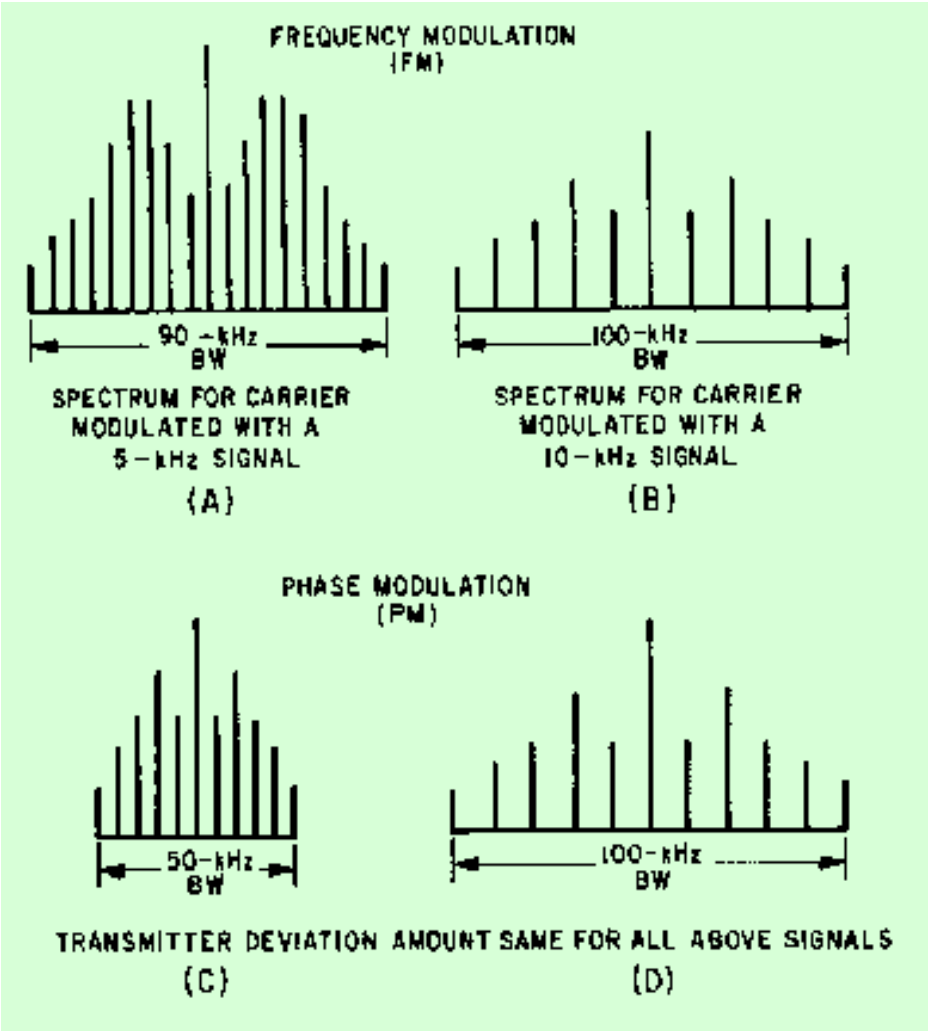
Recall from frequency modulation that modulation index is used to calculate the

number of significant sidebands existing in the waveform. The higher the modulation index, the greater the number of sideband pairs. The modulation index is the ratio between the amount of oscillator deviation and the frequency of the modulating signal:

$$MI = \frac{\text{transmitter deviation}}{\text{modulating frequency}}$$

In frequency modulation, we saw that as the frequency of the modulating signal increased (assuming the deviation remained constant) the number of significant sideband pairs decreased. This is shown in views (A) and (B) of figure 2-21. Notice that although the total number of significant sidebands decreases with a higher frequency-modulating signal, the sidebands spread out relative to each other; the total bandwidth increases.

Figure 2-21. - Fm versus pm spectrum distribution.



In phase modulation the oscillator does not deviate, and the power in the sidebands is a function of the amplitude of the modulating signal. Therefore, two signals, one at 5 kilohertz and the other at 10 kilohertz, used to modulate a carrier would have the same

sideband power distribution. However, the 10-kilohertz sidebands would be farther apart, as shown in views (C) and (D) of figure 2-21. When compared to fm, the bandwidth of the pm transmitted signal is greatly increased as the frequency of the modulating signal is increased.

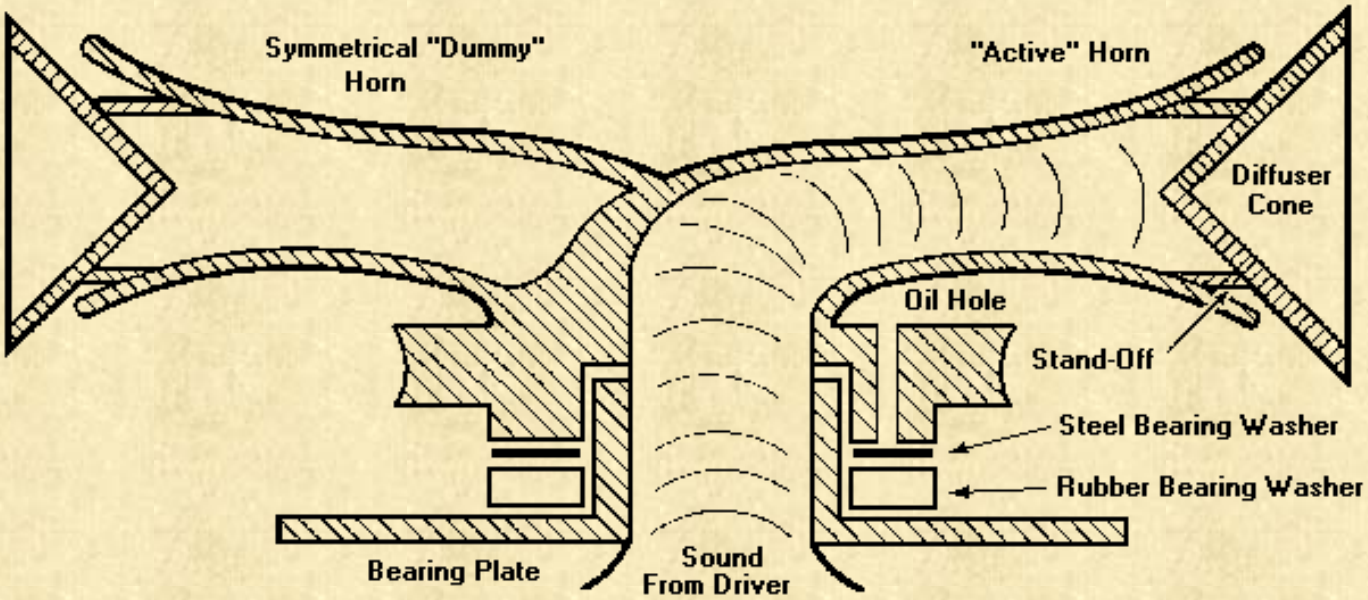

Figure 1. Plan-view of the Leslie Treble Rotor

UNEARTHING THE MYSTERIES OF THE LESLIE CABINET

by Clifford A. Henricksen
Community Light & Sound

First published in Recording Engineer/Producer magazine, April 1981.

The Leslie Rotating Tremolo Speaker System has produced the same unmistakable sound for so many musicians that it has become an international institution for the recording and performing musical arts. Everything from the venerable Hammond B-3 organ, to human voices and electric guitars, have been processed by the Leslie Sound, and have ended up on countless hit records. This article is an attempt to unearth the mysteries of its operating principles, and includes a discussion of the Leslie Cabinet's practical use in both stage and studio situations.

My love-hate relationship with Leslie Speaker began with the purchase of a Hammond organ during the mid-Sixties. The salesman told me I would probably end up buying a Leslie for it, a statement that I dismissed as the usual sales banter. Besides, at the time I had no idea what a Leslie was anyway. The Hammond was purchased because that's what the Animals' organist, Alan Price, used on all the group's early hits, especially "The House of the Rising Sun." I saw the band live in Schenectady, New Youk, where they put a Hammond M-102 direct into a Fender Bandmaster Amp, and I *had* to have this sound. I soon discovered, however, that my new musical heroes had *better* sound. It wasn't long before I knew that Booker T. Jones, Felix Cavaliere, Gary Brooker and

Billy Preston (and many others) were all using Leslies. *This* was The Sound!

My first Leslie, a single-speed Model 45 with a 40-watt tube amplifier sounded great, but it literally got lost in the roar of the Boston-based rock and roll band in which I was then playing. Two big Leslie Speakers were cumbersome to move, they weren't a big improvement in level (plus 3 dB), and the high-frequency drivers broke. From then on, it was guerilla speed shop tactics (mill the heads, oversized pistons, etc.), to the point where I could finally be heard over any guitar player. As a result, I became an expert at Leslie repair, modification and special use, occasionally even letting a few guitar notes into my beloved machines. I've spent the past 15 years in and out of the Music Business, both in studios and on stage. The significant part of this time was spent in some way dealing with Leslie Speaker Systems. As you might guess, this is a rock and roll story. I might as well show my bias here and now. With this in mind, here's what I have learned over the years.

PRINCIPLES OF OPERATION

First and foremost, the Leslie Rotating Speaker is designed as *a sound modification device*. It is not a "Hi-fi" speaker, but rather a part of a musical instrument. You buy a Leslie to *change* the sound of an instrument, not to reproduce it.

The Leslie Speaker System, thoughtfully named after its inventor, Don Leslie, operates on a simple principle: a directional sound source is rotated at constant (or variable) speed around a fixed pivot point.

At a listening point some distance from this whirling affair, three things happen. First, because the source is directional, the intensity of the sound will be at a maximum when it points at the listener (or microphone), The sound intensity will increase as the rotating source approaches dead center, and decrease as it rotates past this point. The resultant effect is called amplitude modulation (AM), which is no big thing, and is a feature on any guitar amp with a "vibrato" or "tremolo" feature. By moving closer to the rotating speaker, the inverse square law will increase the modulation effect.

However, the *big deal* is the Leslie's ability to create frequency modulation (FM). As the source rotates toward the listener, its relative velocity will increase the pitch of any tone it produces; as it rotates away, the pitch well be lowered. This is exactly the same Doppler effect that causes a train whistle (or any other sound on the train, such as grunting pigs, or shrieking passengers), to rise and then fall in pitch as the train approaches and then passes.

Lastly, if you are listening in a room with any significant reverberation, a complete spatial modulation of the sound will happen, as sound is "shot" all around and goes through multiple reflections.

If you want a real treat of all kinds of bizarre whirling horns and things, order copies of Don Leslie's original U.S. Patents: RE#23,323 and 2,622,693, available from The United States Patent Office, Washington, D.C.20231, for a fee of 50 cents per copy. These patent specifications are incredibly entertaining documents, and a must for any Leslie fan.

The Real-Life Leslie

A practical and commercial manifestation of the Leslie principle may take on many forms. Indeed, the manufacturer of Leslie Speakers, Electro Music, Inc. (now a division of Hammond Organ), produces a wide variety. These include models with reverberation, triple channels, and rotating-cone speakers. However, any Leslie afficionado will tell you that the Leslie Models 145, 147, and 122 are the ones with "The Sound". All three Models share the same basic innards: a 40-watt monophonic tube amplifier; an 800 Hz 16-ohm passive crossover; a rotating treble horn and a rotating bass speaker. Both rotating speakers are available with slow and fast A.C. induction motors. (Older Models 45, 47, and 22 are *identical*, except for having single-speed rotors.)

Furthermore, these Leslie models are similar in that they all have components mounted in a three-compartment cabinet. The top compartment houses the rotating high-frequency horn; the middle "box" the high- and low-frequency drivers and crossover (and which also acts as a vented box for the low-frequency driver); and the bottom compartment the low-frequency rotor and amplifier. Louvres located in the top and bottom compartments let out treble and bass sound respectively. All the above speaker systems are virtually identical in terms of their use and sound quality. (The larger Models 147 and 122 allegedly have a better low-end.) Both high- and low-frequency speakers operate on the same principle: a stationary driver (loudspeaker) and a rotating acoustic "projector".

The "Treble Rotor"

The Leslie's high-frequency unit is largely responsible for the "Leslie Sound". Some organists actually find that the bass rotor's slower response to speed changes is distracting, and will actually disconnect the bass rotor drive - especially when playing a bass line. The treble unit consists of a stationary 3/4-inch throat Jensen compression driver, connected to a vertical tube that acts as a thrust bearing (Figure 1). A twin-bell, molded black bakelite horn, which starts vertically but flares horizontally, sits on this bearing/tube, and rotates via a two-speed A.C. induction motor fitted with three (selectable) drive pulleys. This motor drives the treble horn at fast or slow speeds via drive belt and belt tension spring. Direct current is sometimes applied to the "fast" motor so that it will slow down more quickly; this is called a "D.C. brake". The treble horn actually looks like two horn assemblies; in fact, only one is operable as a horn. The other side, a "dummy", acts as a counterweight or dynamic balancer, providing symmetric air drag at high speed. The resulting structure rotates smoothly and without eccentric "wobble" forces.

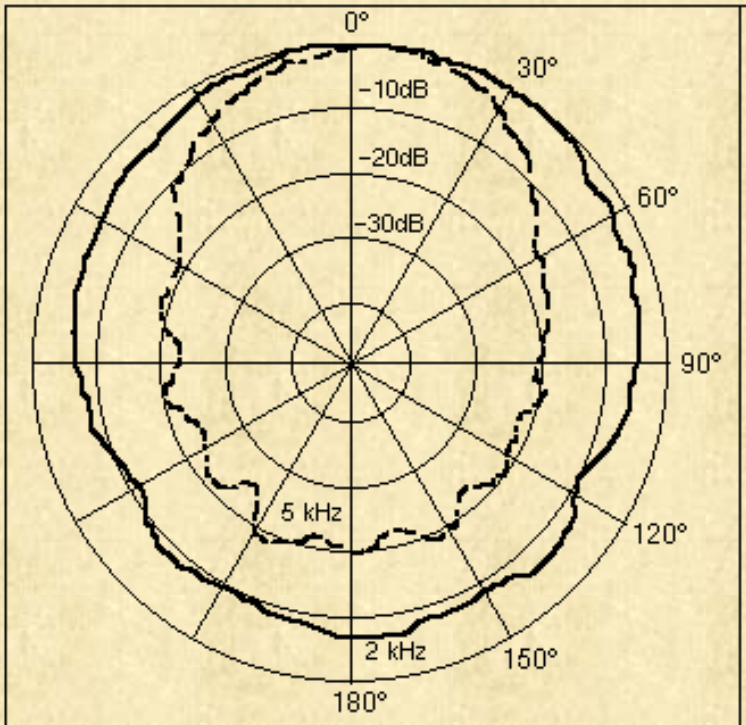

Figure 2. Typical polar response patterns of the Leslie Treble Rotor, with the deflectors removed.

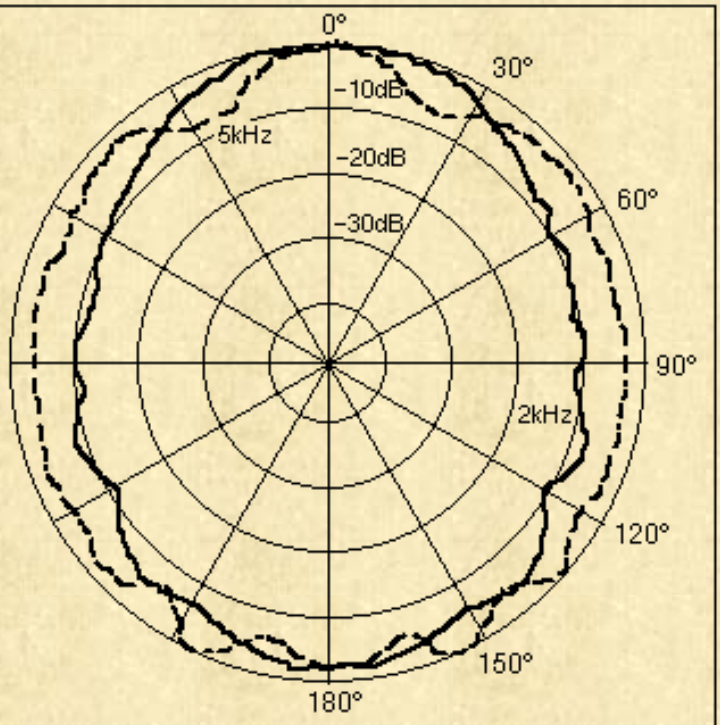

Figure 3. Typical polar response patterns of the Leslie Treble Rotor, with the deflectors in place.

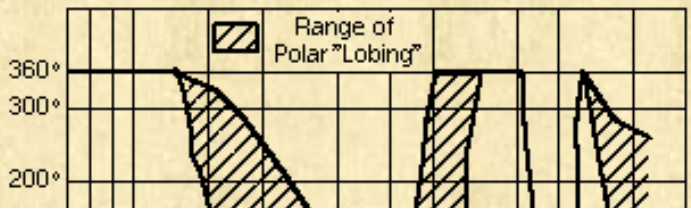

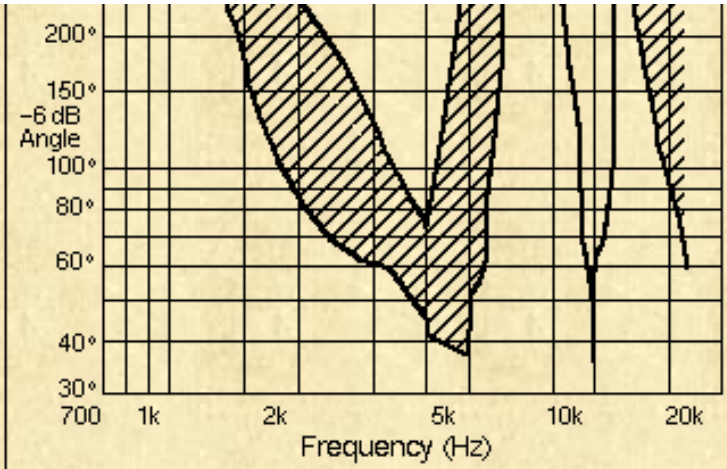

Figure 4. Coverage angle of the Leslie treble horn, with the deflectors in place.

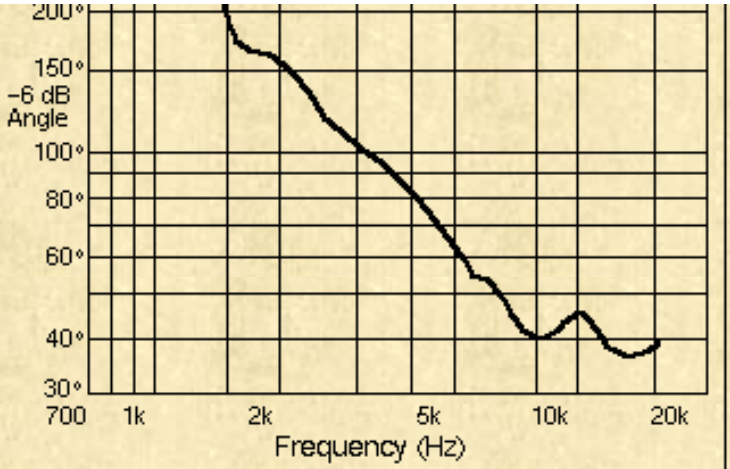

Figure 5. Coverage angle of the Leslie treble horn, with the deflectors removed.

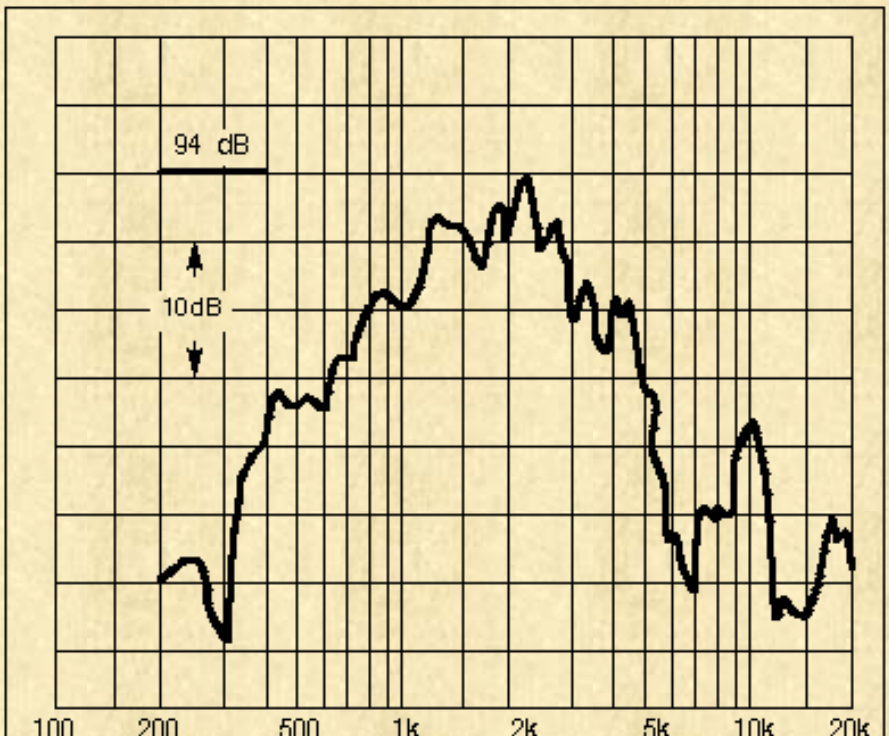
At the mouth of the horn is diffuser cone, which is supposed to widen the dispersion of the horn and make a "more musically pleasing tone". Actually, it does work. Figures 2 and 3 show typical polar response charts of a Leslie Horn with and without the deflector; the results are dramatic. The "without" curve of Figure 2 is typical of a "beamy" straight horn, with a lot of sound concentrated on-axis and very little sound off-axis. The "with" polar response curve of Figure 3 is almost omnidirectional; note, however, the "lobing". As the horn revolves, the sound will actually rise and fall a number of times, giving it an even more characteristic sound.

The horn's so-called coverage angle is taken from polar response charts such as these; it is the included angle between -6dB points from the horn's on-axis level. Figure 4 and 5 show such coverage angles, compiled from a series of third-octave polar response curves. Note how the beamwidth gets smaller and smaller without the deflector. This means that if the deflectors are removed the sound will be much hotter on-axis, but much softer off-axis. Therefore, the AM portion of the Leslie Sound will be much more severe and "choppy", as many a rock and roller will tell you. Many Leslies played in clubs are faced backwards, with the top and bottom rear panels and deflectors removed, because the sound "cuts" better; an effect that translates as, "You can hear it better over the guitar player".

This beaming process will actually raise the on-axis sensitivity of any driver, as can be seen from the frequency-response curves of a University ID-40 driver (a respectable, but typical 3/4-inch throat PA unit) mounted on a Leslie horn with and without deflectors (Figures 6 and 7). It is interesting to note the extra sensitivity above 1.5 kHz available without the reflectors in place. (Note also that the low-end - 800 Hz to 1.5 kHz - response isn't affected by removing the reflector, and that the response is ± 5 dB from 400 Hz to 10 kHz. This latter range could be made even flatter with a real-time analyzer and an third-octave equalizer in the studio.)



Now, this entire discourse is based on the treble horn measured in an anechoic or non-

reflecting, highly absorbent room. In real life, the horn mounted in a louvred wooden box, which means that the picture changes somewhat with resulting internal reflections. The diffuser cone does another important thing: it shifts the apparent sound source position on the horn. With the cone *in*, more of the entire range of the horn will appear to come from the mouth of the horn; with it out, however, while lower frequencies still appear to come from the mouth, higher and higher frequencies will appear to come from progressively further down the throat. They therefore appear to be rotating at a *smaller* radius, which results in less frequency modulation effects. (If the directional sound source was rotating at dead center, there would be no FM effect at all.) So here you are faced with a choice: leave the deflectors in place and the result will be maximum frequency modulation, and a relatively lower amplitude modulation, because of the very wide directional characteristics of the horn. Take the deflectors out though, and the FM will be lost, but you obtain very strong AM - especially at higher frequencies - due to the very narrow beam width of the naked horn. My own ears tell me that the deflectors should be kept on, but you make your choice and you take your chances!

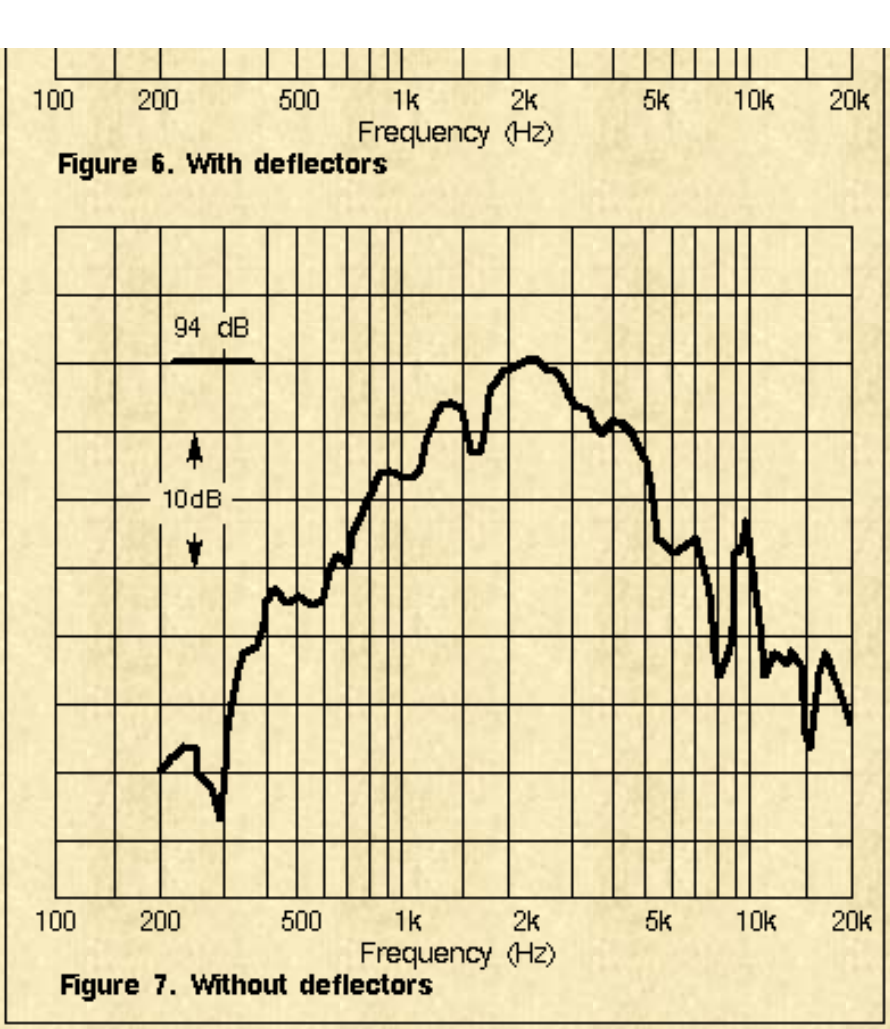


Figure 6. With deflectors

Figure 7. Without deflectors

The "Bass Rotor"

In the lower compartment of the Leslie box is a rotating wooden drum mounted on a vertical shaft, and covered with a black scrim cloth, which provides lower aerodynamic drag on the drum at fast speed (Figure 8). It also works. At the drum's center is a cylinder fitted with a "scoop" which, as in the treble unit, starts vertically (the bass driver faces downward into its entrance) and projects sound horizontally. The drum assembly is driven with a two-speed motor, and ends up at approximately the same rotational speed as the treble unit. The only difference is that the drum's inertia makes it approach final speed over a much longer time period. A D.C. braking voltage can also be applied to the "fast" motor to slow down the speed more quickly when switching from fast to slow. This system works somewhat effectively.

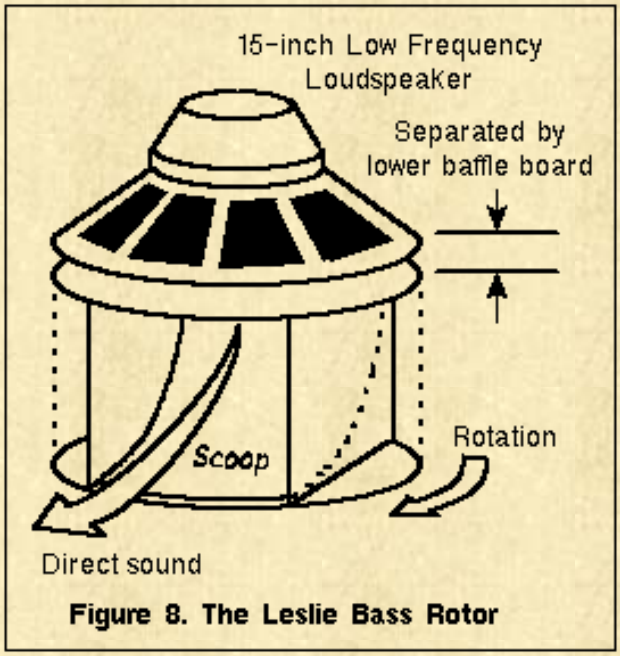

Figure 8. The Leslie Bass Rotor

To my ears and powers of reasoning, the bass rotor works just as an AM device, and only for the upper two octaves or so of the bass section (200 to 800 Hz). Frequencies lower than 200 Hz are probably uneffected by a scoop of this size, since 200 Hz has a wavelength of approximately 5.5 feet. There may be some frequency-modulation effects near the 800 Hz xrossover point, but it sure sounds like AM to me.

The result is a low-frequency "throb", which is very pleasant and especially powerful and beautiful when used in "slow" or "chorus" mode.

The Complete Leslie System

With all these rotating components installed in the box, the System works as follows: an electical signal is sent into the Leslie amplifier driving a 12 dB per octave, 16-ohm crossover, which feeds the 16-ohm bass and treble drivers with the appropriate frequency bands (Figure 9). Input signal, motor controls, and A.C. line voltage (115 V, 60 Hz) are connected to the unit via special plugs and sockets, linked with the "Leslie cable". It is this latter cable that's a major problem for many who would like to use a Leslie. Most self-contained speaker systems have an A.C. cord that plugs into the wall, and an input jack for the music signal. The Leslie, however, has a "Leslie Cord". Just one of the things with which we Leslie fans have to live.

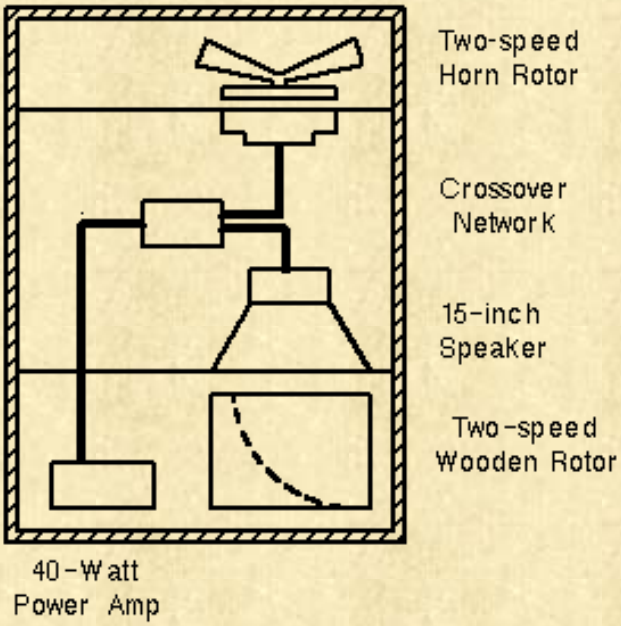

Figure 9. Schematic diagram of the Model 147 Leslie Speaker System

The amplifier chassis contains a 40-watt amp fitted with 6550 tubes - a *wonderful* choice of output tube for instruments - and motor control circuitry. Each rotor is actually driven by two separate motors (fast and slow) mounted in one package. Therefore, there are a total of four rotor motors and four pairs of wires, which all plug into the amplifier chassis. If any of these wires are removed and plugged into a live A.C. outlet, the appropriate motor will turn on safely without any problem, since this is essentially what the motor control does.

Input to the amplifier is via the six-pin plug. The speaker and crossover are both connected by very odd little two-pin connectors that I have never seen in use outside of a Leslie Speaker. They work, however, and seem to be very reliable over long periods of time.

Getting Music In And Out Of A Stock Leslie

Picture the scene. You have just bought a used Leslie; you got a great deal on it just in time for the gig. You excitedly load it up, set up your Farfisa organ and then stare dubfounded at this ugly, black 6-pin Harvey-Hubble *plug*, the only connector visible on your Leslie. Your 1/4-inch phone plug cord hangs limply in your hand... useless... impotent. Mistress Leslie stares back coldly. You can't even plug it in the wall and watch the tubes glow!

Chorus Interruptus... The Horror!

Well, it's a real problem. But, *veehaff vays to do ziss, Fraulein Leslie*. Here's how.

If your studio has a Hammond B3 or C3 organ with a Leslie attached, the latter will probably be a Model 22 or 122. This is a quiet, reliable and troublefree system, although you still can't plug it into the wall and operate the Leslie *independently of the organ*. Most big Hammonds, like the B3 and C3, will have a Leslie plug installed on them. Be careful! Only connect a Hammond Organ to a Model 122, 22, or 122RV; never connect a Hammond via a "Leslie Cord" to a Model 147 ot 145 Leslie. It will basically blow up. Inside the organ a very simple connection can be made via the RCA phono jack fitted to the "expression control box". This jack can be located by taking the back off the organ and merely plugging in. It is a line-level input that will accept most relatively high

impedance signals.

A recent welcome accessory to the Leslie line is the Leslie Combo Preamp. These little beauties actually booost the signal of an instrument to the required level, provide A.C. power for Leslie's amplifier and motors, and have foot switches to change speeds. It also plugs into the wall (via a *real* A.C. cord), connects easily to most instruments (a *real* 1/4-inch phone jack), and attaches the preamp to the Leslie via the standard Leslie Cord.

You may want to build a customized system for your own special use from a stock Leslie 147 or 145. (You'll *probably* want to modify it - this comes later.) Any modifications that involve poking around within the power amplifier should be carried out with *extreme* caution. Remember that the Leslie speaker is fitted with a *tube* amplifier, which has a power supply voltage of over 400 VDC. I've heard that, if you're a player, such a shock can improve 128th note runs, but I wouldn't recommend it. Watch where you put your fingers!

Engineering your own system is actually a simple matter, once you can locate a 6-pin plug that is compatible with the one fitted to the amplifier (or buy a Leslie Cord). Pin 1 is signal ground, and pin 6 signal "hot". Any source capable of delivering over 6 V into a load of 2.5 kohm, or less, will be able to drive the Leslie amp to full power with the "console load resistor switch" set to "open". The switch also inserts an 8-ohm, 10 watt or 16-ohm 10 watt equivalent resistor across the input, which means that a 10-watt power amp could be used to drive the Leslie, with the level control at the right setting. This is the typical setup for many organs equipped with their own power amps. A small guitar amplifier, such as a Fender Champ would do fine. The speaker should be disconnected, and the switch set to "8 ohms". Don't try it with a large power amp, however; your Leslie will sound, and smell, very bad shortly after the input resistors burn up.

Input power (115 VAC) connects via pins 3 and 4. Pins 2 and 5 connect the 115-Volt A.C. coil of the tremolo relay, which is "fast" when off, and "slow" when on. Therefore, a D.P.S.T. switch connecting pin 2 and pin 3, and pin 4 to pin 5 will activate the relay; if you only want "fast" forget pins 2 and 5. (A simpler approach would be to make a direct connection from pins 4 and 5, and use a simple S.P.D.T. switch.)

Modifications To The Leslie

Ah, yes. Audio racing in the streets. Imagine thousands hearing a vocal track through a Leslie... a Leslie that can be heard over a guitar player's Marshall Stack... a clean, Hi-Fidelity Leslie. These things and more can be yours, given the cash outlay in proportion to the desired grandeur, and even more cash if you don't build it yourself. (This country is loaded with local Leslie "speed shops" - and there will probably be 50% more after this article is published.) Electro Music makes Fenderesque Bi-Amp Leslies in vinyl cabinets. However, they are expensive, and are only equipped with amplifiers rated to a maximum of 60-watts. Also, you may very well want to preserve the present walnut beauty and improve its performance. If so, here's how:

External Mono-Amplification

The stock Leslie Models 145, 147 or 122 have a marvelous 40-watt tube amp. When you *really* lean on it, it sounds even lovelier, with a warm rich distortion like nothing you've heard. The show organist at Circus-Circus, Las Vegas has the best sound of this kind I've ever heard. He runs his Hammond B3 on 10, and just keeps the hammer down. However, in a live band situation or a club, or worse, at a concert, even a single 40-watt Leslie just doesn't cut it, even for a keyboard only. The recent rapid expansion of concert sound techniques allows quiter instruments to be miked and simply turned up at the console. I'm told that Keith Emerson and others have actually installed and miked a Leslie in an isolated backstage room during their concerts. (Including Bruce Springsteen's keyboard player, Danny Federici; *R-e/p, February, 1981 - ed.*) The result is a clean Leslie sound with no on-stage bleed from other instruments. In many cases however, a performer prefers more direct level from their own instrument.

The simplest way of enhancing the sound of a Leslie is to disable the built-in amplifier (pull out all four tubes and/

or the fuse) and use the motors only, via a combo preamp or the adapter discussed earlier. The speaker system can then be connected to whatever amplifier you plan to use. This is achieved by disconnecting the crossover from the standard Leslie amplifier, and patching it to a convenient input socket. A 1/4-inch phone jack, or a much-better-but-less standard banana or GR plug would be the answer. A more versatile method would be a 1/4-inch jack which, when accessed, disconnected the crossover input from the Leslie amp, and connected it instead to the jack. The only problem remaining is the power handling capablility of the Leslie Speaker System components, namely the high- and low-frequency drivers and the crossover networks. I'll discuss these as separate modifications.

Treble Driver Modifications

The stock Leslie high-frequency driver is pretty fragile, and is easily overloaded with a stock 40-watt amplifier. Unless for some exotic reason you want to drive it at low levels, plan on a new driver. Choice of drivers is important, and the most expensive ones are not necessarily the best answer. The most expensive professional drivers from Altec, JBL, Electro-Voice, and others, have usable sound reproduction to within the 10 to 20 kHz octave. Such performance probably won't be needed for a Leslie - I'm told that, in fact, a very high frequency harmonic content is actually a deterrent.

Extended-band high-frequency drivers are also rather fragile; a percussion note from a Hammond B3 can easily send a 0.002-inch thick aluminum diaphragm through its full excursion, and into the driver's phase plug. At this point, the musician is off the air, possibly during a now favorite solo, or in the middle of a take. Also, these drivers have large throats (between 1.4 and 2.0 inches in diameter), whereas the entrance hole to a Leslie treble horn is about 3/4-inch. This makes it ideally suited for the 3/4-inch throat PA drivers fitted with screw mounts, such as those made by University, Electro-Voice, Atlas, etc..

Such drivers are relatively cheap, can easily reproduce up to 5 or 6 kHz, and some handle enormous amounts of power. They also have a very similar bandwidth to the stock Leslie driver, which means that the same sound quality will be maintained. Actually, replacing the treble driver would make a stock Leslie much more reliable for "leaned on" use. My own personal preference is the Electro-Voice 1829 driver, a 16-ohm unit ideally suited to the Leslie crossover. I used one on stage for years at full chat with a Bogan MO-

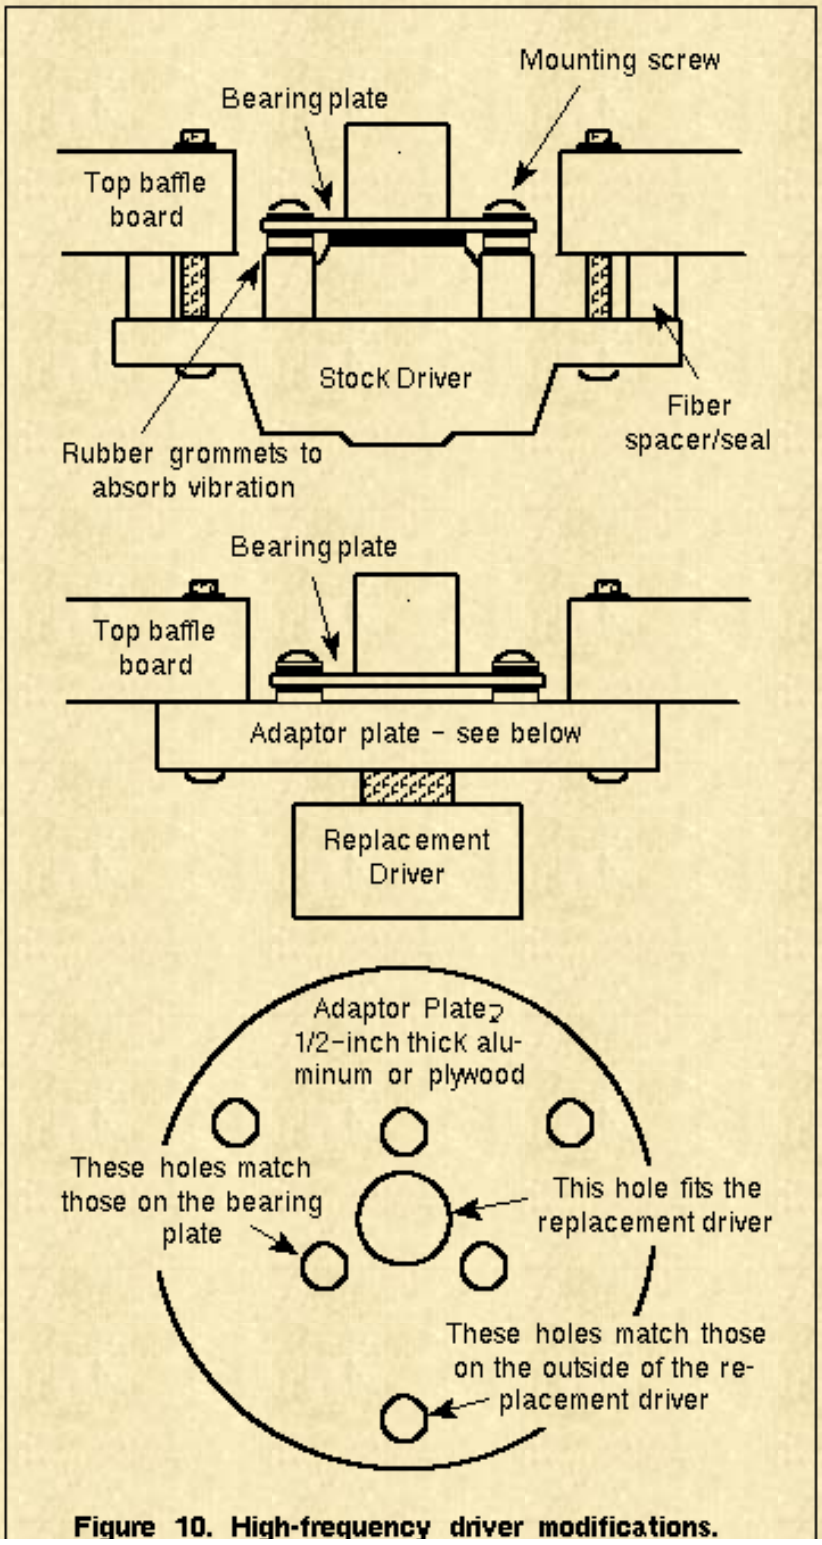

Figure 10. High-frequency driver modifications.

100A 100-watt tube power amp. It's still intact and has a pleasing sound. I'm told by numerous others that the have had similar good luck with an E-V 1829's sturdiness and power-handling ability.

Figure 10. High-frequency driver modifications. Top: standard driver and adaptor plate. Center: changes necessary to accommodate replacement driver. Bottom: layout of special adaptor plate.

Replacement of the Leslie driver involves, first, removing the backs from the upper and middle cabinets to provide access to the driver and horn. A special adapter is necessary to fit the screw throat PA driver to the stock Leslie horn, as shown in Figure 10.

Bass Driver Modification

The stock Leslie Bass Driver is a 15-inch O.E.M. speaker capable of handling about 50 watts. Supply it with 40 watts of a 30 Hz pedal tone and it shakes a lot. You may also be getting dangerously close to the driver's excursion limit, but it seems to be pretty sturdy. I've certainly heard of them breaking with "stock" use. If only a keyboard is used through the system - one without a lot of deep bass - and you protect the driver by filtering out the low-end, the unit may handle lots more as you approach its "thermal limit". If you want to avoid running the risk of breaking the bass driver, the easiest solution is to replace it with another unit capable of handling higher loads. Speaker choice is left up to the individual; since it's a matter of taste I can't really recommend any. An 18-inch speaker will fit with the following modifications: a spacer ring has to be added between the speaker and the Leslie baffle (so that the cone doesn't hit it), and part of the back panel may have to be whittled out for certain larger 18-inch speaker frames.

Crossover Modification

The stock Leslie crossover is a 12 dB per octave, 800 Hz unit requiring both 16-ohm high- and low-frequency drivers for correct performance. Most "mondo-power" 15-inch woofers have an impedance of 8 ohms, which tends to extend the reponse a bit higher than 800 Hz. Although this shouldn't cause any difficulties, it will make an 8-ohm high-frequency driver extend a bit lower, which will definitely cause excursion problems. The answer is to either buy a 16-ohm replacement driver, or perform the following modifications.

If the Leslie is fitted with both 8-ohm high- and low-frequency components, a stock 800 Hz crossover can be obtained from JBL, Altec, and other manufacturers. Community Light & Sound makes a very good crossover, which requires an 8-ohm bass speaker and a 16-ohm treble speaker (if you use it without its attenuation pad). The crossover handles well over 200 watts RMS, and is made from aircore coils and Mylar capacitors. Besides being a true "hi-fi" crossover, it would make an excellent choice for a super-power system. It is also possible to design and build your own crossover network from drawings and circuits published in any of the audio textbooks and cook books.

The best, most versatile and most adjustable solution would be to biamplify the Leslie. Again, it's "art", right? A Crown VFX-2 and stereo power amp would be a great setup with which to experiment.

Lastly, a crossover network consisting of a single series capacitor is a possibility (20 microfarad for 8-ohm units, and 10 microfarad for 16-ohm). It allows full-range sound to pass to the bass speaker, and high frequencies above 1 kHz to the treble speaker with a 6 dB per octave rolloff. Such a crossover network has been used successfully, and produces a very interesting and pleasing sound.

Microphone-Prepared Stock Leslie

This technique has been used very successfully in a live-music situation. A pair of small electret lavalier microphoes are permanently fastened to opposite corners of the treble horn compartment. Output from these mikes is connected to an external stereo mixer equipped with equalization - hopefully by a permanent connector fitted to the back of the Leslie cabinet - and hence to a stereo power amp and a pair of speakers located on either side of the stage. If a stereo PA rig is being used, the mikes can be fed into two channels of the front-of-

house board and panned left and right. As with anything, "good taste" in EQ and general technique is required to achieve a good sound. Actually, bad taste might work well, too; try both.

Wind noise from the horn is not a problem, and minimum mechanical isolation is needed. Lack of wind noise is probably because the cabinet corners are "stagnation" or dead-air spaces. Wind noise, if present, can be reduced by using an open-cell (reticulated Scottfoam) wind screen on the mikes.

An obvious extension of this mike technique is to do the same with the lower rotor, and obtain a mixed top and bottom left and right sound. Apparently, the "top-only" technique works very well in a live situation, but might also serve the purpose for a studio Leslie.

Tandem Rotors

Slower acceleration of the lower rotor is occasionally undesirable - certainly, a matter of personal preference only. To give a more dramatic Leslie sound, the top and bottom rotors can be mechanically linked so that both will turn in sync, and the pair of horns face in the same direction. Silver Sound Systems (337 South Morris Avenue, Crum Lynn, Pennsylvania) built the little screamer with tandem rotors shown in Figure 11, which is an example of a well-prepared custom Leslie unit. It enhances the Leslie action by putting full range sound into the bass unit and only high frequencies to the treble unit. This customized unit was designed for use with electric guitars.

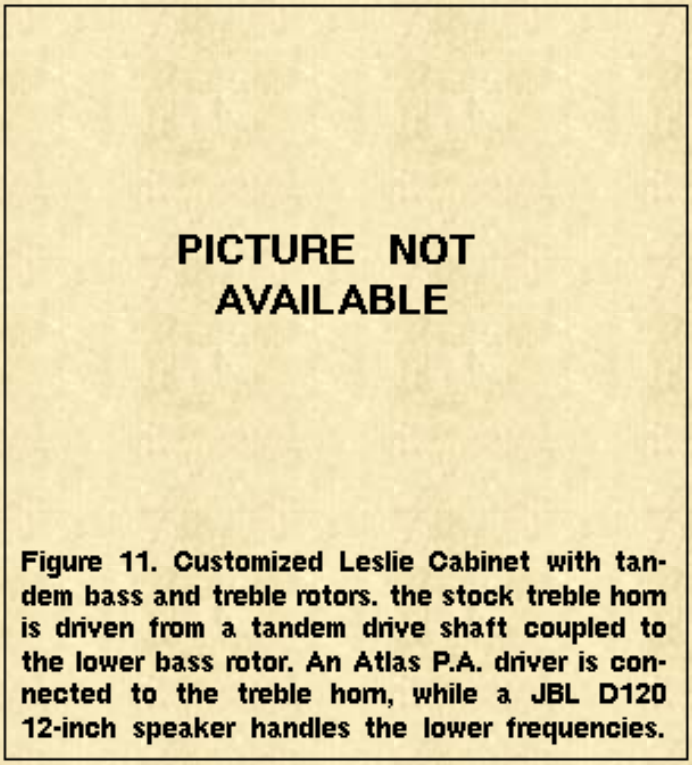

Figure 11. Customized Leslie Cabinet with tandem bass and treble rotors. the stock treble hom is driven from a tandem drive shaft coupled to the lower bass rotor. An Atlas P.A. driver is connected to the treble hom, while a JBL D120 12-inch speaker handles the lower frequencies.

Motor Speed Change

A really effective means of changing the rotor speed is to reach into the treble motors, and move the belt from one of the three drive pulleys to another. (Tricky, eh?) Actually, that's what they are there for; you are *supposed* to do it. My own preference is the middle pulley.

There have been a variety of speed change controls made available for Leslie motors. None have been very successful, however, since they just lower motor voltage, with the result that the motor will usually draw more current and possibly burn out. Watch out for these things. Leslie motors are A.C. induction types and, since they have no brushes, will last practically forever. However, their speed is determined by the 60 Hz frequency input, which is the same problem as varying tape-drive speed. The only solution that makes any sense is to hook-up a 115-Volt variable-speed oscillator. This can be constructed from a generator and tube amplifier that has a 115-Volt output tap. (Just like the old days, Sonny.) I am told it is really not worth the trouble though - the intermediate speed doesn't really sound very good.

STUDIO PRACTICE

As with just about anything, recording a Leslie is a matter of particular taste and purpose. You might want record the best possible recreation of a live Hammond B3/Leslie combination; you might also want to make it sound "better". You migh also want to use it as send and receive device, like an echo unit, with a high level send to the Leslie Amp, and a mono or stereo microphone receive. You could put it in a studio, in a reverb room (or in the bathroom) during the mix, or you might use it live. The possibilities are only limited by your level of creativity and/or insanity. However, the following are some standard techniques and descriptions of behavior.

Mono Recordings

I have recorded Leslies with a single microphone mounted as close as 1 foot from the treble horn, with very pleasing results. If the mike is placed even closer (within several inches) the severe amplitude-modulation effect becomes very annoying, and wind noise from the rotor at high speeds sounds like you have a helicopter in teh room. Which is a sound you might want. The same thing happens on the bass rotor, where up close there is also a lot of mechanical noise. A loose scrim will be real noisy; tighten it up. The sound from both rotors is mellower coming out of the louvres. By removing the back panels and miking the Leslie from the rear, the sound is more "direct" and defined.

Stereo And Multi-Mike Recording

Use of two mikes on the top and bottom of the cabinet is a very effective way of getting a good sound, bearing in mind the AM effects of close-miking. The *best* way I know of recording a Leslie, however, is in stereo. The left and right channels can be recorded with either a top and bottom pair of mixed mikes, or with just single mikes panned between left and right. The stereo image achieved with two pairs panned full left and right is very exciting. Many combinations are possible though, the point being that a Leslie is capable of providng a great deal of spatial information.

I spoke with a few engineers I know about such recording techniques, and here are a few of their preferences:

Jay Mark *(Sigma sound, New York)* has been pleased with a "tight" or "direct" Leslie sound, when recording organ. His principle reason for this is because the organ is used as background and not a featured instrument; the tight sound is needed so that the organ sound is very clear and unmistakable, even when way down in a mix. Jay has used the folloing setup with good results: an RCA 77DX ribbon at back of the top rotor cabinet, about 8 inches from the treble horn, with the high-end rolled of to suit. He also uses, at the back of bottom rotor, a U87 with the lows rolled off, and mixed with the top mike to suit. He remembers experimenting with the top and bottom sound panned left and right, and not liking the effect.

Allen Sides *(Ocean Way Recording, Hollywood)* prefers a pair of tube U67s, located about 5 feet away from the Leslie, aimed midway between top and bottom rotors, and spaced 10 feet apart. The mikes are panned left and right, and recorded on two separate tracks. Allen prefers the U67's natural roll-off on the high-end for de-emphasizing the high-frequency distortion on top. He told me of recording Billy Preston, who played a Fender Rhodes electric piano with stereo vibrato, and sent each channel to two separate Leslies.

Joe McSorely *(Veritable Recording, Ardmore, Pennsylvania)* likes to use a pair of U87s mounted relatively close in top and bottom cabinets. For a "tight" organ sound, he rolls of the lows from the bottom rotor, but records the top flat. Joe echoes a repeating problem - wind noise up close - and he always uses windscreens on the mikes. He says that most organ Leslie recordings done at Veritable are on one track, but a great "fake stereo" mixdown effect can be achieved by panning the dry track to one side, and using a Harmonizer in the "doubling" mode on a second track panned full opposite. Joe describes the resultant sound as "monstrous".

Several Odd Things To Try

An interesting sound results from running a full-range 15-inch speaker with a full range signal into just the bottom rotor. It should be obvious how to do this. The slow acceleration and deceleration of this massive rotor is quite different from the top unit, as is the frequency content. Try it.

There's one other item. Iknow for a fact that certain old Leslie Cabinets have a structural resonance in the wood and probably in the louvres, but it's the real thing. The old wood is simply more resonant, and Hammond percussion notes really set it off. (It's like these guitar players running around in South Carolina pawn shops looking for the ultimate '56 Fender Strat.) I've heard Leslies on records that just have a legendary tone to them,

and others that "just play regular". Go around and knock on a few new and used Leslies - especially the louvres - and see if you think I'm crazy. Anyway, the point to this was, why not try putting a FRAP pick-up on the louvres. Experiment - see if you can bring more of the sound out of the wood.

Specific Examples Of Normal Leslie Use

Normal Leslies are surgically attached to Hammond B3 or C3 organs; usually the former. There are many other brands of organs that have been played through Leslies during recording sessions, but "The Sound" which accompanies this great rock and roll Spirit of America is, pure and simple, a B3 and a Leslie. (Steinway piano, Fender Amp, Gibson, Lesl Paul, Fender Strat/Telecaster/precision Bass - all in the same breath.) The Isley Brothers used the fast Leslie all the way through their hit "Shout". Matthew Fisher combined America Soul, European Bach and B3 lower drawbars through a continuous slow chorus Leslie, and made millions listen to a "Whiter Shade of Pale" with its gorgeous organ theme. Billy Preston, Booker T. Jones and Felix Cavaliere made an art of timely speeding up and slowing down of the Leslie rotor.

These great artists (and many more) pioneered holding single notes (usually the root of the chord) and letting the Leslie provide the dramatics in rotor acceleration. Synthesizer players today *still* haven't found something as exciting. Lee Michaels had hits and toured for a long time with only his B3/Leslie and drummer Frosty. The right players could make a Leslie talk, make it scream, and make you want to dance. The list goes on forever.

...And Deviant Leslie Use (And Abuse)

Steppenwolf organist Goldie McJohn was able to coax an amazing sound from a stock Leslie. He connected the stock bass speaker directly ("full range") to the stock amp and ran the thing flat on 10 (actually it sounds like he found a way to get "11"). You can hear this very clearly on that classic track, "Born To Be Wild". The organ solo features the glorious distortion of a grossly overdriven Leslie amp, and you can hear the big bass rotor slowly speed up and slow down throughout the take. I saw Steppenwolf live at the now physically non-existent Electric Factory in Philadelphia. Goldie used the same setup on stage, only he stacked a bunch of them up right next to him, and miked one through the PA system.

Jethro Tull's *Benefit* album is considered by some to be the prototype Leslie-processed statement, and the hit "Teacher" from the LP is typical. Ian Anderson put both his flute and vocal through a Leslie, as did guitarist Martin Barre. It sounds like the Leslie was kept far away from distortion, a good example of a clean Leslie processing. I wish I know more about the particulars of this record, since it's another classic heavy.

Guitars Through Leslies

Many guitarists have used Leslies to modify the sound of their instrument. One unusual and very successful instance was Rusty Young of Poco. Rusty achieved some marvelous sounds with Poco by putting his steel guitar through a Leslie, producing a very distinctive and attractive effect. The instrumental line in Player's recent hit, "Baby Come Back", and J. Geils' soulful intro to "The Usual Place" are some more typical but outstanding examples of tasty Leslie guitar. I'm sure your lists contain a lot of others.

Personal Madness

I am arranging and putting together this article using a Norelco Dictating Machine, which has a microphone at the end of a coil cord that also acts as a loudspeaker. You can push a button on the recorder and the sound will come out of the microphone end. By grabbing the microphone by its cord and swinging it in circles, this entire article can be played back to me with a very strange and mysterious Leslie-like effect. It's really okay. No... I'm really allright. It's just like a Leslie, you see...

Acknowledgements

Thanks to Ralph Brownlowe, Robert Rankin and Ed Sciaky (WIOQ, Philadelphia) for some priceless and

valuable information used in the compilation of this article.

[This was stated by the author to be Gary Brooker, but he was not the organist for Procol Harum to play "Whiter Shade of Pale" - it was Matthew Fisher. The correction has been made here and will be forwarded to the author. -ed]

Doppler Distortion

Piston Vibrating in a Tube Including the Effect of Excursion

In other sections of this web site the wave produced by a vibrating piston is analyzed, but the effect of the piston excursion is neglected. That is, the piston has velocity, but the piston face is always treated as if its deviation from a fixed location is negligible. Here we obtain an exact solution where the excursion is taken into account. The excursion introduces harmonic distortion even when the piston is vibrating with a pure sinusoidal motion at a single frequency. When two frequencies are present intermodulation frequencies are created. Calling this "Doppler Distortion" may be a misnomer, but that is what people have called it for a long time.

There are people who believe that this is all a myth. As a believer in physics and mathematics, for me the derivation below is conclusive, and ends the debate. For the mathematically challenged among us, there is a heuristic description of the cause of this distortion at the end of this section.

Introduction: Fundamental Cause of Doppler Distortion

Consider a vibrating piston whose position x_p is defined by the equation

$$(1) \quad x_p(t) = -\frac{v}{\omega}\cos\omega t$$

The piston velocity is

$$(2) \quad v_p(t) = v\sin\omega t$$

Now consider an ideal sound wave in the tube, a single harmonic tone at the same frequency ω. We assume that the sound obeys the linear one-dimensional wave equation, i.e. that the sound intensity is within the region where air behaves linearly. Neglecting a multiplicative constant, the mean molecular velocity u, in the x-direction, at any point $x \geq x_p$, and at any time t satisfies

$$(3)\quad u(x,t)=\sin\left(\omega\left[t-\frac{x}{c}\right]\right)$$

Where c is the speed of sound. This form follows directly from the wave equations.

The crux of the situation is this:

At any fixed point x in the tube, the time variation of u is a pure sine wave. The time variation of the piston velocity is a pure sine wave when it is measured at the face of the piston, $x=x_p$,

The time variation of u is not a pure sine wave at $x=x_p$. Thus the piston velocity of equation (2)

does not match the sound wave velocity of equation (3) at the interface of the piston and the air. Since this is the basic boundary condition that must be satisfied, equation (3) is not a valid solution for the assumed piston motion. So at this point we know the piston is not generating a pure tone - i.e. there is Doppler distortion.

This velocity mismatch raises several interesting issues. We will first determine what tones are generated by a piston velocity defined by equation (2). We will return to a discussion of the interesting issues at the end.

Harmonic Vibration at a Single Frequency: Exact Solution

The necessary and sufficient conditions for an exact solution for the sound wave are: (1) the solution satisfies the wave equation, and (2) the wave velocity equals the piston velocity at the piston face. It should be emphasized that this means an exact solution everywhere in front of the piston, from smack dab on the piston face to plus infinity.

As a trial solution, consider

$$(4)\quad u(x,t)=b_0+\sum_{n=1}^{N}a_n\sin\left(n\,\omega\left[t-\frac{x}{c}\right]\right)+b_n\cos\left(n\,\omega\left[t-\frac{x}{c}\right]\right)$$

By construction this trial solution always exactly satisfies the wave equation. Equation (4) defines the wave velocity for any value of x, at any time t. As discussed above, we need to

match the piston velocity at the location of the piston face at any given moment. Therefore we will have a valid solution if we can find coefficients such that at $x=x_p(t)$ the wave velocity matches the piston velocity, meaning

$$(5)\quad v\sin\omega t = b_0 + \sum_{n=1}^{N} a_n \sin\left(n\left[\omega t + \frac{v}{c}\cos\omega t\right]\right) + b_n \cos\left(n\left[\omega t + \frac{v}{c}\cos\omega t\right]\right)$$

Equations (4) and (5) have some superficial similarity, but the crucial difference is that equation (4) gives the velocity as a function of both position and time, whereas equation (5) gives the velocity as a function of time alone at one loci in space, namely the piston face. So equation (5) is used to solve for the coefficients, and then they can be plugged into equation (4) to define the wave everywhere in the tube. If the objective is simply to know the resulting harmonic content, that is given directly by the coefficients themselves.

Being a lazy type, I don't even want to think about solving this nasty equation analytically. But it turns out that a pretty simple Matlab program generates very accurate solutions very quickly (I will send the program to anyone who wants it).

A piston in a tube is ideally loaded, and doesn't need to move much to generate very loud sound levels. For example, at a sound level of 117 dB SPL in the tube the peak piston velocity is only .0488 meters per second, and from equation (5) the first harmonic is 83 dB down from the fundamental. But a piston in an infinite baffle has to move a lot more. A loudspeaker cone with a peak excursion of 5 millimeters at 100 Hz moves at a peak velocity of 3.14 meters per second. At this velocity first harmonic from equation (5) is down 47 dB. A plot of the harmonics for a very high peak cone velocity of 10 meters per second is shown here [34 kB].

There is a constant velocity term b_o in equation (5). Much to my delight the numerical results for b_o from equation (5) agree perfectly with the constant that I predicted a long time ago, based on totally different considerations; see equation (36) in the section on plane waves. Since this is a pretty interesting result by itself, I have appended further discussion of this effect at the end of this section.

In any case, even with a "perfect" piston vibration, and with the air behaving in a perfectly linear manner, there are harmonics. The non-linearity arises strictly from the effect of the piston excursion.

Harmonic Vibration at Two Frequencies: Exact Solution

The numerical solution is in principle easily extended to the two-frequency case. The second frequency term is simply added to equations (1) and (2). To formulate equation (5), the "x" in equation (4), where we need to match the velocity, becomes the new $x_p(t)$ for the combined frequencies. Additional terms are added to equation (5) at frequencies corresponding to the new harmonics and intermodulation frequencies. Note that you can put whatever potential frequency terms you want in equation (5), as long as they satisfy the wave equation. If the frequency is not present, the program simply outputs a zero for that coefficient. In fact many of the coefficients output by the program are totally negligible. The "proof of the pudding" is if coefficients can be found such that the new equation (5) equals the new combined velocity. With the proliferation of terms the numerical solution is a little trickier than the one-frequency case. My current Matlab program only works for a large ratio of the high frequency to the low frequency. But for this situation, and with a little care, accurate solutions can still be found.

As an example, I have evaluated the case of frequencies of f1=50 and f2=1000 Hz, with peak velocities of 1 and .1 meters per second respectively. A plot of the piston velocity overlaid with the wave velocity is shown here [35 kB]. In other words, this is a plot of both the right and left hand sides of equation (5). The first harmonic of f1 is down 56.7 dB relative to the fundamental at f1. The first harmonic of f2 is down 76.7 dB relative to the fundamental at f2. The first sidebands at f2-f1 and f2+f1 are down 30.7 dB relative to the fundamental at f2. Therefore the intermodulation distortion is the dominant effect when these two frequencies are present. A plot of the harmonic content near f2 is shown here. [33 kB].

Harmonic Vibration at a Single Frequency: Approximate Solution

The above analysis is not easy to grasp intuitively. There is an approximate analysis that yields an answer quite close to the exact solution, and is much more intuitive. Given a piston vibrating at a single frequency, imagine a probe at some fixed location in the tube that measures the sound signal. To keep the argument simple, ignore any harmonics at this point, and assume we have a pure sine wave with wavelength λ. If the center of vibration of the piston is moved forward a distance d to a new fixed location, the phase of the signal measured by the probe will increase by a fixed value of $2\pi d/\lambda$ radians. So a forward motion imposed on the piston changes the phase. If we assume that the same phase change occurs when the piston face is displaced dynamically from its center of vibration, then there is a phase modulation of the signal due to the piston excursion. Assuming such a phase modulation, for the single frequency case with the piston location given by equation (1) the resulting signal measured by the probe, neglecting unimportant constants, would be

$$(6)\quad s(t)=\sin\left(\omega\left[t+\frac{x_p(t)}{c}\right]\right)=\sin\left(\omega t-\frac{v}{c}\cos\omega t\right)$$

Equation (6) can be expanded in an infinite series of harmonics of the fundamental

$$(7)\quad s(t)=-J_1\left(\frac{v}{c}\right)+\left[J_0\left(\frac{v}{c}\right)+J_2\left(\frac{v}{c}\right)\right]\sin\omega t-\left[J_1\left(\frac{v}{c}\right)-J_3\left(\frac{v}{c}\right)\right]\cos 2\omega t+\cdots$$

Where J_n is the Bessel function of the 1st kind. For a quite high piston velocity of 20 meters per second, which produces a first harmonic 30.7 dB below the fundamental, the coefficients produced by equation (7) agree with the three equivalent coefficients produced by equation (5) to within 0.2%. The coefficient of the 2nd harmonic term is approximately equal to $v/(2c)$ for $v<<c$.

Harmonic Vibration at Two Frequencies: Approximate Solution

Again to keep things relatively simple, assume that the piston excursion is dominated by the movement at a low frequency ω_1. Then the high frequency signal at ω_2 will have an approximate phase modulation given by

$$(8)\quad s(t)=\sin\left(\omega_2\left[t+\frac{x_p(t)}{c}\right]\right)=\sin\left(\omega_2 t-\frac{\omega_2 v}{\omega_1 c}\cos\omega t\right)$$

So the result is similar, except the effect is magnified by the ratio of the frequencies. The approximate coefficient solution for the 2nd harmonic, $(\omega_2 v)/(2\omega_1 c)$ also gives a result quite close to the two-frequency case presented above.

Interesting Issues

The approximate analysis is so accurate one might ask why I went to the trouble of generating the exact solution. I would turn this around, and say that what interests me is why the approximate solution is not exact! For very high velocities there is a significant disagreement. So the dynamic phase shift argument is approximate and needs verification, which is provided by the exact analysis.

The common method of computing Doppler distortion for the two frequency case is to: (1) compute a dynamic Doppler frequency offset based on the cone velocity at the low frequency, and (2) apply that as a FM modulation of the higher frequency. It is not obvious at first sight, but it is not difficult to show that (with one minor qualification) this is mathematically identical to applying a phase modulation based on the cone position, as done here. That is, the sidebands predicted by both analyses have exactly the same magnitude and phase. But for the single frequency case there isn't a Doppler frequency shift per se, and the phase modulation approach is the only way to get an answer.

Another question is: if an amplifier outputs a perfect sine wave voltage, what is the cone motion of a good speaker? I went back over the details of the Thiele-Small analysis to confirm that it is in fact the sinusoidal motion assumed in equations (1) and (2), as long as the speaker is in its linear region. Mainly this means that the voice coil stays in the linear region of the magnetic field, and the cone excursion is in the linear region of the suspension.

An important question one might ask is if there are similar effects during a sound recording process, and maybe the "distortion" actually washes out. If the musical instrument is a piston in the tube, and if the microphone is a piston in the tube, and if the speaker is a piston in the tube, in principle I think this is possible. But there is still an immediate qualification: the harmonics are amplitude dependent, so if, for example, the playback volume is different than the original "music" volume, the harmonics in the playback will be different - i.e. distorted. In the real world of course the sound source, microphone, and speaker all have very different velocities of motion.

What about Fourier analysis? Certainly the piston motion can be represented by a Fourier transform, and all of the usual spectral analyses can be performed. The same is true for the sound wave velocity generated by the piston motion. However, the two spectra will differ. In most practical cases the difference is small, but the sidebands produced by the modulation of a high tone by a low tone can certainly be significant.

The last question regards beat notes. Since my Matlab program only works for widely separated frequencies, I can't look for these, but you certainly have to guess that they would be there as well.

This type of distortion can only be reduced by minimizing the motion of the surface generating the sound. A larger surface moves less for a given sound level. The large diaphragm of an electrostatic speaker moves very little, and this might at least partially explain the wonderful clarity of some ES speakers. A three-way system is better than a two-way in this regard. A 4th order crossover is better than a 1st or 2nd order. Of course there are other factors involved in all of these design choices, and Doppler distortion may not be the most critical factor.

Heuristic Description of Doppler Distortion

Consider a piston vibrating in a perfect sinusoidal motion at 500 Hz. The wave generated in the tube will look a lot like a 500 Hz sine wave at first glance. But let's consider the zero crossings of the wave. Say the piston position vibrates between x=0 and x=1 centimeter (cm), and begins at x=0 with zero velocity at t=0. So the velocity wave begins with a pulse shape that starts at zero followed by a rising pulse slope. The pulse begins to travel down the tube at the speed of sound, 344 meters per second. At t=1 millisecond (ms) the piston is at x=1 cm and its velocity is zero. At this instant in time the wave consists of a positive half-cycle pulse with the first zero that has traveled down the tube to x=34.4 cm, and the second zero at x=1 cm. The zeros are 33.4 cm apart, and they will remain at that separation as the pulse continues to travel down the tube. At t=2ms the piston is back at x=0 and again has zero velocity. At this instant in time the wave consists of one full cycle, a positive pulse followed by a negative pulse, with zeros that are now at x=68.8 cm, x=35.4 cm, and x=0 cm. This pattern with a wavelength of 68.6 cm will then continue to be replicated as time goes on. The crucial point is that the zero crossings are not equally spaced; on the positive pulse section they are 33.4 cm apart, and on the negative pulse section they are 35.4 cm apart. We have a distorted sine wave.

Mass Transport for a Piston Vibrating in a Tube

To understand this, it is necessary to understand a sound wave as the motion of air molecules. For a pure tone, defined by equation (3), the average molecular velocity forms a perfect sine wave. At the wave peaks, the molecules, on average, are moving forward. At the troughs, they are moving backward at exactly the mirror image of the forward velocity. At the wave crests the molecular density is higher than at the wave troughs. Therefore there is a net flow of molecules in the direction of wave propagation. If you calculate the power flow in watts per square meter, you find that the wave is carrying more power than the piston is putting out. (In this calculation piston excursion is neglected). In other words, you are literally creating energy "out of thin air." Now everyone knows that there really isn't a net flow of molecules, and you can't violate the conservation of energy. What's wrong is that equation (3) by itself is not the right solution. If you add the constant term mentioned above, both problems are perfectly cleared up: there is no net flow of molecules, and the piston puts out exactly as much wattage as the wave carries down the tube. All of the physics and math to back all of this up is given elsewhere on this web site. Follow the link above, and subsequent links.

Acknowledgement: I benefited from technical exchanges in carrying out this analysis. Due to issues beyond my control that is all I am going to say.

SOUND

Sound appears to be a topic distinct from motion and heat. However, we now understand sound to be an ordered motion of the molecules of the medium through which the sound propagates. The study of sound provides the opportunity to understand wave motion in preparation for the more abstract study of electromagnetic waves. The subject of sound should be of particular interest to anyone who enjoys music[1-7].

Safety Considerations with Sound

Most experiments involving sound are relatively safe except for the hazards not directly associated with the sound as discussed elsewhere. However, it is possible for very intense sounds to permanently

damage the ear especially after prolonged exposure[1,2]. Consequently, in the demonstrations described here, the sound intensity should always be kept at a level well below the threshold of pain (see Table 3.1).

As a general rule, prolonged exposure to sound levels above 85 dB will cause slight hearing loss and above 90 dB will result in mild to moderate loss. Prolonged exposure to sound levels above 95 dB causes moderate to severe hearing loss. Above 100 dB, even short exposure can cause a permanent loss of hearing.

The ear has an acoustic reflex that protects the inner ear from loud sounds in the same way that the pupil of the eye protects the eye by contracting in the presence of bright lights. However, the reflex requires a few hundredths of a second to respond, and thus cannot be relied upon to protect the ear in the event of a short duration sound such as an explosion.

The damage is typically by way of tearing or ripping the microscopic hair cells of the cochlea. Such damage is usually only temporary unless the sound is frequent or sustained. Especially intense sounds are capable of rupturing the eardrum. The damage threshold is frequency-dependent, and the ear is most susceptible to damage by sounds of around 3000 Hertz in part because the auditory canal is a closed tube having a resonance in this region. Prolonged exposure to sounds of a particular range of frequencies can permanently reduce the sensitivity of the ear to those frequencies.

The monitoring of sound levels requires an A-scale sound level meter with a frequency response matched to the response of the ear or one capable of displaying the sound level for all of the various frequency ranges[3]. Protection can be provided by ear plugs and/or ear muffs. Cotton in the ears is not an effective protection unless the cotton is wax-impregnated.

3.1

Breathing Helium and Sulfur Hexafluoride

The peculiar sound of one's voice after breathing helium or sulfur hexafluoride provides an amusing demonstration of the variation of the velocity of sound with the density of a gas.

MATERIALS

- helium and sulfur hexafluoride*
- balloon
- funny hats (optional)

*Specialty gases and equipment can be procured from Matheson Gas Products, P. O. Box 1587, Secaucus, NJ 07094.

PROCEDURE

A dramatic illustration of the variation of the speed of sound with the density of a gas is performed by breathing a low density and a high density gas and talking as the gas is expelled from the lungs. Suitable gases are helium and sulfur hexafluoride. Xenon, though more expensive, can be used in place of sulfur hexafluoride. The gases are most conveniently breathed by first filling a balloon from a gas cylinder with a pressure regulator set to about 5-10 psi. One should exhale the air from the lungs and then inhale the gas through the mouth as if sucking a straw. The gas is then slowly exhaled as one talks. A duck hat

for the helium and a cowboy had for the sulfur hexafluoride adds to the humor.

One can also fill a balloon with sulfur hexafluoride and tie it off. It is distinctly heavier than an equivalent air balloon as can be illustrated by dropping the two side by side.

An especially instructive demonstration is to breathe a mixture of helium and sulfur hexafluoride in a proportion such that its density is close to the density of air. This can be done by first filling the balloon with helium and then adding just enough sulfur hexafluoride so that the balloon is slightly heavier than air (like an air-filled balloon). In principle, one's voice should sound normal after breathing such a mixture, but in practice the helium rises first into the nasal cavity and is expelled, leaving the sulfur hexafluoride which is exhausted at a slower rate. Such a demonstration shows that the density of the gas rather than its particular composition is the relevant variable.

DISCUSSION

The speed of sound in a gas is proportional to the square root of its density. For helium the speed is 2.7 times the speed of sound in air. For sulfur hexafluoride the speed is 0.44 times the speed of sound in air. The speed of sound in air is 343 m/s or 750 mi/hr at 20°C and is proportional to the square root of the absolute temperature.

The voice sounds different because the natural resonant frequencies of cavities in the head are raised or lowered in proportion to the speed of sound[1]. Of course the resonant frequencies of these cavities are only one ingredient in the way we sound. The gas does not alter the frequency of the vocal cords nor does it affect how fast we talk. The vocal tract acts as a filter for the sounds produced by the vocal cords in a manner similar to the treble and bass controls on a stereo.

Most people have heard the distinctive yet highly amusing sound that results when one breathes helium. Deep sea divers often breathe an atmosphere that is largely helium so that they can exist in a high pressure environment without exceeding the body's tolerance for nitrogen and oxygen. Most people have not heard the equally amusing sound that results from breathing sulfur hexafluoride. Sulfur hexafluoride has the additional property that, since it is a high density gas, it tends to remain in the lungs for a long time, and thus the effect on the voice persists much longer.

HAZARDS

The major danger in performing this demonstration is hypoxia from not getting enough oxygen while the gas is being breathed. Thus one should not immediately repeat the demonstration but wait a minute or so before breathing more gas. It is a good idea to take a few deep breaths before and after each demonstration. One should point out to the audience that the breathing of most gases (even some air) is potentially harmful. Helium and sulfur hexafluoride are two of a very small number of gases with which this demonstration can be safely done. The substitution of other gases, especially flammable gases such as hydrogen, is not recommended.

3.2

Oscilloscope Waveforms

An oscilloscope is used to display the waveforms of various musical instruments in order to show the effect of frequency and wave shape on the sound.

MATERIALS

- oscilloscope
- microphone
- various musical instruments
- tuning forks (optional)
- electronic keyboard (optional)
- function generator (optional)
- noise generator (optional)
- amplifier and speaker (optional)
- inexpensive transistor radio (optional)

PROCEDURE

An oscilloscope with a large screen can be connected directly to a microphone or to the output of an audio amplifier or function generator to illustrate the waveforms produced by various sounds.The oscilloscope should be set to sweep at a rate of about 200 Hz (5 milliseconds per sweep). This rate is fast enough to prevent flicker but slow enough to observe the low frequencies. If the oscilloscope has a triggered sweep, it should be set on "internal" and the triggering level set to a low value to make the resulting pattern as stationary as possible. A storage scope allows the waveform to be saved so that it can be discussed. In a large room, a TV camera and monitor(s) can be used to improve visibility of the oscilloscope, and in such a case the oscilloscope and camera can be backstage and connected to the PA and TV system.

Sine waves can be produced with tuning forks or organ pipes or with an electronic function generator. One could first show the sounds corresponding to sine waves of different frequencies. Anyone in the audience with perfect pitch should be able to identify the musical notes (see Table 3.2). The way in

which musical scales are constructed makes an interesting digression[1,2]. The standard of A-440 is not universally accepted, nor is the even-tempered scale. Some scientific manufacturers once adopted a standard of 256 (2^8) for middle C, but musicians ignored it. With a function generator, one can show the frequency limits of hearing (approximately 20 Hz to 20 kHz).

Musical instruments such as a violin and a trumpet have distinctive waveforms[3,4]. The clarinet somewhat resembles a square wave. One could show examples of string, wind, and percussion instruments. One can illustrate frequency modulation (vibrato) and amplitude modulation (tremolo). If someone in the audience can play the instruments, it adds a touch of interest to have them do so. Alternately, an accomplished musician can be planted in the audience who when called upon pretends minimal skills until suddenly launching into "The Flight of the Bumblebee" or some similarly intricate piece.

Modern electronic keyboards can be used to emulate a wide variety of musical instruments. Demonstrating the difference in waveform between a real instrument and a synthesized instrument can be quite interesting. The complex waveform required to transmit speech and music is especially dramatic.

Square waves and other waveforms can be produced with a function generator connected to an amplifier and speaker as well as to an oscilloscope. One could illustrate the different sounds produced by sine waves and square waves of the same frequency. The difference results from what musicians call "overtones" and physicists call "harmonics." Harmonics are integral multiples of the fundamental frequency, but overtones may or may not be related to the fundamental in a simple way. In most string and wind instruments, the overtones form a harmonic series, but in percussion instruments such as the drum, the overtones are more complicated and less "harmonious" (not a single discernible note). The combination of overtones is what gives each musical instrument its characteristic quality, or timbre.

This demonstration offers the opportunity to exhibit unusual musical instruments and other sources of sound. One might try blowing over the top of a soft-drink bottle and alternately drinking from it to change its pitch. The same can be done with a flexible plastic tube (1/2" diameter Eastman Poly-Flo) partially filled with colored water, fruit juice or wine, which one can drink when done. The bottom can be cut out of a Coke bottle, and different notes played by blowing over the top while it is dipped different depths into a beaker of water. Wine glasses stuck with a small mallet or rubbed along the rim with a clean, grease-free finger emit good sine waves. Music has been written for such a glass harmonica. A bent saw blade, whistles, horns and sirens are other possibilities. A long, hollow pipe, open on both ends, lowered over a Bunsen burner can also be made to emit a sound[5], as was first done by Sir Charles Wheatstone (1802-1875) in a series of public lectures at the Royal Institution in London [6].

An especially impressive demonstration can be done with an aluminum rod about a centimeter in diameter and at least a meter long. Hold the rod at the center in one hand. Put powdered resin on the fingers of the other hand and stroke the rod along its length to excite longitudinal vibrations. These

vibrations have a high pitch and vibrate for a very long time after one stops stroking. Thus they are extremely sinusoidal. The sound can be stopped abruptly by touching one of the antinodes at either end of the rod. Then grip the rod at a point one quarter of the length from one end and repeat the stroking to excite the second harmonic. It helps to place a mark at the right spot.One can compare these longitudinal vibrations with the transverse vibrations that occur when the rod is struck with a mallet. The transverse vibrations are at a much lower frequency unless the rod is very short as in a xylophone.

One can illustrate that the perceived loudness of a sound depends upon its wave shape. The square wave sounds louder than a sine wave of the same frequency because of the harmonics, even when the amplitude of the square wave is lowered by $(pi/2)^{½}$ to account for its larger average power. Also the perceived pitch of a sound depends slightly on its intensity[7]. Usually the pitch change is downward at low frequencies and upwards at high frequencies as the loudness increases, but the effect varies considerably with the individual[8]. Furthermore, the effect is noticeable only for sine waves[9,10]. These perceptions can be demonstrated with a pair of function generators and a switch to alternate between the two. If the sources are sounded simultaneously, the presence of beats can obscure the effect.

An inexpensive transistor radio can be connected to the oscilloscope to illustrate the distortion that results when the volume is turned up too high and the waves are flattened due to saturation of the transistor amplifiers. This could lead to a discussion of high fidelity audio equipment and the need for high power amplifiers to minimize distortion due to the generation of harmonics.

By tuning a radio or television between stations, one can demonstrate what noise sounds like. There are many types of noise such as white noise (all frequencies present in equal amounts), 1/f noise (sometimes called pink noise), $1/f^2$ noise (sometimes called brown noise since it is characteristic of brownian motion), and others. Commercial noise generators are available that produce the various types. Alternately various kinds of noise can be simulated by filtering white noise through an audio equalizer (adjusted to unequalize).

DISCUSSION

It is interesting to note that the shape of a waveform is determined by its Fourier frequency components. The phase as well as the amplitude of the individual frequency components will affect the shape of the waveform, but since the ear is insensitive to the relative phases of the components of a wave[11], waveforms of quite different shapes may sound identical to the ear.

HAZARDS

There are no precautions other than keeping the sound intensity down to a safe level.

A#	466.16 Hz
B	493.88 Hz
C	523.25 Hz

[a]A-440 is used as the standard, and the interval between each note is $2^{1/12} = 1.05946$.

3.3

Doppler Effect

A reed mounted on the end of a rotating arm produces a tone whose pitch wobbles up and down as the arm rotates.

MATERIALS

- sound reed
- motor with rotating arm*
- strobe lamp (optional)
- tape recording of train whistle or car horn (optional)

*Available from Fisher Scientific and Sargent-Welch Scientific Company

PROCEDURE

The Doppler effect (named after the Austrian, Christian Johann Doppler, 1803-1853) can be illustrated in a device which consists of a reed mounted on the end of an arm that is spun by means of a motor with suitable gears to control the speed[1]. The rotation causes air to pass over the reed producing a sound whose pitch wobbles up and down as the reed successively moves toward and then away from the observer. It helps if the speed of rotation can be adjusted. If a microphone is being used, it should be turned off or placed on the side of the apparatus toward the audience to reduce the interference between the direct and amplified sounds. The spinning arm can be viewed with a strobe lamp to freeze its motion. Alternate techniques for exhibiting the Doppler effect are also available[2-4]. A smoke detector wired so as to emit a continuous tone can be swung around on the end of a rope.

One can illustrate the effect verbally, but a tape recording of a train whistle or a car horn is more effective. Recordings of the Doppler effect can often be found on sound effect albums at record libraries or made quite easily with a tape recorder and automobile on a country road. This makes a good weekend family project for students who can then share their results with their classmates.

DISCUSSION

The frequency heard by a fixed observer for a source in motion is given by $f = f_o v/(v \pm v_s)$, where f_o is the frequency of the source, v_s is its velocity and v is the velocity of sound (about 343 m/s in air at 20° C). The plus sign holds for motion away from the observer, and the minus sign holds for motion toward the observer. Thus if one wants to produce a ±5% frequency shift for a reed at the end of a 25-cm-long arm, a rotation speed of about 650 rpm is required.

The Doppler effect was tested by a rather bizarre experiment in Holland a few years after Doppler derived his formula in 1842. For two days a locomotive pulled a flat car back and forth at different speeds. On the flat car were trumpeters sounding a particular note. On the ground, musicians with a sense of absolute pitch recorded the note as the train approached and receded.

There are many examples in nature of the Doppler effect. In addition to the usual train whistle and car horn, the Doppler effect also occurs for electromagnetic waves, but since the velocity of light is much larger than the velocity of sound, the effect is much smaller for a given source velocity. Even so, the police use Doppler radar to catch speeders. Doppler radar is now used to measure the speed of baseballs and tennis balls. In air traffic control, the Doppler effect is used to discriminate against stationary targets and to detect wind shear. The Doppler effect is also important in the reception of radio signals from earth-orbiting satellites. The Doppler effect is used in the determination of the distance of galaxies[5,6] (the Hubble constant) and in the Möessbauer effect.

HAZARDS

The main hazard in this demonstration is coming in contact with the rapidly rotating arm. A switch and speed control should be provided that permits operation from a safe distance. The apparatus should not contain parts that could come loose and be thrown out into the audience.

3.4

Bell in Vacuum

An electric bell in a jar makes a sound that decreases in intensity as the air is evacuated from the jar.

MATERIALS

- electric doorbell
- battery or power supply
- bell jar*
- vacuum pump
- pressure gauge (optional)
- sound meter (optional)

*Available from Carolina Biological Supply Company, Central Scientific Company, Fisher Scientific, Frey Scientific Company, Nasco and Sargent-Welch Scientific Company

PROCEDURE

The necessity of a medium for the propagation of sound can be demonstrated by means of an electric bell (a doorbell type) in an evacuated bell jar. The electrical leads for the bell can be brought out of the bell jar through vacuum feedthroughs. Transmission of sound by the electrical leads can be kept to a minimum if they have a small cross-section and are rather long and coiled up. They can be led through a rubber stopper in a hole in the glass to further dampen the transmitted sound. The bell should be suspended by its leads so as not to touch the bell jar. The bell is turned on, and the bell jar is evacuated to a pressure in the millitorr range with a mechanical pump while the sound slowly diminishes until it is almost inaudible. With a sound meter and pressure gauge, one could plot the sound intensity as a function of pressure.

In a simpler version, a small bell with a clapper is mounted inside a jar small enough to be held in the hand and shaken. The jar is equipped with a rubber stopper, hose and shut-off valve.

DISCUSSION

The sound propagation should cease when the mean free path for air molecules becomes longer than a

few centimeters. At room temperature and 760 torr of pressure (1 atmosphere), the mean free path is about 2×10^{-5} cm and is inversely proportional to pressure. Thus the pressure should ideally be reduced to about 10 millitorr to reduce the sound to the lowest possible level.

HAZARDS

The only significant hazard with this demonstration is implosion of the bell jar. If the jar is designed for vacuum use (heavy flint glass), it should be safe so long as it is not struck with a heavy object or otherwise cracked. The bell should be of the type that operates from a low voltage (0-6 volts) so as not to pose an electrical hazard. A variation of the demonstration, in which one places a battery inside the bell jar to operate the bell, is not recommended since the battery may explode when exposed suddenly to a vacuum.

3.5

Wave Speed on a Rope

The difference in wave propagation speed for transverse waves on ropes of different masses and tensions is illustrated with a stick and two, 3x5-inch index cards.

MATERIALS

- various ropes
- various weights
- 2 pulleys
- 2 3x5-inch index cards (preferably different colors)
- stick

PROCEDURE

One end of a rope is attached to the wall at about eye level. The rope is stretched across the room, and the free end is given a flick with the wrist. One can show that the speed of the wave on the rope increases with the tension in the rope but is independent of the shape of the wave. Dispersion (change in the shape of the wave as it propagates) can be observed. The reflection of the wave at the fixed end can be discussed. Note that the wave is inverted upon reflection from the fixed end.

Two identical ropes are strung across the front of the lecture room. The tension is made different by placing one end of each rope over a pulley and hanging different weights on each with the other end of the ropes anchored securely in the opposite wall. Two, 3x5-inch index cards (preferably different colors)

are folded and placed one over each rope about a foot from the anchored end. The opposite ends of the ropes are then struck simultaneously with a stick while the audience is told to watch the cards. The card over the rope with the greatest tension will jump off the rope slightly, but very noticeably, before the other.

To illustrate the variation of velocity with mass density, two ropes are used, with obviously different masses (say a quarter-inch-diameter and a half-inch-diameter rope). For ropes of the same material, the mass per unit length is proportional to the square of the diameter of the rope. The ropes are attached together and passed around a single pulley so as to produce the same tension in each. Cards are placed over the ropes near the ends that are anchored separately to the wall, and the ends that are passed around the pulley are struck with a stick as described above. The card over the smaller rope will jump off before the other.

One can combine the two demonstrations by using two ropes with different mass densities under different tensions, but with the same ratio of tension to mass density. In such a case, the cards should jump off simultaneously.

DISCUSSION

Fundamental to understanding the operation of musical string instruments is the velocity of a transverse, traveling wave on a string or rope under tension. Usually the velocity is so great that it is difficult to observe directly. The wave velocity is given by $(T/\mu)^{1/2}$, where T is the tension and μ is the mass per unit length. Under the same tension, a string or rope of the same material but twice the diameter as another will propagate sound a factor of two slower. String instruments have thick strings (large μ) for the low notes and thin strings (small μ) for the high notes as well as some means to adjust the tension in the strings.

HAZARDS

The ropes should be strung across the room above head level to prevent walking into them. Care should be exercised to ensure that the weights do not fall on a foot if a rope breaks, comes loose from its anchor in the wall or slips off its pulley.

3.6

Beat Frequencies

Two sound sources of nearly equal frequencies and amplitudes are made to exhibit beats if the frequency difference is less than about 10 Hertz.

MATERIALS

- 2 tuning forks or organ pipes with adjustable pitch
- 2 sine wave generators with amplifier and speaker (optional)
- oscilloscope (optional)
- 2 glass tubes to fit in organ pipes (optional)
- nichrome wire and power supply (optional)

PROCEDURE

The beating of two tones of nearly equal pitch sounds to the ear like a single tone whose intensity varies at the beat frequency. The demonstration can be performed using any two sound sources, but the effect is most striking if the the sources are sinusoidal and of equal intensities. The cleanest effect results from using two sine wave generators of equal amplitude connected to the same loudspeaker, in which case the amplitude varies from zero to twice the amplitude of each source[1-4]. The voltage applied to the speaker can be displayed on an oscilloscope. Two identical tuning forks also work well if a small piece of wax is placed on one of the forks to alter its frequency. Similarly, two identical organ pipes can be used if one is detuned by partially covering its mouth or by adjusting a movable plug if the pipe is so equipped.

The beating of two identical organ pipes can be used to illustrate the variation of the velocity of sound with temperature[1]. Two identical glass tubes are placed one in each organ pipe, and the pipes are tuned for zero beating. A nichrome wire is lowered into one of the glass tubes and heated to 250-300°C by an ac current. A noticeable beating should occur as the resonant frequency of the heated pipe rises with the increased velocity of the sound. The wire can then be cooled until the beats disappear.

The explanation of the beating can be presented graphically by drawing two sine waves of slightly different frequencies on the blackboard and showing how they constructively interfere at certain times and destructively interfere at others. For an audience versed in trigonometry, a single trigonometric identity yields the result: $\sin(w_1 t) + \sin(w_2 t) = 2\sin[(w_1+w_2)t/2]\cos[(w_1-w_2)t/2]$. Thus two sounds of frequency w_1 and w_2 will be perceived as a single frequency $(w_1+w_2)/2$ but with an intensity that reaches a maximum twice during each cycle of the frequency $(w_1-w_2)/2$. Thus the beat frequency is w_1-w_2 (assuming w_1 is the larger frequency). If the two sounds are of unequal amplitude, the cancellation will not be perfect when the waves destructively interfere, and the intensity variation of the beat will be less pronounced. Note that there is no wave present at the beat frequency. This can be illustrated by using two frequencies above the audible range of hearing but adjusted so that the beat frequency is within the audible range. Actually, if the sounds are sufficiently intense, it is sometimes possible to hear the beat frequency of two inaudible sounds because of nonlinearities in the ear.

DISCUSSION

Beats provide a means for musicians and piano tuners to tune their instruments. The tension in a violin string is adjusted until a given note gives a zero beat frequency with a standard note being played by the concert master. Other notes can then be adjusted so that their overtones beat with the overtones of the standard. In fact, the just diatonic scale is arranged so that the different notes are related in frequency by the ratios of small integers so as to minimize the beating of the overtones when two notes are played together. Such a scale seems to give the most pleasing sound, although instruments are more typically tuned to the even tempered scale in which the notes have twelve even logarithmic intervals within each octave and thus produce some low frequency beating among their harmonics.

Beats appear to play an important role in our perception of the quality of music[5]. A low frequency beat (a few Hertz or less) can sound pleasing, in that it emulates the trembling of the human voice. Rapid beats can be very unpleasant to the ear just as a flickering light is unpleasant to the eye and a fingernail scratched across a surface is unpleasant to the touch. Thus when one singer in a chorus or one instrument in an orchestra is off key, the resulting beats render the sound highly obnoxious. The famous german physicist and acoustician (and chronically bad lecturer), Hermann von Helmholtz (1821-1894), had a reed organ built that was based on a 24 note scale optimized to reduce the beating between the harmonics of the various notes. The sound was reported to be very pleasing but apparently not sufficiently so to revolutionize the way in which music is written and played.

HAZARDS

There are no precautions other than keeping the sound intensity down to a safe level.

3.7

Breaking a Beaker with Sound

A glass beaker exposed to a sufficiently intense sound wave at its natural resonant frequency is made to shatter.

MATERIALS

- 2000-ml, clean, glass beaker or large wine goblet
- small mallet
- small, high-power loudspeaker
- audio amplifier (at least 50 watts)
- variable-frequency, sine wave generator
- oscilloscope (optional)
- microphone (optional)
- digital frequency meter (optional)
- strobe lamp (optional)

PROCEDURE

In this classic demonstration[1,2] the input of the audio amplifier is connected to the variable-frequency, sine wave generator, and the output is connected to the loudspeaker. The glass beaker is set on some material such as a styrofoam pad that allows it to ring with minimal damping and is placed a few inches from the speaker. The beaker is tapped near its open mouth with a small mallet to ensure that it rings with a slowly decaying tone. With a microphone and oscilloscope, the resonant frequency can be measured and shown to the audience. Alternately, the speaker can be connected directly to the input of the oscilloscope and used as a microphone. The sine wave generator must be tuned to exactly the same frequency as the natural resonant frequency of the beaker.

Without an oscilloscope, one can adjust the frequencies to be equal by repeatedly tapping the beaker with the mallet and listening for the beats with the sound from the speaker as the generator frequency is slowly varied. This works best if the sound level is about the same from the speaker and from the beaker. Alternately, one can put the speaker near the beaker at a low sound level and listen for the increase in sound intensity as the resonant frequency is approached. Still another method is to watch or feel the vibrations of the beaker with the fingertips as the frequency is varied. Strips of paper folded over the edge of the beaker give an indication of the amplitude of the vibration. It is best to find the proper frequency beforehand using a digital frequency meter and to record the value (to a precision of at least one Hertz). This is so that the resonance condition can be quickly found for the demonstration, although there is considerable pedagogic value in showing how the resonance is found if time permits.

The members of the audience are then cautioned to cover their ears, and the sound is turned up to a high level. A slight readjusting of the frequency may be required. The frequency must be adjusted *very*

slowly, and one must wait a few seconds for the oscillations to build to a value sufficient for the glass to break.

The demonstration can also be done with a wine goblet or any other glassware with vertical sides that exhibits a high quality resonance in the acoustical range. All that is required to test the quality of the resonance is to tap the glass with a fingernail or a pencil and listen to how long the resulting ringing lasts. Any glassware that can be made to ring for more than a few seconds should suffice. Glass with a high lead content works best. In a variation of the demonstration, one can use a fixed frequency sound source, tuned slightly below the natural resonant frequency of the glass, and then slowly add water or other liquid to the glass until its resonant frequency is lowered to match that of the sound source.

A strobe lamp tuned near the resonant frequency of the beaker or one of its harmonics allows one to observe the vibrations of the glass, although visibility is difficult except for those relatively close. A television camera and monitor can be used to improve visibility. Prior to breaking, the glass may deflect by as much as a centimeter.

DISCUSSION

This demonstration illustrates that a sound wave is a compressional wave with a characteristic frequency. The wave carries significant energy from the source to the point where it is absorbed.

More importantly, the demonstration illustrates the phenomenon of resonance. The Q (quality) of the resonance is defined as 2(pi) times the number of cycles (number of radians) required for the energy of an oscillation to decay to 1/e (37%) of its initial value. Thus the highest Q resonance is the one for which the ringing lasts the longest. A piece of glassware with a resonance at 1000 Hz that decays to 37% of its initial energy in one second has a Q of about 6000. The Q is also a measure the amplitude which an oscillator driven at its resonant frequency will acquire. Thus the glass with a Q of 6000 will vibrate with about 6000 times more energy when driven at resonance than when driven well off resonance with a sound of the same intensity. However, it takes about Q radians (one second in this example) for the oscillation to build to near its full amplitude. The driving frequency also has to be matched to the natural frequency to a precision of about 1/Q (one part in 6000 in this example). Since the sound intensity has to be high (in excess of 90 dB), precisely of the right frequency, and sustained for a few seconds, there is little danger of breaking one's wine glass while casually listening to music on the stereo!

Dorothy Caruso denies rumors that her husband Gigli could shatter wine glasses with his unamplified voice[3]. Although it might be possible for a singer to do so, there are no documentated cases of any having succeeded. The Memtek company in Forth Worth, Texas produced a television commercial showing Ella Fitzgerald and others breaking glasses with recordings of their voices on Memorex tape.

HAZARDS

Unless the demonstration is designed very carefully, the sound intensity required to break a beaker can

damage one's hearing. The sound should be turned up slowly to allow the audience to take protective action. The members of the audience should be encouraged to cover their ears. When the glass shatters, the glass fragments tend not to be ejected with great force but rather to fall straight down. Even so, it is best to perform the demonstration at least ten feet away from the audience or to use a transparent protective screen and to wear safety goggles. A tray underneath the glass will catch most of the glass fragments, but the broken pieces should be collected promptly and disposed of.

3.8

Flame Pipe

A pipe several meters long filled with natural gas and connected to a loudspeaker produces a flame whose intensity varies with position along the length of the pipe.

MATERIALS

- specially constructed pipe
- source of natural gas, methane or propane
- matches
- loudspeaker
- audio amplifier (few watts)
- sine wave generator
- meter stick (optional)

PROCEDURE

A brass or copper pipe about 5 cm in diameter and 2 meters long contains several hundred small-diameter holes in a line along the length of the pipe. A downspout pipe will also work. One end of the pipe is sealed and fitted with a nozzle through which natural gas, methane or propane can be admitted. On the other end of the pipe is mounted a loudspeaker so as to make a reasonably tight seal. The loudspeaker is connected to the output of an audio amplifier whose input is connected to a sine wave

generator of variable frequency.

The gas is turned on, and after waiting a few seconds for the air to be expelled from the pipe, the gas is ignited with a match where it exits the holes along the pipe. This produces a nearly continuous wall of flame several meters long. A considerable throughput of gas is desired, and the effect is best when viewed in subdued illumination. The frequency and amplitude of the sound emitted by the speaker is adjusted until a clear standing wave pattern is seen in the flame. At certain frequencies, the wave will resonate in the pipe, and the required amplitude will be quite small. More amplitude is usually required as the frequency is increased, but one should be careful not to burn out the speaker. As the frequency is raised, the distance between adjacent wave crests will decrease. The demonstration can also be done with other wave shapes such as square waves or the waves corresponding to speech and music.

DISCUSSION

The fundamental principle illustrated in this demonstration is the compressional wave nature of sound. Where the average pressure is greatest, the gas emitted through the holes is greatest, and the flame is most intense. The flame intensity is low where the wave displacement is maximum as a result of the Bernoulli effect. The information resembles that displayed on an oscilloscope but is more direct and less mysterious.

The variation of wavelength with frequency (or pitch) of the sound is easily illustrated. With a meter stick one can show that the product of frequency and wavelength is a constant equal to the velocity of sound (about 460 m/s in methane at 20°C). Note that the distance between the nodes of the flame is half a wavelength.

This demonstration also illustrates the resonant frequencies of a closed organ pipe. The closed end of the pipe is a displacement node (the air cannot move there) and thus is a pressure antinode (maximum) since the displacement and the pressure are 90° out of phase with one another. Conversely, the end driven by the speaker is a displacement antinode and a pressure node.

A resonance will occur in the pipe when the length of the pipe is an odd multiple of a quarter wavelength. At resonance the pressure variation within the pipe becomes quite large, and a relatively low sound intensity results in a large variation in flame intensity. As the pipe heats up, the sound velocity changes (proportional to the square root of the temperature in Kelvins) and a slight readjustment of the frequency is required to maintain resonance. Variation in the air-to-gas ratio also causes the resonance to drift.

HAZARDS

The flame should be placed well away from any materials that it might ignite. The pipe becomes quite hot after prolonged operation and requires some time to cool off. If the flame is lit too quickly after the gas is turned on while there is still air in the pipe, the flame could be sucked into the pipe, destroying the

speaker. The substitution of other flammable gases such as ethane or hydrogen is not recommended.

3.9

Ultrasound

Various sources of sound with frequencies above the range of audibility are used to illustrate the distinction between a physical sound wave and the perception of sound.

MATERIALS

- ultrasonic dog whistle*
- variable-frequency audio oscillator with speaker (optional)
- ultrasonic cleaner (optional)**
- ultrasonic microphone and oscilloscope (optional)

*Available from most pet supply stores

**Available from Carolina Biological Supply Company, Cole Parmer Instrument Company, Edmund Scientific and Sargent-Welch Scientific Company

PROCEDURE

This demonstration can be introduced with the old question of whether a tree falling in a deserted forest makes a sound. The answer depends upon whether sound is defined as a physical wave or the perception of that wave by the ear and brain of a living creature. Sources of ultrasound provide a means to produce a sound wave that is not perceived by humans as being a sound.

Probably the least expensive and most convenient source of ultrasound is a dog whistle. A dog trained to come to the sound of the whistle who interrupts the presentation when it is first demonstrated will get the attention of the audience. Such whistles can usually be adjusted from a frequency that is barely audible to most people to well above the range of hearing. Ultrasonic pest repellers are sold that emit a very intense burst of ultrasound every few minutes.

A variable-frequency audio oscillator with a high-fidelity audio amplifier and good quality speaker (tweeter preferred) can be used to explore the whole range of audible frequencies. One can point out that high frequency audible response deteriorates with age (a condition known as "presbycusis"). If the audience consists of many ages, one could perform an experiment on this. One reason that children and

small animals are more responsive to high frequencies is a simple matter of size scaling. An ear with smaller components is more sensitive to the shorter wavelengths of a high-frequency sound.

An oscilloscope with microphone can be used to prove that there is a sound present. Most microphones have low sensitivity to ultrasonic frequencies, but with a sensitive oscilloscope they can usually be made to indicate the presence of a sound. A high-pass filter between the microphone and oscilloscope is of considerable help. A small capacitor will often suffice. Ultrasonic microphones can also be purchased.

Another common source of sound above the audible range is an ultrasonic cleaner which usually consists of a vat of liquid with an ultrasonic transducer that creates sound waves in the liquid. Typically the liquid is some organic compound capable of dissolving oil and grease. Jewelers often use ultrasonic cleaners to clean rings and other jewelry. A freshly opened plastic bottle of carbonated beverage partially emersed in the liquid can be made to erupt and spray its contents several feet into the air.

Because of the short wavelengths, ultrasonic transmitters and receivers are well suited for the display of interference and diffraction effects usually demonstrated with microwaves or light. This helps to dispel the mystery of why, if light and sound are both waves, we can hear around a corner but we cannot see around one.

DISCUSSION

A sound wave is a compressional disturbance that will propagate in most materials. The range of human hearing is usually taken to be about 20 Hz to 20 kHz, although it is more accurate to say that the ear is most sensitive to frequencies around 4000 Hz and becomes progressively less sensitive at higher and lower frequencies requiring greater sound intensity to produce a detectable response. The product of the frequency and the wavelength is equal to the speed of sound in the medium. In air at 20°C, the speed of sound is 343 m/s, and so the corresponding wavelengths are 17.15 meters to 1.715 cm, respectively. Typical ultrasonic sources produce frequencies from about 20 to 100 kHz, corresponding to wavelengths as short as a few millimeters.

The reason it is difficult both to produce and to detect ultrasound is that something has to move to create or to respond to the sound wave. The inertia of the object (eardrum or whatever) prevents it from moving appreciably during the short period of the wave. Even so, the human ear is a remarkable instrument, responding to displacements of the ear drum that are hardly larger than the diameter of an atom!

HAZARDS

It is possible to damage one's hearing by exposure to sufficiently intense ultrasound even though the sound is inaudible, but it is unlikely unless one places an ultrasonic transducer directly in the ear, which is definitely not recommended. Internal damage can occur if one places a finger or other part of the body in the vat of an ultrasonic cleaner that is turned on.

Elliott Sound Products **Project 71**

Subwoofer Equaliser
(Using The Linkwitz Transform Circuit)

Rod Elliott (ESP)

PCBs are available for this project. Click the image for details.

Introduction

The Linkwitz transform circuit is a hugely flexible way to equalise the bottom end of a sealed loudspeaker enclosure. Unlike the "EAS" (Electronically Assisted Subwoofer) project or the ELF™ systems, a speaker that is corrected using this method is flat from below resonance to the upper limit of the selected driver. The low frequency rolloff point is determined by the parameters of the transform circuit. Should the enclosure size be too small and cause a lump in the response before rolloff, this is also corrected. A conventional active crossover network is then used to divide the subwoofer signal from the main channel signals.

For a detailed look at how the circuit works, please click here to see the article that describes the operation of the circuit.

The original Linkwitz Transform spreadsheet was presented by TrueAudio (2), and is reproduced here with their permission. One of my readers added an extremely useful extra page that calculates the driver response in the box, and I added the ability to use litres instead of cubic feet if desired. The transform circuit was invented by Siegfried Linkwitz (1), and is another of his gifts to the audio world (the other is the Linkwitz-Riley crossover).

The Linkwitz Transform spreadsheet can be downloaded here, or from the Downloads page.

Driver Selection

A quick word is warranted here, to allow you to determine if the speaker you have will actually work in a small sealed enclosure. The Linkwitz transform circuit (or EAS principle) will allow any driver to extend to 20 Hz or even lower. A good quick test is to stick the speaker in a box, and drive it to 50 or 100W or so at 20 Hz - you should see a lot of cone movement, a few things will rattle, but you shouldn't actually hear a tone. A "bad" speaker will generate 60 Hz (third harmonic) - if you don't hear anything, the speaker will

work in an equalised sub.

If a tone is audible, or the speaker shows any signs of distress (such as the cone breaking up with appropriate awful noises), then the driver cannot be used in this manner. Either find a different driver, or use a vented enclosure.

Description

The schematic for a complete equaliser is shown in Figures 1 and 2, and considering the flexibility of the circuit, it is not at all complicated. The complex part would normally be determining the component values based on the speaker driver's response in a given enclosure. This is simplified by the spreadsheet, which requires only a small amount of input from you to be able to calculate the box response, and the equalisation needed to achieve the desired response.

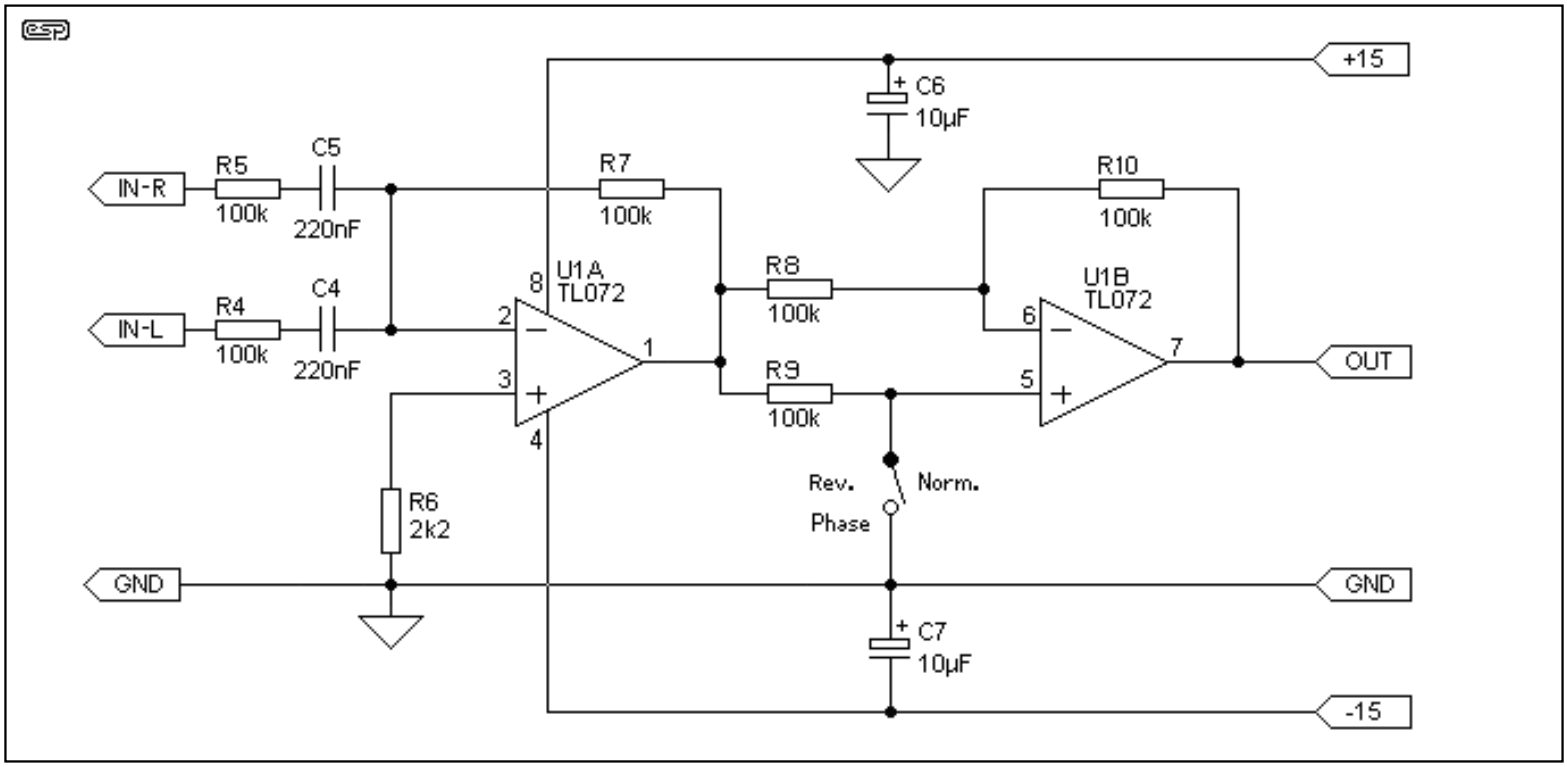

Figure 1 - Input Mixer and Phase Switch

A simple mixer circuit is shown in Figure 1, and this is simply be added to the front end of the circuit in Figure 2. The mixer stage completely isolates each channel from the other, since the summing point is a "virtual earth" because of the feedback. The second opamp is used only as an inverter, so the polarity of the signal may be switched to find the optimum setting. When the switch is open, the phase setting of the equaliser is non-inverting (both the input and Linkwitz transformer are inverting). Closing the switch reverses the phase.

Figure 2 shows the circuit of the Linkwitz "transformer" (for a single channel). The values of the unmarked components are determined using the Linkwitz Transform calculator spreadsheet (see below for more information). This circuit must be driven from a low impedance, such as the output from an opamp (as shown in Figure 1). The output capacitor as shown is a bipolar electrolytic, but a conventional polarised electro can be used if you prefer. The polarity will be different with different

opamps, so measure the DC output voltage (it will only be a few millivolts) to determine the correct polarity.

If you don't want to use the mixer of Figure 1, to create a mono signal from a stereo source, a simple resistive mixer may be used. A resistive mixer requires that the source impedance from each preamp output is quite low to prevent crosstalk. If you are using a typical valve preamp, I suggest the use of buffer amplifiers prior to mixing, as the output impedance of most valve preamps is too high to allow resistive mixing without introducing crosstalk. This is not a problem if the summing inputs are used. In any case, the Linkwitz transform circuit will need to be driven from an opamp to ensure low source impedance.

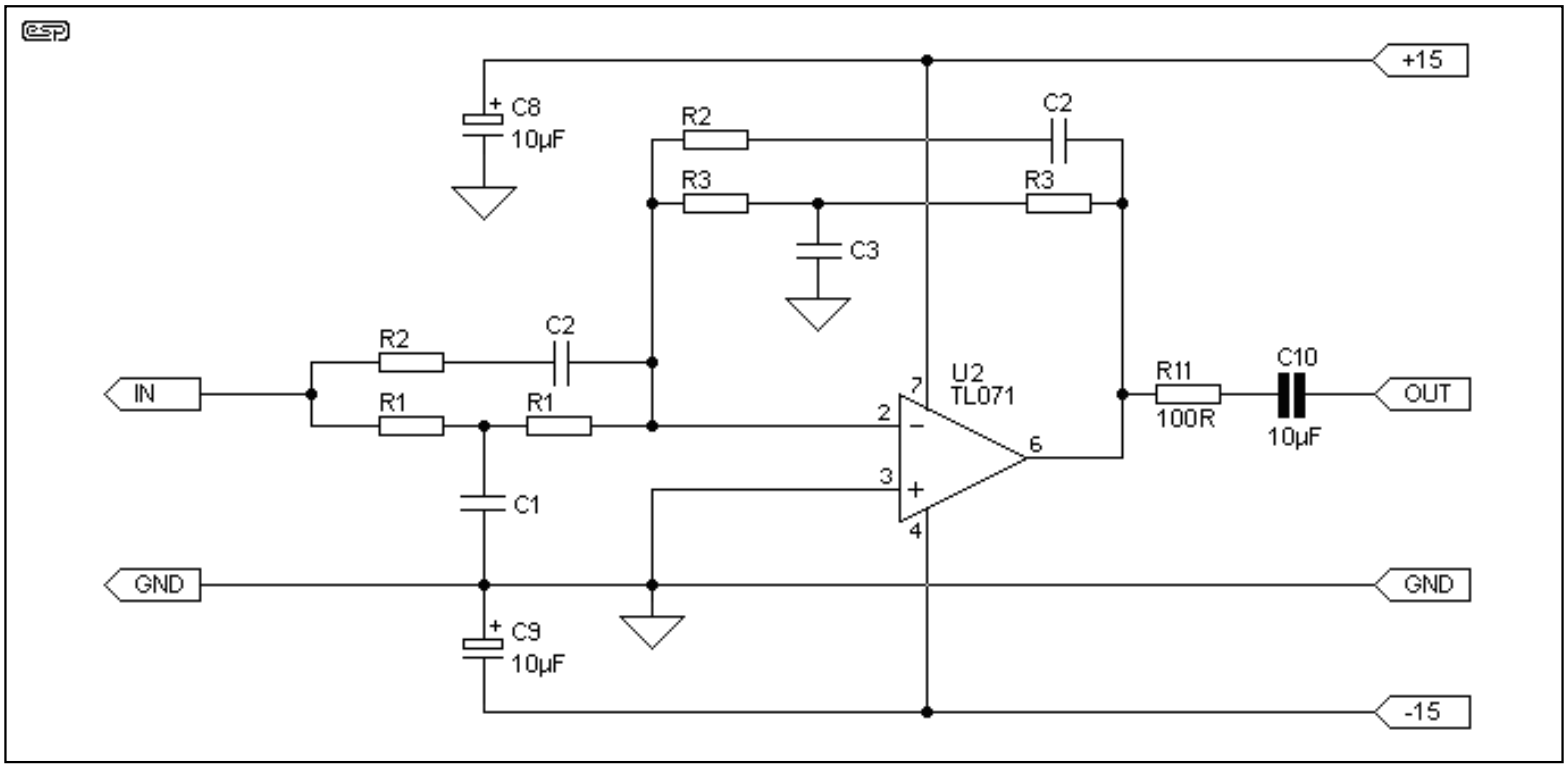

Figure 2 - Linkwitz Transform Circuit

When designing the circuit from the spreadsheet, the dire warnings about DC gains above 20dB may be ignored, as the circuit shown has zero gain at DC. The input circuit has been designed to roll off (i.e. is 3dB down) at 7Hz, with a 6dB/Octave slope. The spreadsheet does not show this, but it must be considered regardless.

I will instead issue my own dire warnings about excessive (greater than 20dB) gain at any frequency. Not allowing for the reduced radiating efficiency of any driver at very low frequencies, this is a simple case of determining the power requirements to obtain a flat response down to (say) 20Hz.

Let's assume that the power needed at 100Hz is 25W to keep up with the main system. if a given design shows that there is a 3dB gain at 50Hz, this means that 50W is needed for this frequency. As frequency reduces, the gain increases, and each 3dB of additional gain demands double the power. A mere 6dB of gain requires 100W, 9dB means 200W, and 12dB of gain means that 400W will be needed. For a gain of 15dB, we are now into serious power requirements, with a system power of 800W.

If you make the box as large as practicable, the amount of boost is reduced considerably - as always, there is a tradeoff between the allowable size of the enclosure, and how much power you are willing (or can afford) to use. The power limits of the driver itself must also be considered, and although most loudspeakers can tolerate transient signals higher than their rated power, they will have excessive distortion if excursion limits are exceeded.

Fortunately and perhaps surprisingly, the very low bass signals typically recorded are not that loud, so you will never need the full amount determined from the estimations above. One thing that is essential is to use a speaker with high efficiency - the higher the better.

Loudspeaker Driver Selection

Selecting a high efficiency driver with a low free air resonance and a relatively small equivalent volume (Vas) means that the minimum amount of equalisation can be used. Again, each 3dB increase in efficiency means half the power is needed for the same SPL, so a speaker with 92dB/W/m is preferred over one with 89dB/W/m (all other things being equal), as only half the power is needed for any given SPL with the more efficient driver.

I will not suggest drivers, and it is entirely up to you to find suitable components based on manufacturer's details. I suggest that you look at loudspeakers intended for car sound systems, as these usually have a reasonable efficiency and low Vas. The range is enormous, and there are many excellent drivers that will not cost the earth. There are also many other excellent drivers that *will* cost the earth - your choice.

Apart from efficiency, Vas, resonance (etc), also consider the excursion limits of the driver. A speaker that has Xmax of 20mm will perform much better (and with a lot less distortion) than another similar driver with an Xmax of 10mm. In much the same way, a 380mm (15") speaker will produce more SPL with less excursion than a 300mm (12") speaker can. Also consider using multiple smaller drivers - two 300mm drivers have more cone area than a single 380mm speaker, and can move more air.

A simple test for drivers is to apply a signal at 20Hz from a clean audio oscillator. Using an amp of about 100W or so, and with the driver mounted in an enclosure of no less than about 28 litres (1 cubic foot), increase the level until the amp starts to clip - this will be immediately audible! Just below the clipping level, listen carefully for any audible frequency that is not 20Hz (which itself is virtually inaudible). In particular, if you hear 40Hz or (more likely) 60Hz, the speaker is distorting, and generating harmonics. With a good driver, you should be able to see the cone rushing back and forth, but should only feel the air movement - no audible harmonics should be heard.

An Example Calculation

Let's look at a hypothetical driver with the following characteristics (these are inserted in the "Box" page) ...

Measurement	Symbol	Value
Free air resonance	fo	24 Hz

Total Q	Qts	0.38
Equivalent volume	Vas	134 litres
Box volume	Vb	28 litres

We would like to get to 20Hz (-3dB), so insert these values into the spreadsheet. For Q(p) (total Q of transformed" system) of 0.8, we get a very small rise before the rolloff starts, which extends bass response marginally.

Now, select a value for C2 - this will determine the values for the remaining components, and is a compromise. As its value is increased, the resistances needed are reduced (this is good), but the value of C1 increases (sometimes to rather large values - this is bad).

I have been asked for definitions of "good" and "bad" in this context, so here they are ... "good" is resistance in the range of about 2.2k up to around 220k or so. Lower resistance loads the opamp, and higher resistance may increase noise levels. "Bad" capacitance values are those that are big and expensive, and if possible, I suggest that you keep the maximum capacitance below 2.2uF or so. Higher values will not hurt anything, but are bulky and expensive, or (in the case of non-polarised electros) may be small and cheap, but have a wide tolerance so accuracy will be compromised.

In the end, you will have to settle on values that are probably outside these goals, and in the end, noise is not really a big problem at low frequencies. The primary aim is to get values that are available - designing the perfect circuit is pointless if it won't do the job.>/p>

With the selected value of 56nF for C2, the following values are calculated for the remaining components ...

Component	**Calculated Value**	**Use ...**	**Actual Value**	**Error**
R1	8.44 k	8k2 + 220R	8.42 k	0.24%
R2	36.98 k	33k + 3k9	36.9 k	0.22%
R3	70.32 k	68k + 2k2	70.2 k	0.17%
C1	1.905uF	1uF + 1uF	2 uF	5.0%
C2	56 nF	56 nF		0%
C3	228 nF	220 nF		3.5%
Maximum gain	18.41 dB			

It will be necessary to use resistors / capacitors in series (or parallel) to obtain the required values - this can often be quite irksome, but only needs to be done once. A final error of up to 5% is almost certainly going to be OK, as the speaker characteristics will usually vary much more than this, and our hearing is incapable of resolving such small errors - especially when the room acoustics interact with the total system!

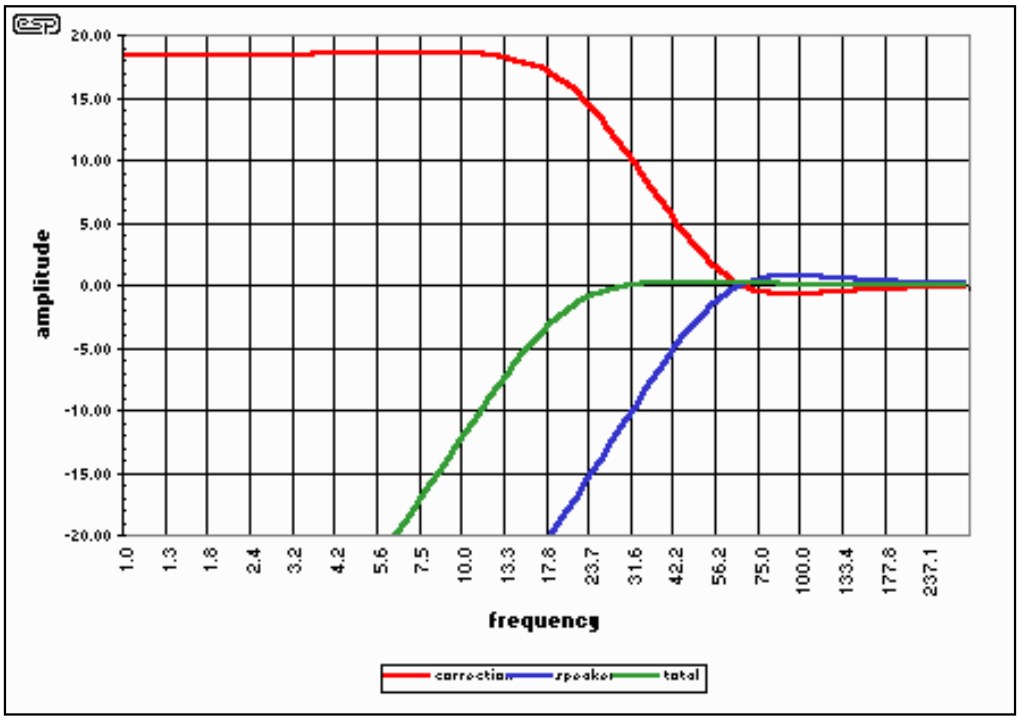

Figure 3 - Response Curves

Note that the maximum gain is over 18dB - this is rather high, but the energy levels at such low frequencies are actually very low as well, so although it may seem that an enormous amount of power will be needed, this is probably not really true in reality.

To work this out, let's have a look at the speaker sensitivity. We will make an assumption that it remains constant, although this is rarely true as the frequency falls, due to the radiating efficiency of the driver itself. The assumption will work out well enough in practice (he says from experience).

Assume a quoted efficiency of 90dB/W/m as a starting point. For "normal" high level listening, an SPL in the listening room might be around 100dB, which represents a power of 10W. Remember, this is worst case, and assumes that the LF energy level is the same as at upper frequencies. For all practical purposes, the lowest frequency is about 25Hz - our ears respond very poorly to anything lower.

> For what it is worth, a good source of a 25Hz signal is the heartbeat at the beginning of Pink Floyd's "Dark Side of the Moon". This should rattle windows, and be felt as much as heard.

So, 10W to get 100dB (which is pretty loud), and we have a 15dB boost at the 25Hz point. Since each 3dB increase involves doubling the power, we get the following ...

First, the power needed to get to 100dB ...

Power	1W	2W	4W	8W	10W
SPL	90dB	93dB	96dB	99dB	100dB

Now, the power to maintain 100dB as the speaker rolls off and the equalisation compensates ...

Power	10W	20W	40W	80W	160W	320W	640W

Boost	0dB	3dB	6dB	9dB	12dB	15dB	18dB

This is not entirely correct with music signals, because the above figures are for steady state signals, and music is transient in nature (well, most of it, anyway :-). Peak power levels may be much higher at some frequencies, typically around 70-80Hz where kick drums make most of their noise, but the amp has copious reserve power at these frequencies. The underground railway rumble in that otherwise wonderful orchestral recording will be at a very low level, and most music has very little below 30Hz. If you enjoy pipe organ music, I suggest two to four 380mm drivers in a reasonable sized box (around 50 litres per loudspeaker), and equalised as described here. To get realistic response to 16Hz will require about 300W per speaker, for a quoted sensitivity of 90dB (actual figures will vary depending on the drivers selected, of course). This will be truly awesome, and if your dwelling survives, you may be able to defray some of the system costs by acquiring adjoining properties at an advantageous price :-)

The biggest benefit of a subwoofer that goes to such depths is that you will find yourself listening at lower levels than before, since the "feel" that used to require an SPL of perhaps 110dB or more, is now attainable at maybe 95dB SPL. There is no loss of realism - indeed it is enhanced - and your ears will love you for it, and for all the right reasons.

PCB Version Of Circuit

The PCB for this circuit is available. It has been simplified from the circuits shown above, and retains a rudimentary phase switch but no mixer. Mixing can easily be done using a pair of (say) 22k resistors from each channel to the input, provided the impedance is low enough from the preamp to prevent crosstalk.

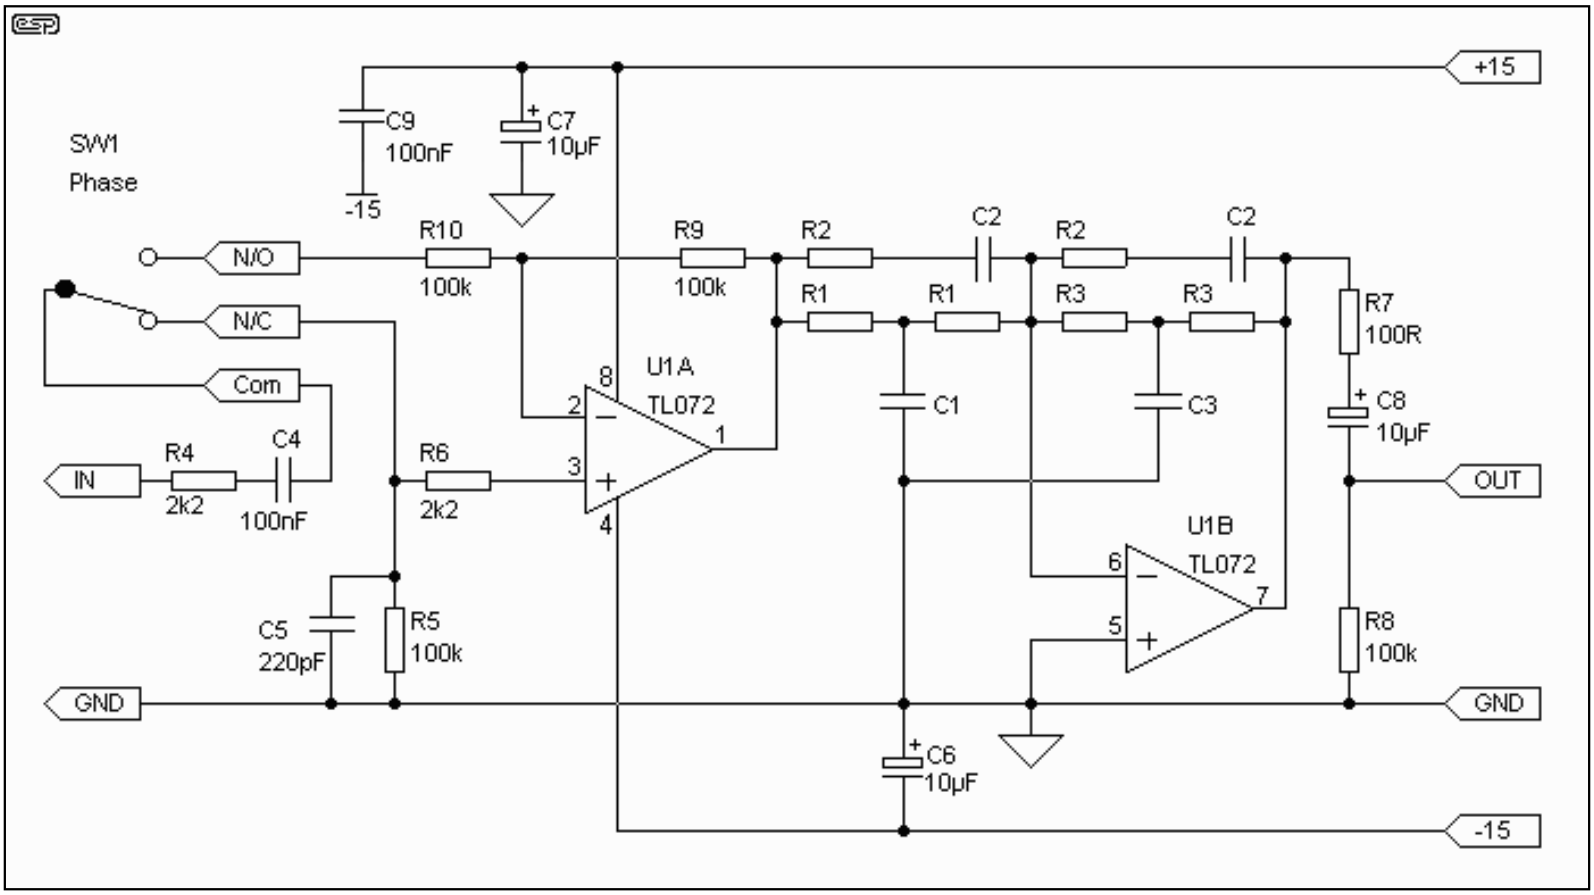

Figure 4 - PCB Version, Complete Circuit

If you don't want to use the phase switch, the Com and N/O (Common and Normally Open) pins can be linked on board to give a non-inverting configuration (note there are two inversions in the circuit). Link Com and N/C for inverting operation.

Because of the DC gain in the circuit, you may find that C8 is incorectly polarised when the circuit is powered on. I suggest that you either use a non-polarised cap, or measure the DC, and determine the correct polarity before this cap is installed. Because of the different way opamp inputs are configured, the output will be positive or negative, and I cannot predict which way it will go, since constructors will want to use different opamps in many cases. The polarity is correct for the TL072, but will be reversed if (for example) an LM1558 were to be used, since the latter has a bipolar input instead of FETs. The exact offset voltage is also difficult to predict, but using the TL072, should be less than 300mV. Other opamps can be expected to be similar.

This circuit was devised to be as cheap as possible to build, but provides for parallel connection of caps for C1 and C3, and series resistances for R1, R2 and R3, since these will usually be odd values (as shown above).

VP103 Hi-Fi Valve Preamplifier

Price - AU$1,800 (+ 10% GST for Australian residents)

The design is no compromise, with the following features:

- Massive overload margin - input signals up to 10V rms will not clip the input amplifier
- A timer changes the front panel power indicator as the unit warms up
  - Red - Should not use, not temperature stable
  - Orange - May use, but not completely stable yet
  - Green - Unit is ready for use
- The power supply uses massive capacitance (for a valve circuit), completely eliminating hum on the DC supply, and providing excellent rejection of short-term mains variations as well as providing an extremely low impedance voltage source
  - Fully regulated 12.6 Volt DC heater supply to eliminate induced hum and noise and provide optimum heater operating voltage at all mains voltages
  - Current limited heater supply, to reduce inrush current (typically a major cause of valve heater failures)

- Standard valves are used at the lowest practicable voltage and current, ensuring maximum valve life · Local feedback is used on each amplifying stage to reduce the effects of valve ageing, and reduce output impedance and distortion
- Very low distortion. Even at an output level of 5 Volts rms and a load impedance of 10k, distortion remains below 0.2%
- Frequency response from 10 Hz to 150 kHz (-1dB)
- Channel balance better than 0.5 dB
- Auxiliary mains output for VR102 Phono preamp or other low current device (this must not be used for power amplifiers). NOTE: Aux mains output is switched but not fused
- Rear panel level controls for CD and Tuner inputs, to allow their level to be matched to other components in the system
- All signal paths use traditional point-to point wiring, and not a printed circuit board
- All signal paths are shielded by a ground plane, made from un-etched fibreglass PCB to ensure minimal hum and noise pickup
- Valves are matched to ensure optimum channel balance is maintained
- High quality 1% metal film resistors are used exclusively (except for one 1 watt resistor in the power supply), to provide low noise and long term stability
- All electrolytic capacitors in the signal path are low leakage types, and are bypassed with polyester caps to ensure optimum high frequency performance

---

Please Note

The ***VP103*** is not a production item, and for the time being will be built to order only. If the unit goes into regular production, this will be determined by the response I get to various market probes (this being one of them). A photograph of the interior of the prototype is shown at the end of this section. The final version uses a high quality custom made case with CNC engraved front and rear panels.

This preamp sounds superb - open, with a stable stereo image, and detailed highs. The

specifications are as follows:

Specifications (all measurements relative to 2V rms output unless otherwise stated)

Distortion	< 0.2% (10k load)
Signal to Noise Ratio	> 70dB
Maximum input level	10V rms
Maximum gain	18dB / 10dB*
Tape Output Gain	6dB
Crosstalk (at 1kHz)	- 65 dB
Crosstalk (at 10kHz)	-50 dB
Frequency Response	10 Hz - 150 kHz (-1dB)
Channel Balance	Within 0.5dB **
Operating voltage	115 / 230 / 240 Volts AC

* I have found it necessary to provide two gain settings (switch selectable), since a gain of 18dB is too high for many power amplifiers.
** Channel balance is expected to be better in the production version, but it is not possible to predict by what margin at this stage.

The unit follows the minimalist approach, with the only front panel controls being the power switch and indicator, a 6 position rotary input selector switch and a volume control.

Inputs are provided for:

- CD Player
- Tuner
- Phono (external preamp required)
- DVD Player
- Tape
- Auxiliary

And the outputs are

- Tape (to Cassette, MiniDisk, DAT, etc)
- Main (to amplifier)

Note that the phono input is a simple line level input, since the ***VP103*** has no inbuilt RIAA equalisation amplifier. The ***VR102*** Phono Equaliser is likely to become available shortly after the ***VP103*** is in production, or the user may choose any other RIAA equaliser which has an output voltage of around 300mV to 1V rms.

Rear panel level controls are provided for the CD and Tuner inputs, since these devices rarely have output level adjustment. This allows the gain for each device to be set, so there are no radical differences in sound level when changing signal sources.

In anticipation of the ***VR102*** Phono Equaliser, there is a switched rear panel mains output. This is not to be used for the power amplifier (however tempted one may be), as it is low current only (<2 Amps max.).

All input and output RCA connectors are gold plated.

The case design for production is not complete, but will be all aluminium, powder coated in dark grey, with ventilation slots on the top and bottom. The front panel is black anodised aluminium, with all markings engraved.

Dimensions are fairly standard for hi-fi equipment, being:

- 44mm (1 3/4") High (1RU)
- 420mm (16 1/2") Wide
- 300mm (11 3/4") Deep

Photo of the interior of the prototype VP-103

The 3 dual triodes can be seen on the right, and are mounted on a piece of PCB for shielding only. The power supply occupies the left hand side, and the heatsink is for the 12.6V DC heater regulator.

Input switching is all performed at the rear (hence the long extension shaft), close to the input connectors. The two pots at the rear are for the tuner and CD inputs, to allow them to be adjusted to match the level of other sound sources.

As this is the prototype, the case is not a final design, but an off the shelf 1 Unit rack cabinet (with the ends cut off). The final design is completed (but not yet available), and is far more robust and looks better, too.

Some Musings

There is something of a resurgence of valve (or tube) amplifiers of late, and it is worth while taking a look at the reasons. There are those who will simply buy whatever is in fashion, but they are a small minority, so what is about valves that has experienced hi-fi buffs waxing lyrical about technology that is (or was thought to be) well past its use-by date?

I don't have the answer (unless 42 is acceptable), but during the design of the ***VP103***, some very interesting facts came to light (or to be more precise, I was reminded of a few things which had faded somewhat).

Distortion

Everyone knows that valves have greater distortion than transistors or integrated circuits, but is this a bad thing? Apparently not, provided the levels are kept low and are predominantly second harmonic. This is a characteristic of valves - if properly designed - and it seems to be accepted as a part of that 'valve sound'.

Where it gets interesting is in overload. All transistor and IC amplifiers are limited by relatively low supply voltages (typically +/- 15 Volts), and at some point just below the power supply voltage they clip - not gently or progressively, but hard and fast. So fast in fact, that harmonics are immediately generated well beyond the limits of our hearing.

"Ah, but a preamplifier should never clip - there should be plenty of headroom for all practical input sources", I hear. I agree with this, and in my own testing have never seen a properly designed preamp clipping internally (unless you do something silly, like turn the power amp gain right down and then drive the preamp into distortion).

However, it stands to reason that 20dB of headroom might just help with transients, and perhaps this is one of the deciding factors?

Slew-Rate

Then of course there is 'slew-rate', which is the speed that the output can change. This is typically measured in volts per microsecond (V/us), and most modern IC devices have a slew rate which is greater than 10 V/us. This is far greater than is needed for audio, where a measly 0.5 V/us is actually sufficient even for a low power amp - except it sounds awful.

Valves have no slew-rate limit as such, since there is no compensation capacitor used (although the internal grid to plate capacitance does have a similar effect, but is much less savage). Instead, the signal simply rolls off smoothly once the upper limit has been reached. At no frequency or amplitude will a valve convert a sine wave into a triangular wave, as will many opamps and power amplifiers.

Negative Feedback

When a preamp is built using IC or discrete opamps, there are actually tens to several hundred active devices in the signal path. Each of these contributes it own little bit (gain, noise, distortion, etc), and the overall signal is tidied up using negative feedback. This works so well that with the latest opamps, distortion cannot be measured with a simple noise and distortion measuring set. Indeed, the signal source is likely to be an order of magnitude (or several) worse than the device under test.

Perhaps it is this clinical treatment of our sounds that is somehow to blame - can an amplifier be too good, too clean? I don't know, but there is a marked difference between a 'solid state' and a good valve preamp - with the latter having more 'air', and a sense of openness that IC and transistor units don't. Even here, it is difficult to be objective, since I used an opamp preamp for quite a few years, and it is quite possible that the difference is imagined.

Most valve circuits use little or no negative feedback in the preamp stages. The ***VP103*** is an exception, but even here, the level of feedback is very low. Valves have a relatively low gain (especially compared to opamps, which have a low frequency gain of over 100,000), so massive feedback is not an option, since there is not enough gain to spare.

Class-A

A valve preamp is pure Class A - it has to be, since it is too difficult (and a completely useless exercise into the bargain) to build a Class B valve preamp. Virtually all IC opamps have a push-pull output stage which spends some of its time in Class B. Perhaps this generates some artefact which I have been completely unable to measure (along with many others), but which is audible. The various laws of acoustics would indicate that any such artefacts would be inaudible (due to masking, among other things), but there seem to be many things in audio which don't seem to obey the law! (At least according to some reviewers and the like.)

Open-Loop Frequency Response

This is one area where the valve is measurably vastly superior to opamps. The gain of an ordinary opamp from DC to (about) 100 Hz is typically 100,000 - but after the compensation circuit is added, this rolls off at 6dB/octave after the 100 Hz point is reached. This means that at 200 Hz, the gain is down to 50,000 and by the time you get to 25 kHz, the gain will be down to a little under 400 (or less). Premium opamps are better, but the same thing still happens - its just not as severe.

What this means is that the input signal gets less and less feedback compensation as the frequency increases, so the distortion and output impedance will both increase in proportion.

With a valve preamp circuit, the gain is (or should be) pretty constant from the lowest operating frequency (determined by coupling capacitors, which cannot be avoided), up to 50 kHz or so, and will roll off very gently after this. Even if feedback is used, it will be constant over the audio range and beyond, which may account for some of the perceived difference.

Conclusion

I don't know! What I do know is that my valve preamp really does sound better than (or maybe just different from) a transistor or IC preamp. As little as 10 years ago I would have probably taken the opposite view, but upon reading reviews and then deciding to build one just to hear it has changed my thinking.

Elliott Sound Products **Project 82**

Loudspeaker Test Box

Rod Elliott (ESP)

Introduction

Testing loudspeakers is covered in some detail in the passive crossover article (see Design of Passive Crossovers), but it is irksome at best to have to fiddle about with clip leads and components lying all over the workbench. This simple project is intended to make life that little bit easier when you are trying to determine the optimum frequency compensation network for woofers and midrange drivers.

Description

They don't come much simpler than this. A suitable plastic box, a couple of switches, 4 combination binding posts / banana sockets, a handful of capacitors and a wirewound pot complete the entire project.

Of all the components, the pot is most likely to cause problems. The suggested value of 30 Ohms was used in my case because I just happened to have one lying around in my junk box, but they don't seem to be easy to get. A very basic tweeter attenuator may work OK, and the value is not that important. Even a resistance as low as 8 Ohms could be used, with a switchable 8.2 Ohm resistor in series so that the range will be from 0 to 16 Ohms (near enough). I shall leave it to the individual to determine the best way to achieve the required range, which is typically 0 to 20 Ohms.

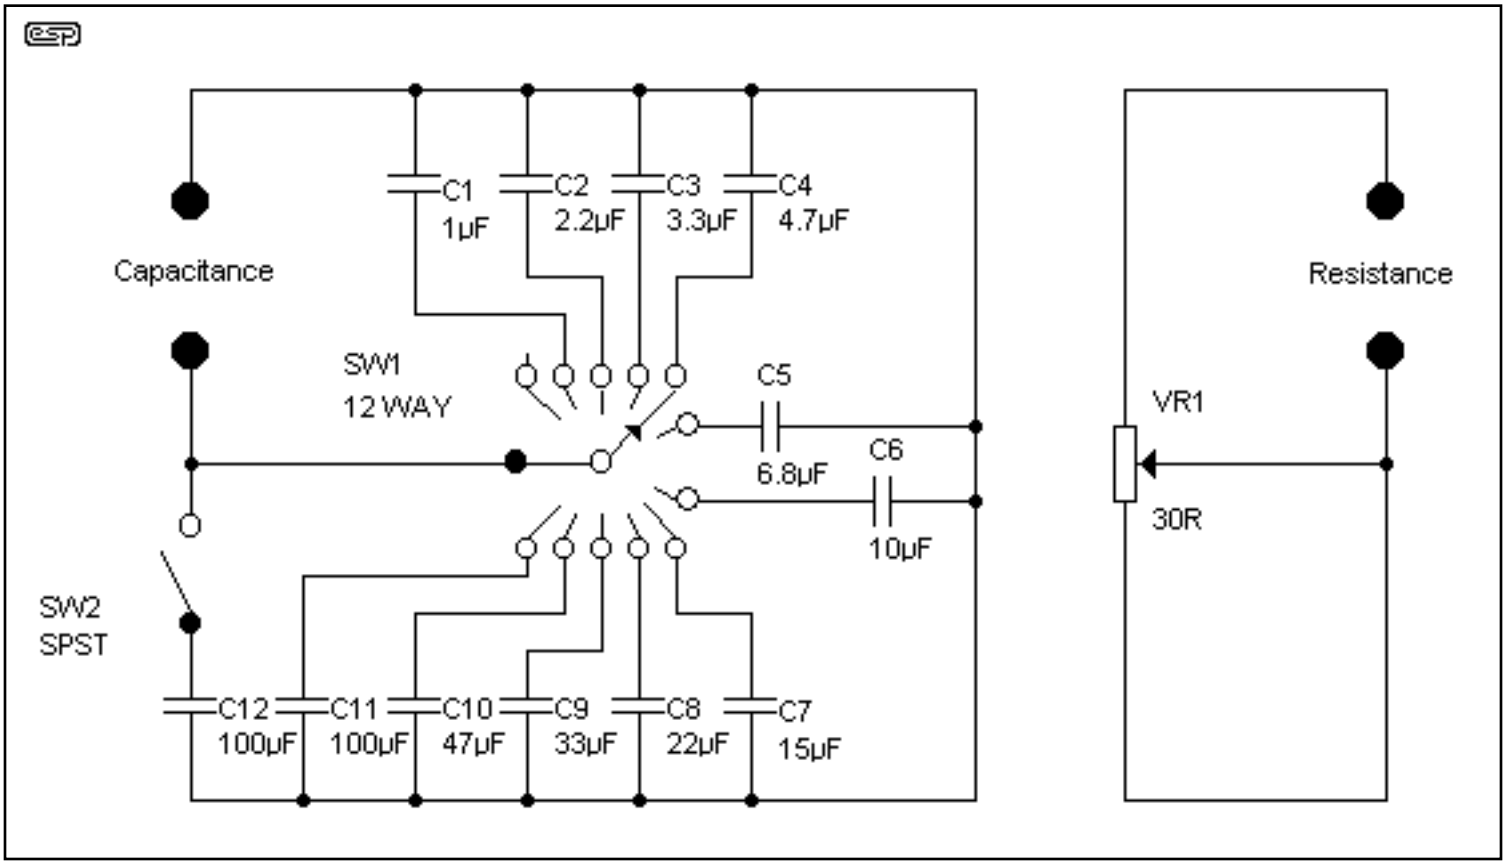

Figure 1 - Complete Circuit of Test Box

The switch SW2 and associated 100uF cap is optional, and increases the range up to 200uF - in most cases this won't be necessary though. The caps are all bipolar electrolytics, and this is perfectly OK, since they will not be used at high power, and their sonics are not important (assuming that you can hear the difference anyway).

To use the box, simply connect it across the speaker - mostly you will want the caps and pot in series, so a lead between the two (or even a switch) makes this easy. From the output of suitable small amplifier, place a 100 ohm or so resistance in series with the output. Sweep the signal frequency across the speaker. Resonance will not be affected, but there will be a "magic" combination of capacitance and resistance that will make the impedance above resonance completely flat. No maths, no spreadsheets, just a quick frequency scan and twiddle a couple of knobs to get the values needed to ensure that the crossover actually will work at the design frequency.

The network derived from the testing will be placed in parallel with the speaker, and prevents the rise of impedance with increasing frequency. This rise is caused by the inductance of the voice coil, and plays havoc with the performance of any passive crossover network.

Impedance Measurements

One of the most difficult measurements to make in audio is impedance, but this is also made relatively simple. Carefully measure the voltage across the speaker at the crossover

frequency - this will (of course) be the same as the voltage anywhere else outside of the resonance affected area of the impedance plot.

Dissconnect the speaker, and without changing anything, connect the pot (all by itself) instead. Adjust the pot until the voltage is exactly the same as you measured before, when the speaker and parallel network were in place. Disconnect the amp, and measure the resistance of the pot - this is the speaker impedance, and it is this - ***not*** the "nominal" impedance - that must be used to calculate the crossove network components.

Don't change the frequency from the generator or the amp level just yet ...

In many (OK, all) cases, it is highly recommended that the tweeter is also measured for impedance, and a resistance used in parallel so that the impedance at crossover exactly matches that of the woofer or midrange driver. Simply connect the tweeter across the amp, with the pot in parallel. Carefully adjust the pot until the voltage is exactly the same as that measured before (this is where a pot that goes up to about 30 Ohms is useful). When the voltage is the same, disconnect the amp and tweeter, and measure the setting of the pot. This is the resistance that should be used in parallel with the tweeter to make everything work properly.

This is a simple procedure that works extremely well, and my test box has been used quite a few times in the short time I have had it. The measurements described in the Design of Passive Crossovers article work well, but this is much quicker, and is "real", in that you can see the effect of varying resistance or capacitance easily. There will nearly always be a compromise in the crossover design, and this little test box lets you see exactly what happens, and select the best possible combination for the speaker drivers you are using.

Cross-Over Network; Air Core Inductor Calculator

6/98 - Jens Moller - http://www.colomar.com/Shavano/inductor_info.html
updated 5/02, 3/04, 5/04 and 07/05

Many people have asked me for a copy of this program. It is not for sale (it remains a free service of this Web Site). This Web Site's goal is provide solutions for Musicians who are making their own gear, and in general, are not interested in the math; rather, they simply need working solutions.

The program is based on a series of equations that are available in many Electrical Engineering texts dealing with Inductors, along with a knowledge of wire characteristics. If you want to duplicate the effort for your own purposes, please consider discussing it with an Electrical Engineer or a College Professor who teaches Electrical Engineering, and see if they will assist you in your efforts. You will need to be fairly good at math and programming to recreate the functions of this application.

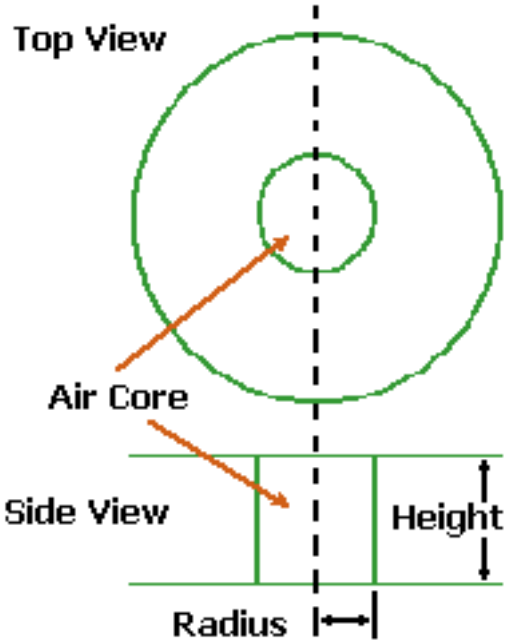
If you are building your own cross-over network, you'll find that the inductors used most frequently for high powered systems are simply large coils of wire. You might be able to save some money by winding your own. You also might be able to more specifically design your cross-over by creating an inductor that is specifically the value you need rather than a standard value.

The following application will generate a design, if you tell it what the inductance needs to be (in milli-Henries - mH). It is intended for solutions within Audio frequency ranges.

Please fill in the following Information.

Inductor mH: [ ] (milli-Henries)

Generate Results | Reset



When you make the form, it should allow you to create an inductor that has this general shape. It may be possible to find pre-made forms, but you really don't need one once the wire has been wrapped and secured.

You'll need to create a form (this could be made of plastic or wood; what ever you have available) to wind your inductor in. You'll need to be able to have the correctly sized opening to wind the core onto (the program gives that as Radius - multiply this by 2 to get the diameter), and you'll need to be able to brace the form to keep the windings together at the right width.

Once wound, use plastic/ nylon Wire Ties, or electrical tape, to hold the inductor together. These can become quite warm when in use. The DC Resistance is an indicator of how much power these will soak up - the lower the DC Resistance the better. For example, if you create a 10 mH inductor using 26 gauge wire, its DC Resistance is 8.27 Ohms - which is approximately the same as the 8 ohm impedance of the Woofer - this implies that the Inductor will absorb an equal amount of power as the Woofer will. If you try to pump 200 Watts into this, the Inductor will dissipate 50 percent (or 100 watts) and will most likely fail in short time. Using 14 gauge wire changes the DC

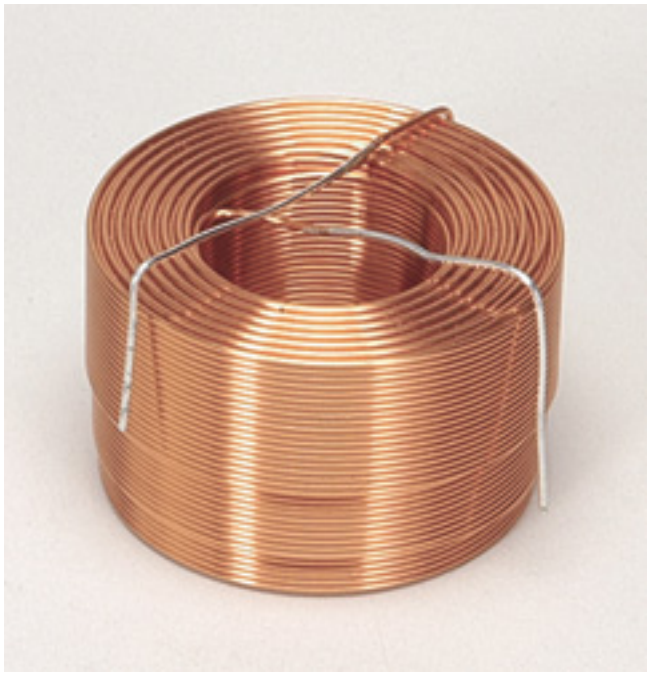
Resistance to .90 Ohms, and instead, the Inductor absorbs only approximately 10 percent of the power (or 20 watts). It still gets warm, but it won't fail catastrophically.

Use transformer wire that has a lacquer finish. Do not use wire that has plastic sheathing around it - this is not appropriate for winding these Inductors.

The program rounds up or down to the next full turn.

For assistance in determining cross-over points, See: First Order Crossover Networks and Second Order Crossover Networks

The end results will looks something like these:



You may need a source of this type of wire (it needs to be solid wire that has a thin coating that insulates it electrically). This is normally called 'magnet wire' or 'bell wire'. For your reference, here are the first three sites that came up when I looked for 'magnet wire 18 gauge' in a search engine (I have no association with these at all):

- http://www.parawire.com/18gaugemagnetwire.shtml
- http://www.powerwerx.com/magnet-wire.html
- http://www.elexp.com/cbl_mg30.htm

This one was suggested by someone who buys lots of wire:

- http://www.mwswire.com/

I often buy my wire at electronic surplus houses - you can get exceptional deals there if you are lucky.

All Wire gauges are AWG - see Comparing SWG to AWG - Wire Gauge for more information.

Barry's Inductor Simulation

LC Time Simulation Home Up Site Map Wire Loop

This is a Java simulation of an air-core inductor. You should see an applet (below) with slider controls to select the coil's dimensions and wire size. (Trouble? See below.) Note this is only the coil and does not include a projectile.

Inductor Simulation

This program calculates inductance using Wheeler's Formula:

$$L\ (uH) = \frac{0.8 * (N*A)^2}{(6A) + (9B) + (10C)}$$

where N = number of turns, A = average coil radius, B = coil length, and C = coil thickness. All dimensions are in inches and the result is microhenries. The simulator handles all necessary conversions to metric and millihenries.

The simulator will incidentally give you other handy information, such as the number of turns and the length of wire needed.

Your goal in this simulator is to design a coil with a certain amount of inductance. You should have **already chosen** a target inductance value somehow, perhaps by experimenting with the RLC Simulator program. Here you can try various wire sizes and physical dimensions to see what happens. The idea is to design a coil which can be physically built, and which has a reasonably low amount of resistance.

Q. What is a circular mil?
A. Unit of measure used to define the area of a wire. The area of a circle one one-thousandth (0.001) inches in diameter.

Trouble?

This program requires Java Runtime Environment (JRE) 1.4 or above. You can download it by visiting http://java.sun.com/j2se/1.4.1/download.html and scroll to the section "**Download J2SE v 1.4.1_06**". Look in the "**JRE**" column for your own operating system.

Download and install the JRE, or if you write Java code then get the software developer's kit (SDK) instead.

If my applet still doesn't work, try to open your Java Console window in your web browser. Copy and paste its contents into a message and e-mail it to me for trouble-shooting.

About the Program

The program was written with NetBeans (www.netbeans.org) and IntelliJ (www.intellij.com) using AWT classes. My Java source code is open and **freely available** in these files:

- InductorSim8.java runs the user interface and simulates the coil.
- CopperWire.java is a helper class that describes characteristics of copper wire, using values graciously supplied by WireTron, a manufacturer of wires for electromagnets. Any errors are solely my own.
- CopperWireTest.java is a unit test (based on JUnit) to help keep it working while I make changes.

I want to keep the Internet clean so please report bugs, request features, make suggestions and send me compliments about this simulator. Of course I am also grateful if you send suggested updates in Java source code form!

hits

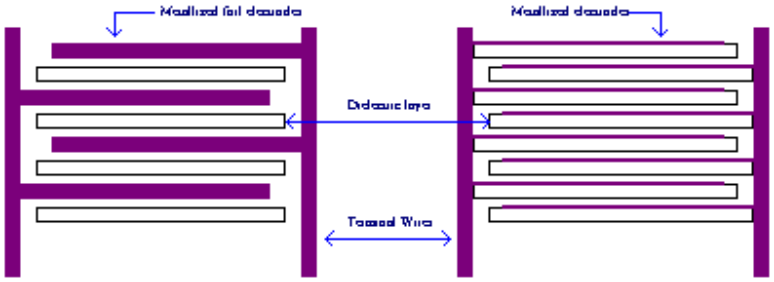
This data sheet is a compendium of facts and recommendations on the usage of capacitors readily available at Caltech. Important parameters to consider and their effects: ESR (power dissipation in the capacitor and useful frequency range), tolerance (ability to plug it into frequency sensitive circuits), temperature/aging drift (capacitance changes in sensitive circuits), ESL (useful frequency range).

Film capacitors: A relatively large family of capacitors, they differ pretty much just in their dielectric properties. Available capacitance ranges from 10pF - 15uF depending upon the actual type of capacitor. Members include polyester (polyethylene terephthalate or Mylar™ from DuPont), polystyrene, polypropylene, polycarbonate, metallized paper, etc.

Temperature coefficients of selected dielectrics:

Capacitor Type	Typical Temperature Coefficient
polyester (Mylar)	600 to 900 ppm/deg.C
polypropylene	-200 ppm/deg.C
polystyrene	-125 ppm/deg.C
polycarbonate	+100 ppm/deg.C

Two distinct subfamilies of the film capacitors are film and foil and metallized film .



film and foil metallized film

Quoting from The Circuit Designer's Companion:

There are two common methods of providing the electrode; one has a separate metal foil wound with the film dielectric, the other has a conductive film metallized onto the dielectric directly. The film and foil construction requires a thicker dielectric film to reduce the risk of pinholes, and therefore is more suitable to lower capacitance values and larger case sizes. Metallized foil has self-healing properties - arcing through a pinhole will vaporize the metallization away from the pinhole area - and can therefore utilize thinner dielectric films, which leads to higher capacitance values and smaller size. The thinnest dielectric in current use is of the order of 1.5um.

Generally, higher power and more precise applications will require film and foil, but the metallized film capacitors are very nice.

Metallized paper capacitors hold a niche high voltage application because when arcing occurs, less carbon buildup occurs, keeping the risk of fire low.

Look at temperature and voltage limitations to aid in trimming down your choices.

Ceramic: The common form is the multi-layer or stacked ceramic (monolithic); single layer also exists (ceramic disk). Physically, the multi-layer looks like the film and foil above, a dielectric stuffed between metal plates. The multi-layer is marginally more expensive than the single layer.

Ceramic capacitors are separated into three common grades of dielectric. The three grades go by the following names:

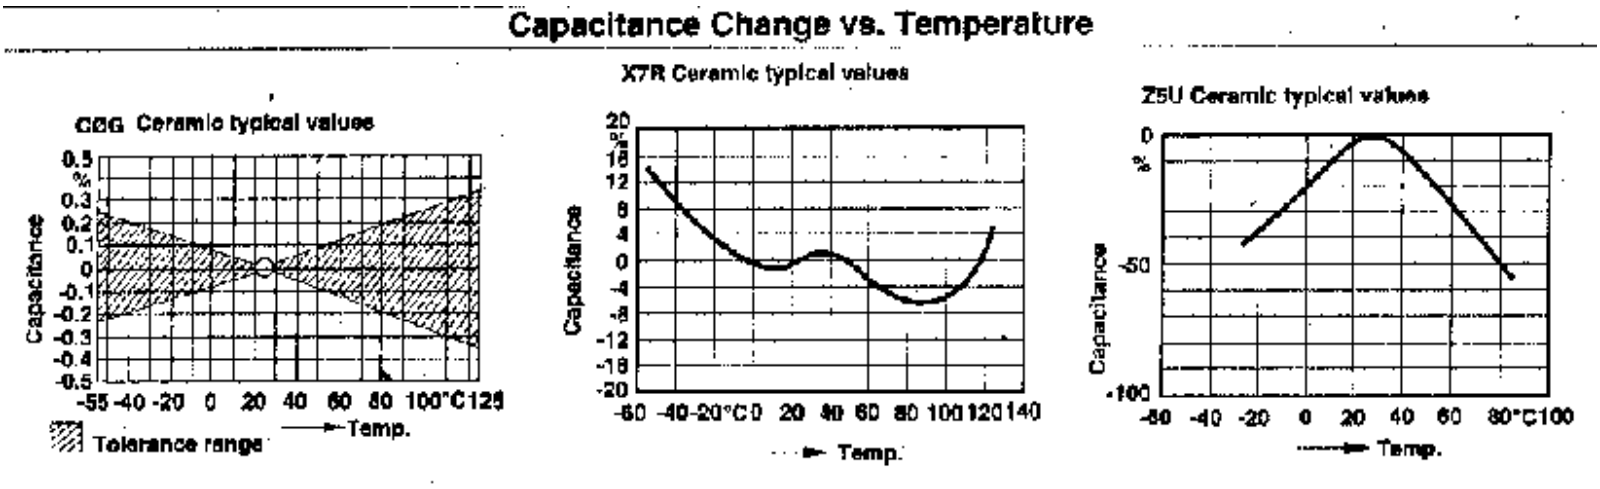
C0G or NP0: best in all features except permittivity; due to the low K (dielectric constant) of the dielectric, these are physically larger than equivalent values in the other grades; also, typically range of values 4.7pF to .047uF. Typical tolerance 5%.

X7R: just a bit more expensive than the low grade Z5U, but improved in tolerance and temperature characteristics. Temperature coefficient is

non-linear, however. Typical range of values 3300pF to .33uF. Typical tolerance 10%.

Z5U: Suffers from a relatively large temperature coefficient. Good points include price and size. These are the classic bypass capacitors. Typical range of values .01uF to 2.2uF. Typical tolerance 20%.

Temperature behavior of the 3 ceramic dielectric grades:



How to use these capacitors?

Z5U: bypass, coupling

X7R: notice the lack of small values; similar to cheaper film capacitors; useful for non-critical timing, coupling.

C0G: very good capacitors; tightly specified in tolerance and temperature. Tradeoff is size.

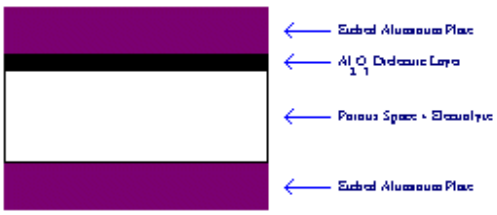
Ceramic disk capacitors are simpler to make than the monolithics. They hold a niche area as a cheaper and physically smaller (for the same capacitance value) alternative to silver mica. They are available with higher voltage ratings than monolithics. Since they only have a single slab, they are found with lower capacitance values (typical range 1.5pF to 2.2uF) than the monolithics (which can have 60-80 layers), but can still get large with a noticeable increase in physical size. At the upper end, too, the tolerance and temperature coefficients get extremely large.

Silver-mica: Another stacked, low K capacitor. Mica is really the general family name (mica is the dielectric); silvered mica is just the most popular form. Good points: low ESR, temperature coefficient between 0 and +100ppm/deg.C. These are very similar to C0G ceramics. They suffer, however, from high dielectric absorption. They are popular for their high frequency characteristics (up to 500Mhz). Typical values range from 2pF to 1500pF

Electrolytics: A "breakthrough" in capacitor technology in the early 1900's. Instead of placing a solid wedge of something (which can be quite thin), an electrolyte solution is used. The electrolyte serves as the 2nd electrode. The electrolyte is not the dielectric. The dielectric is a very thin layer of oxide which is grown electro-chemically in production. The thickness of this oxide layer is on the order of .01um, much smaller than any piece of plastic or ceramic that could be used as a separator. To contact the electrolyte, another piece of foil is used, but it is the electrolyte that is truly the plate.

There are 2 common electrolytic capacitors:

Aluminum Electrolytic: A side view of an aluminum electrolytic capacitor:

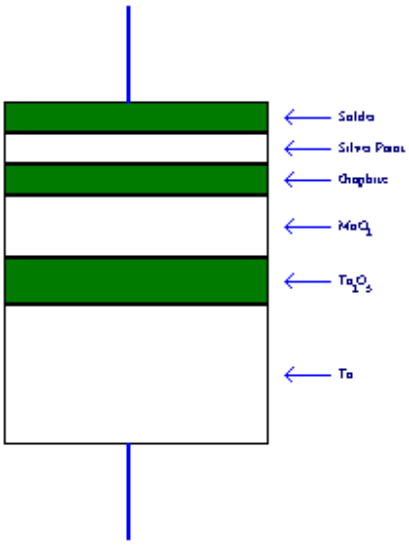


The electrolyte is held in a porous spacer. The Al plate is finely etched. Since the oxide is so thin, this etching increases the surface area, increasing the capacitance. A slab capacitor like ceramic would not benefit from this approach.

The porous spacer and both plates serve to thicken a single layer, but the important distance is the dielectric thickness, which is, of course, extremely small. Thus, electrolytics enjoy a huge capacitance density advantage over other capacitor technologies. One limitation to this technology is its polarized nature. With just a small reverse voltage, the oxide breaks down and current will freely flow. Another byproduct of this technology is the reduction in capacitance as you approach the working voltage of the capacitor. This is caused by a growth in the thickness of the oxide layer as a high voltage is placed across the capacitor. All the common aluminum electrolytics are prone to have the electrolyte dry out. This means that their lifetime is shorter than other capacitors, anywhere between 3 and 20 years depending upon the quality of the line, according to The Capacitor Handbook. If you really want your design to last, check out the aging information for your aluminum electrolytic. Typical values range from

Tantalum Electrolytic: Comes in both wet and dry electrolytes. The dry, or solid tantalum is the most common, and can't truly be called an electrolytic capacitor. Electrolytic is normally reserved for those capacitors in which one of the terminals is an electrolyte. Solid tantalums use manganese dioxide as the second terminal.

A side view of a solid tantalum capacitor:



The capacitor starts with solid Ta powder which is worked onto Ta wire. The pellet is immersed in an acid bath and attached to a DC supply. Current flow encourages the Ta2O5 oxide growth. The MnO2 layer is created by dipping the pellet into Mn(NO3)2 solution and then heated. The rest of the processing is just to get a wire connected. The solid tantalum shares the extremely thin dielectric, high capacitance behavior of the aluminum electrolytic with an added bonus that since it is dry, its lifetime in much longer, and it also has a lower leakage current (higher Rdc). Also, tantalum capacitors can tolerate a little reverse voltage (as much as 15% of the working voltage according to some sources). Typical values range from 0.047uF to 330uF. Tantalums also do not come in as high a working voltage rating (typical max voltage = 50V) as aluminum electrolytics (available with at least 450V, probably higher)..

Bipolar electrolytics are available when you need to have large capacitance but cannot maintain a unipolar bias. Electrolytics generally suffer from larger ESR and Rdc than other capacitors.

Terminology:

Capacitor Model Parameters:

ESR: Equivalent series resistance. A resistive element of the capacitor model found in both the ac and dc domains. Contributing factors: electrodes, leads, dielectric. This value can change with frequency, time, whatever.

ESL: Equivalent series inductance. An inductive element of the capacitor model; effect only seen in ac or transient domains. Contributing factors: electrodes, leads.

Rdc: a dc leakage current through the dielectric. This value varies with temperature and age.

Rac: a parameter to describe ac losses in the dielectric; may vary nonlinearly with frequency and temperature

Rd, Cd: parameters to describe dielectric absorption

dielectric absorption: phenomenon where after a capacitor has changed value, stored charge will migrate out of the dielectric over time, thus changing the voltage value of the capacitor. This is apparently an important issue in sample and hold circuit applications; perhaps someone might want to investigate this on their own.

dissipation factor (D.F.), tan(Á): This is a measure of the lossiness of the capacitor. It takes into consideration the ESR and the capacitance

through the ratio ESR/Zc = (2[[Eth]]fC)(ESR). The tangent expression comes from the phasor diagram for impedance (Á = loss angle).

K: relative permittivity, dielectric constant

Q: 1/D.F. = cot(Á)

Miscellaneous quotes from High-Speed Digital Design, A Handbook of Black Magic:

A power supply provides low impedance at low frequencies.

Local bypass capacitors provide low impedance at higher frequencies.

The best way to get very low inductance is to parallel a lot of small capacitors.

Lead inductance acts like an inductor in series with a capacitor.

ESR acts like a resistor in series with a capacitor.

Together they degrade a capacitor's effectiveness as a bypass element.

For large-valued capacitors, smaller packages have higher series inductance and ESR than larger packages.

Capacitor performance varies widely.

Higher-dielectric-constant materials pack more capacitance into a smaller space but have poor temperature coefficients and aging instability.

Aluminum electrolytics do not work well in cold applications.

Failure in capacitors is a statistical phenomenon, accelerating at high voltages (voltages near the voltage rating).

A couple of final notes:

- Amongst similar sized capacitors, the physically larger one generally has features which might make it desirable (voltage rating, stability, higher tolerance, etc.). Except for electrolytics, which are way out on the dielectric constant scale, higher K values are achieved by sacrificing ideality.

- Price is not such a poor indicator of quality; just don't pay for a quality you don't care about. Read critically!

ASA 130th Meeting - St. Louis, MO - 1995 Nov 27 .. Dec 01

1pEA4. Time Align(registered) loudspeaker crossovers.

Edward M. Long

E. M. Long Assoc., 4107 Oakmore Rd., Oakland, CA 94602

A Time Align(registered) loudspeaker system must produce an acoustical output at the listening position such that the fundamental and overtones of a complex, transient signal have the same relationships that they have at the electrical input to the system. To qualify for the use of the Time Align(registered) trademark, the natural time offset between the acoustical outputs of the loudspeaker drivers must be corrected. This time offset is caused by the natural low-pass filter characteristics of the drivers and the electrical crossover filters. The time offsets between the acoustical output of each of the drivers must be corrected and the electrical crossover filters must be designed to produce an acoustical output from adjacent drivers that is 6 dB down from its passband level. When the coherent acoustical outputs of adjacent drivers are combined, the result is a uniform acoustical output. The polarity of the acoustical outputs is also affected by the crossovers; this is also a major consideration in the design of a Time Align (registered) crossover. A Time Align(registered) loudspeaker system must be able to produce acoustical square waves and have a short impulse response. Time Align(registered) design techniques are shown by practical examples.

Human Hearing - Phase Distortion Audibility Part 2
Thursday, April 7 2005

Human Hearing - Phase Distortion Audibility Part 2

by: Mark Sanfilipo

Given all the foregoing research presented in various academic, scientific & industry journals, as well as other media, variously indicating the audibility of phase distortion, there remains no valid doubts regarding the existence of phase distortion.

See for yourself: pass an audio signal through, for example, a 4th order LR crossover network and view the output on an oscilloscope and the waveform will appear to be a grossly distorted copy of the original.

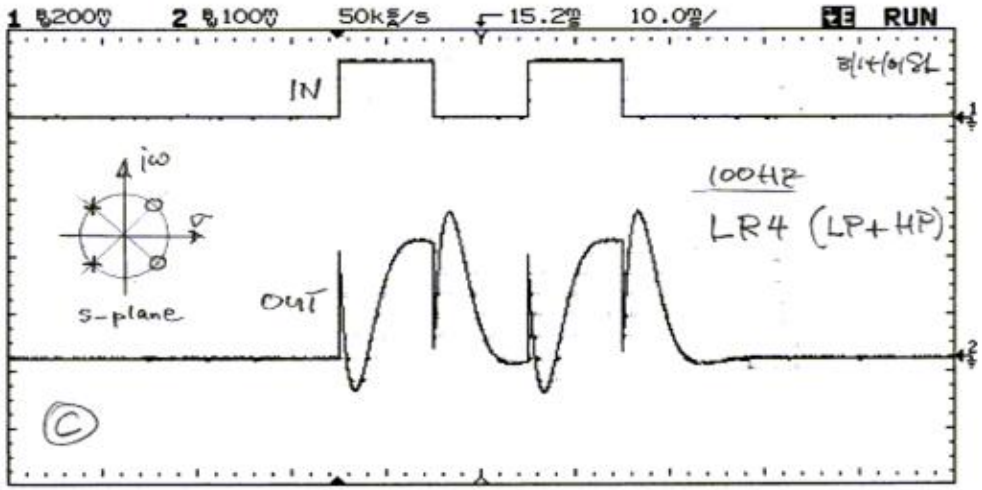
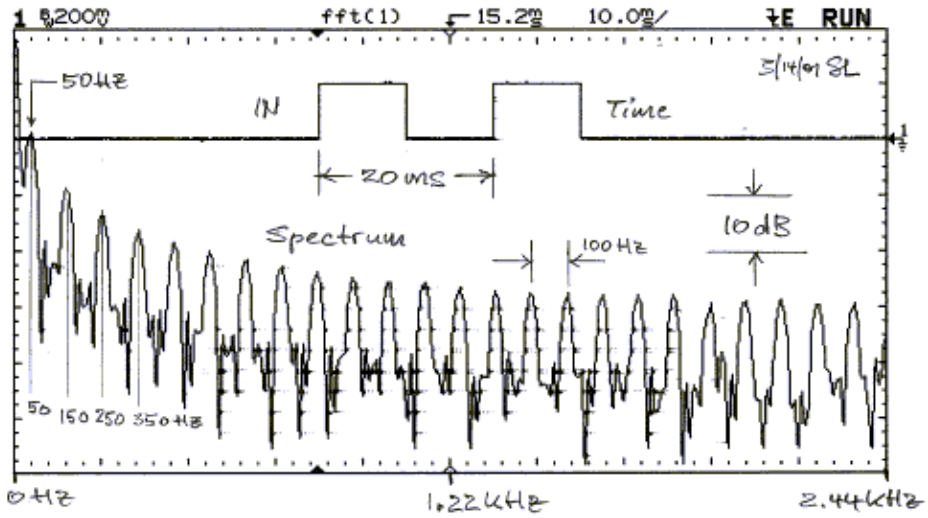
Flushing Out Myths In Consumer Audio
Monday, May 15 2006



Pass the same output signal through a spectrum analyzer and the amplitude of the various components will be correct, but their relative phase will have changed. Given the ready availability of software-based spectrum analyzer software and signal generators, investigation of this phenomenon is today almost a trivial exercise in signal analysis.



With these tools, it's certainly easy to visually assess phase distortion, but how easy is it to *aurally* assess this form of phase distortion? Let's take a look at a few examples of results & opinions arising from some commonly-cited research efforts.

In "On the Audibility of Midrange Phase Distortion in Audio Systems" by Lipshitz, et. al. we have:

"*1) Even quite small midrange phase nonlinearities can be audible on suitably chosen signals.*
2) Audibility is far greater on headphones than on loudspeakers.

3) Simple acoustic signals generated anechoically display clear phase audibility on headphones.
4) On normal music or speech signals phase distortion appears not to be generally audible, although it was heard with 99% confidence on some recorded vocal material."

Lipshitz. et .al. used 1st & 2nd order unity-gain all-pass networks with f0s of ~ 100 Hz to 3kHz, switchable in increments. For the 2nd order networks Q ranged from .5 to 2 in increments. Some highlights of their experiments and results were:

	Item
1	Using 150 Hz square waves, pitch & timbre changes were notable for all Q and fo's. Though the effect was audible down to ~ 60 db SPL, it was most noticeable at higher dB SPL's.
2	Using 2 – 5 Hz repetition rate square waves audible phase effects were again noted, this time as a ringing of the networks at fo. This effect was most noticeable with high network Q settings and across the 113Hz to 529 Hz frequency range, with detection becoming more difficult above 1 kHz.
3	Using a raised-cosine tone burst, audible signal changes in the 160 Hz to the 353 Hz range fed through a 2nd order all-pass network, with Q's ≥1. When the same tone bursts were fed through Low-Q, 1st order networks, the audible signal changes were that occurred were of a much lower magnitude.
4	Using pre-recorded music (male & female singing) fed through a 2nd-order all-pass network, with a Q of .5, audible effects were noted with a 95% confidence level. Using a variety of unpitched sounds recorded anechoically, phase effects were again audible.

And from Dr Floyd Toole:

"*It turns out that, within very generous tolerances, humans are insensitive to phase shifts. Under carefully contrived circumstances, special signals auditioned in anechoic conditions, or through headphones, people have heard slight differences. However, even these limited results have failed to provide clear evidence of a 'preference' for a lack of phase shift. When auditioned in real rooms, these differences disappear...*"

Essentially, Dr Toole expressing the opinion he does here (based on decades of his own, often groundbreaking research), captures the essence of the conclusions reached by Lipshitz et. al.

In Daisuke Koya's "Aural Phase Distortion Detection":
"*Although not in large numbers, previous research in investigation of the audibility of phase distortion has proven that it is an audible phenomenon. Lipshitz et al. has shown that on suitably chosen signals, even small midrange phase distortion can be clearly audible. Mathes and Miller and Craig and Jeffres showed that a simple two-component tone, consisting of a fundamental and second harmonic, changed in timbre as the phase of the second harmonic was varied relative to the fundamental. The above experiment was replicated by Lipshitz et al., with summed 200 and 400 Hz frequencies, presented double blind via loudspeakers resulting in a 100% accuracy score.*

An experiment involving polarity inversion of both loudspeaker channels resulted in an audibility confidence rating in excess of 99% with the two-component tone, although the effect was very subtle on music and speech. Cabot et al. tested the audibility of phase shifts in two component octave complexes with fundamental and third-harmonic signals via headphones. The experiment demonstrated that phase shifts of harmonic complexes were detectable.

Another very simple experiment conducted by Lipshitz et al. was to demonstrate that the inner ear responds

asymmetrically. Reversing the polarity of only one channel of a pair of headphones markedly produces an audible and oppressive effect on both monaural and stereophonic material. This effect predominantly affects frequency components below 1 kHz.

Because reversal of polarity does not introduce dispersive or time-delay effects into the signal, but merely reverses compressions into rarefactions and vice versa, these audible effects are due only to the constant 180° phase shift that polarity reversal brings about.

Since interaural cross-correlations do not occur before the olivary complexes to which the acoustic nerve bundles connect, it must be concluded that what is changed is the acoustic nerve output from the cochlea due to polarity reversal. This change owes to two factors: cochlear response to the opposite polarity half of the waveform, and the waveform having a shifted time relationship relative to the signal heard by the other ear. This reaffirms the half-wave rectifying nature of the inner ear."

A frequent argument to justify why phase distortion is insignificant for material recorded and/or reproduced in a reverberant environment is that reflections cause gross, position-sensitive phase distortion themselves. Although this is true, it is also true that the first-arrival direct sound is not subject to these distortions, and directional and other analyses are determined during the first few milliseconds after its arrival, before the pre-dominant reverberation's arrival. Lipshitz et al. do not believe that the reverberation effects render phase linearity irrelevant, and there exists confirmatory evidence."

Let's take a closer look at Daisuke's test and results.

The test signals employed were:

1. 70 Hz sawtooth wave
2. 3.5 kHz sawtooth wave
3. 10 kHz sawtooth wave
4. Impulse
5. Jazz-vocal group
6. Percussion instruments.

A Kwalwasser - Dykema based test model was employed by the researchers. In this particular implementation, the test subjects were presented with two signals, one all - pass filtered, the other not. The test subjects (15 in all) then had to indicate whether or not a difference was heard. The 6 – signal test run was done using first headphones, then loudspeakers.

First, the headphone-series results:

Test Signal		**Average Correct Responses** (N = 15)
70 Hz Sawtooth Wave	$t$max = 4 msec	9

70 Hz Sawtooth Wave	*t*max = 8 msec	9.5
3.5 kHz Sawtooth Wave	*t*max = 4 msec	5.5
3.5 kHz Sawtooth Wave	*t*max = 8 msec	4
10 kHz Sawtooth Wave	*t*max = 4 msec	1.5
10 kHz Sawtooth Wave	*t*max = 8 msec	4.5
Impulse	*t*max = 4 msec	13
Impulse	*t*max = 8 msec	14
Jazz-Vocal	*t*max = 4 msec	6.5
Jazz-Vocal	*t*max = 8 msec	4
Percussion Instruments	*t*max = 4 msec	4
Percussion Instruments	*t*max = 8 msec	4

Here, τmax is peak group delay for the particular filter used, msec

And the results for the loudspeaker run:

Test Signal		**Average Correct Responses** (N = 15)
70 Hz Sawtooth Wave	*t*max = 4 msec	7
70 Hz Sawtooth Wave	*t*max = 8 msec	7

3.5 kHz Sawtooth Wave	*t*max = 4 msec	5
3.5 kHz Sawtooth Wave	*t*max = 8 msec	3.5
10 kHz Sawtooth Wave	*t*max = 4 msec	2
10 kHz Sawtooth Wave	*t*max = 8 msec	2
Impulse	*t*max = 4 msec	8.5
Impulse	*t*max = 8 msec	6.5
Jazz-Vocal	*t*max = 4 msec	4.5
Jazz-Vocal	*t*max = 8 msec	3.5
Percussion Instruments	*t*max = 4 msec	4
Percussion Instruments	*t*max = 8 msec	2.5

Comparing the results encapsulated in both tables it would appear we can reasonably draw the following conclusions:

1. The number of correct responses given for the loudspeaker-based test is lower for just about every test signal used when compared to those reported in the headphone run.

2. The results from the loudspeaker run appear more independent of the level of phase distortion present than that presented by the headphone run.

3. The audibility of phase distortion in steady state signals was frequency dependent for both the loudspeaker and headphone runs.

Research work done in a controlled, scientific manner is a good first step in sorting fact from fiction – this holds true whether the study's subject matter is subjective or objective in nature.

An essential second step is the correct application of statistical analysis to the results. Oftentimes, the raw data that are the study's results present an impression or picture that can easily lead to false or otherwise incomplete interpretation. From that, incorrect conclusions can easily be drawn. Quality research simply requires the application of statistical analysis in order for the results to be correctly interpreted.

Now have a look at the next table, which outlines the correct number of responses, r, needed to conclude that the performance in each trial was better than that obtained by simple chance.

N	***r***	**Type 1 Error** (*a*) actual value	**Type 2 Error** (*b*)			
			p = 0.6	*p* = 0.7	*p* = 0.75	*p* = 0.8
15	14	0.0005	0.9948	0.9647	0.9198	0.8329
	13	0.0037	0.9729	0.8732	0.7639	0.6020
	12	0.0176	0.9095	0.7031	0.5387	0.3518

11	0.0592	0.7827	0.4845	0.3135	0.1642
10	0.1509	0.5968	0.2784	0.1484	0.0611
9	0.3036	0.3902	0.1311	0.0566	0.0181
8	0.5000	0.2131	0.0500	0.0173	0.0042
7	0.6964	0.0950	0.0152	0.0042	0.0008
6	0.8491	0.0338	0.0037	0.0008	0.0001

For this experiment in the audibility of phase distortion, the researchers chose $r \geq 9$ as that point where r represents a statistically significant result.

Applying the $r \geq 9$ requirement to classify a result as statistically significant, we can now view the data presented in the two tables in a very different light.

When applying the $r \geq 9$ requirement, none of the 12 trials run in the loudspeaker series indicated a statistically significant result, though the Impulse test signal @ 4 m Sec comes very close at r = 8.5 . Only 4 of the 12 headphone trials indicated a statistically provable presence of the audibility of phase distortion.

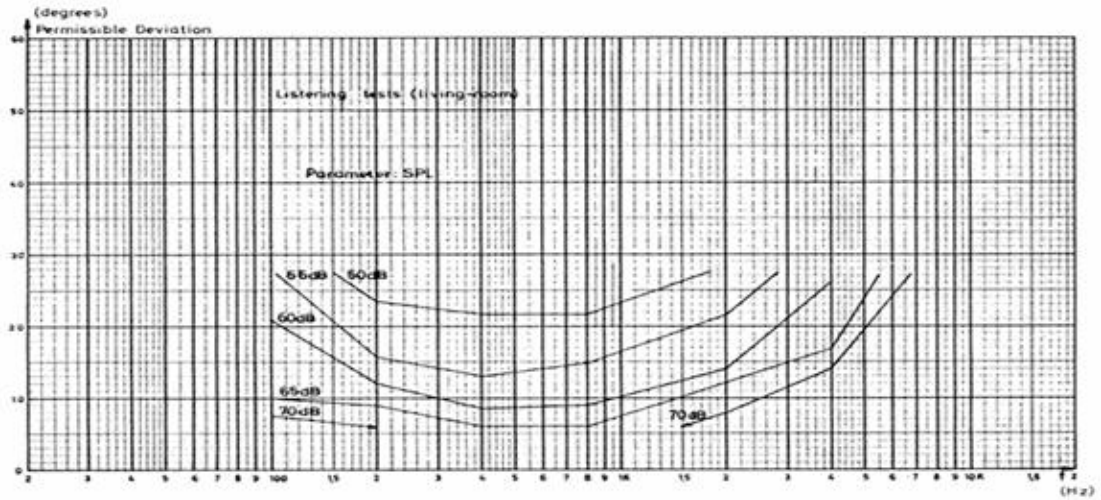
So what useful information can we draw from this particular study?

1. Phase distortion is audible, but only under very specific circumstances, using very specific, types of test signals.

2. There exists in this study no statistically significant evidence supporting the audibility of phase distortion in the musical samples provided, using the all-pass filter implementations chosen by the researchers.

3. Introducing the room acoustic variable in to the equation further lowers the already poor scores phase distortion audibility scores..

One other study I'd like to cite was that done by V. Hansen and E. R. Madsen. Originally published in the Journal of the Audio Engineering Society, in a 2-part series of articles.



They presented their test subjects a series of test tones, from the resulting data they were then able to determine permissible phase deviation levels for a variety of dB SPL levels. Of particular interest is how the presence of the positive slopes at the upper frequency portions of the curves support item 3 mentioned above in the first set of Daisuke study conclusions. These are given in Graphic 3.

So what conclusions regarding the audibility of phase distortion can we draw from the all of the above?

1. Given the data provided by the above cited references we can conclude that phase distortion is indeed audible, though generally speaking, only very subtly so and only under certain specific test conditions and perception circumstances.

2. The degree of subtly depends upon the nature of the test signal, the dB SPL level at which the signal is perceived, the acoustic environment in which the signal was recorded and/or played back as well as the Q & fo of any filter networks in the signal stream. Certain combinations of conditions can render it utterly inaudible.

3. Room acoustics further masks whatever cues that the hearing process may depend upon to detect the presence of phase distortion.

Read Part 1: Human Audibility to Amplitude Variation

Feedback from Dr. Floyd Toole (Added 4/08/05)

Thanks for bringing these articles to my attention. I guess the only comments I might have added relate to the differences in the perceptual tasks in the various studies leading to minimum audible amplitude shifts. Some were basically broadband or single tone, turn the volume up, kinds of tests. These 'difference limen, or just-noticeable difference' for loudness tests are fundamentally different from the ones that Sean Olive and I did, which was a just-noticeble timbre difference test - only a portion of the total sound spectrum was altered. Somewhere in the recesses of auditory signal processing they are probably related, but they are very different at a higher perceptual level. In any event, it is interesting to see anyone discussing the topic.

As was mentioned, our sensitivity to the timbral changes was very much dependent on the Q, or bandwidth of the

phenomenon - with much lower 'thresholds' being found for wider bandwidth spectral changes. Interesting, because the narrower the bandwidth, the more the resonant system rings. Except, perhaps, at very low frequencies, it seems that we do not exhibit a primary response to the time-domain (ringing) problems but instead to the spectral features. Our sensitivity to resonances was also dependent on program material - pink noise was the most revealing, big band/symphonic with reverb was next, and the least revealing was close-miked pan-potted pop and jazz. Reverberation alone could increase our sensitivity to a medium or low-Q resonance by about 10 dB - a huge effect. This latter fact explains why music is so much more satisfying in a reverberant space than outdoors - timbrally richer because we can hear more of the resonant subtleties. It also explains why the toughest test for loudspeaker accuracy is in a room with some reflections, and why headphones (which have no added reflections) have an inherent advantage, and can sound acceptable when measurements indicate that there really are resonant problems. Killing all early reflections with absorbers not only changes imaging, it also makes loudspeakers with poorly controlled directivity sound better. All interesting stuff for audio folk.

The piece on phase distortion was a refreshing change from the semi-science floating around our business. All things being equal, and if one has the option, of course get the phase correct - at least at the one point in space where it can be done!! However, this presents problems for two-eared listeners in multiple seats in reflective rooms (solve this one and a Nobel prize awaits). It is indeed fortunate that humans are so unresponsive to this effect because, if we could hear phase shift, we would go absolutely nuts in everyday life. Every time a reflected version of a sound adds to the direct sound, the phase shifts are enormous, and it happens in abundance in all rooms, even carrying on a conversation across a table. Do the stand up/ sit down test while speaking. The voice changes very subtly, but our hearing system compensates immediately and, on a scale of 10, the voice quality remains a 10. Yet the transfer function between the voice and the ears has greatly changed in both amplitude and phase. I cannot help but think of all the opera recordings and film voice overs that are done with librettos and scripts on large angled (sound reflecting) surfaces between the mouth and the mic. The signal is corrupted at the source! Thank your favorite diety for human adaptability.

Keep up the good work.

Hi-Fi PC Speaker System

Rod Elliott (ESP)

Updated 31 Aug 2004

All required PCBs are available for this project. Click the image for the price list.

Introduction

If you like listening to music while using your PC, or enjoy games with all their sound effects, you will generally be disappointed with most of the PC speaker systems available. Few systems use anything other than moulded plastic boxes, ratty little tweeters that don't really do very much at all, and commonly using only a tiny bipolar electro as the "crossover". Zero acoustic damping and a 5W amplifier completes the picture.

As for the sub-woofer, if it manages to wheeze its way down to 50Hz you are indeed fortunate, and with as much as 20W in a tiny ported plastic enclosure you can think yourself lucky to get that far. I know this from experience, and eventually got so sick of the grossly inferior sound that I just had to do something about it.

This is not so much a project in its own right as a collection of existing projects, and using some of the boards that I sell (I bet that came as a real surprise!). With a bit of work and not too many dollars, pounds, shekels or whatever, you can make a PC speaker system that will outperform many small hi-fi setups.

Description

There are two parts to the project, small satellite speakers that sit on the desk next to the monitor, and a sealed, equalised sub-woofer that also contains all the amplifiers, power supplies and other electronics. The sub extends happily to 30Hz, and makes quite a good account of itself considering its size. It also makes a fine foot rest :-)

Is this an audiophile project - no. It is head and shoulders above any PC speaker system I have ever heard, regardless of price, and also makes a great little hi-fi. The sound is very clean, and it has extended lows that put a lot of "proper" systems to shame.

The selection of speaker drivers is up to you, since I have no idea what you will be able to get from your local suppliers. Don't be too cheap - the better the drivers, the better the overall sound, and the happier you will be with the end result. At the other end of the scale, using the best drivers you can find is probably not worth the effort either, since there is already a limitation in sound quality imposed by your sound card.

Please note that all dimensions shown are in millimetres. For those who insist on those inch thingies, divide by 25.4. Litres can be converted to cubic feet by dividing by 28.

The parameters of the speaker drivers I used are shown below. These cost me a little under AU$150 from local Australian suppliers. The only speaker likely to be recognised is the Peerless tweeter.

Woofer	Re/sponse 200mm	**Midrange**	Unknown 100mm	**Tweeter**	Peerless 812978
Impedance	8 Ohms	Impedance	8 Ohms	Impedance	8 Ohms
Power	120 W	Power	30 W	Power	100 W **
Sensitivity	90 dB/W/m	Sensitivity	91 dB/W/m	Sensitivity	91 dB/W/m
Resonance	40 Hz	Resonance	91 Hz	Resonance	907 Hz
Total Q (Qts)	0.47	Total Q (Qts)	0.72	Total Q (Qts)	0.8944
Vas (litres)	32.8	Vas (litres)	2.11	Vas (litres)	n/a
Cone Area (m²)	0.0214	Cone Area (m²)	n/a	Cone Area (m²)	n/a

Parameters For Prototype System Drivers

** This is the nominal system power - the tweeter would self destruct with this power within its normal operating range
n/a - Not Available / Not Applicable

The above information is mainly for the sake of interest. The drivers you use will have to be those you can obtain, but the above figures give you a goal to aim for. If you can get drivers with similar specs, then you will have a system as good (or better) than mine.

Satellite Speakers

Firstly, you need to obtain some magnetically screened drivers. Ordinary drivers must not be used, as they will distort the colour and even the picture shape on your monitor. The ones I used are 100mm diameter (outside) and are rated at 30W RMS or 50W peak. They are both 91dB/W/m and are 8 ohms. The crossover is a simple passive 6dB network at 4kHz. This is not ideal, but is a reasonable compromise between complexity and performance. With an internal volume of about 3 litres, the boxes are sealed, well damped with fibreglass, and have a resonance of 110Hz.

It is important that the low-midrange driver and tweeter have the same efficiency. If not, make sure that the tweeter has the higher efficiency so it can be padded back to match the midrange. If not, you will have to pad the midrange driver, and this will soak up much more power (as heat), and reduces damping - neither is acceptable. A simple resistive pad can be used to reduce the tweeter level, or you can use a

"proper" wirewound attenuator pot so it can be adjusted.

The boxes are covered with carpet (the thin stuff for covering speaker boxes), which helps to eliminate diffraction, and adds extra damping to the boxes. The boxes themselves are made with 10mm medium density fibreboard (MDF) and because of their small size, are extremely rigid.

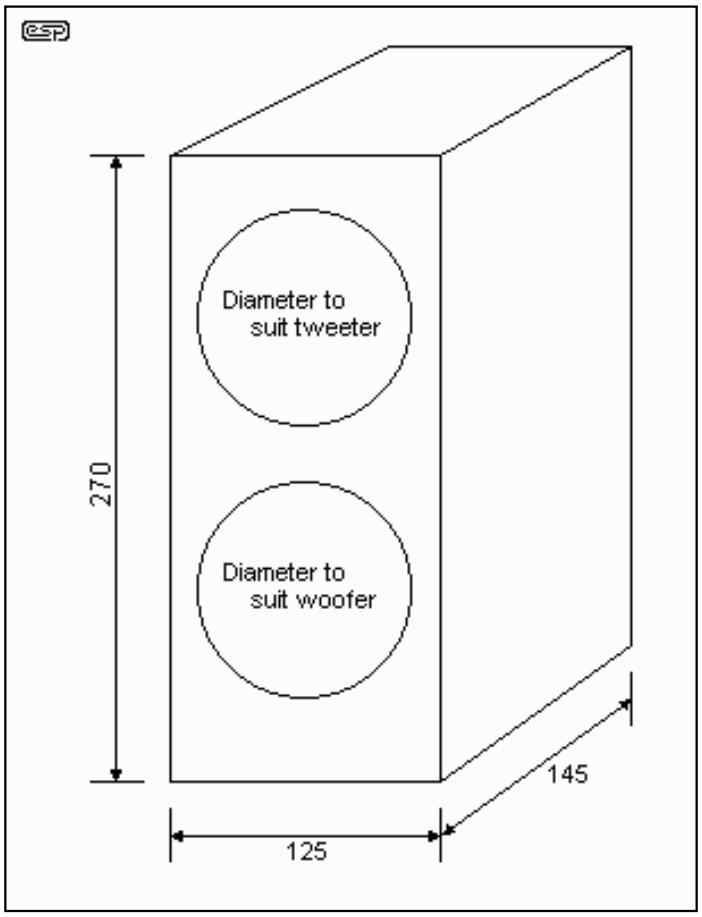

Figure 1 - Satellite Speaker Dimensions

The boxes measure 125(w) x 270(h) x 145(d) outside. I rounded off all the edges with a router, but this is not really essential if you don't have access to one. If you do, use a rounding bit with a 10mm or smaller radius, or you will remove too much of the material next to the joins.

The crossover consists of a single 470uH inductor and a 3.3uF polypropylene capacitor, wired as shown in Figure 2. This is a 6dB network, so it is important to make the crossover frequency high enough to ensure that there is sufficient attenuation at the tweeter's resonant frequency. I measured the woofer's impedance at 4kHz, and found that it was only marginally higher than at the midband frequency (about 400Hz), so decided against using an impedance correction network. Although I'm sure that this would improve matters, I suspect that it would be marginal, and not really worth the effort.

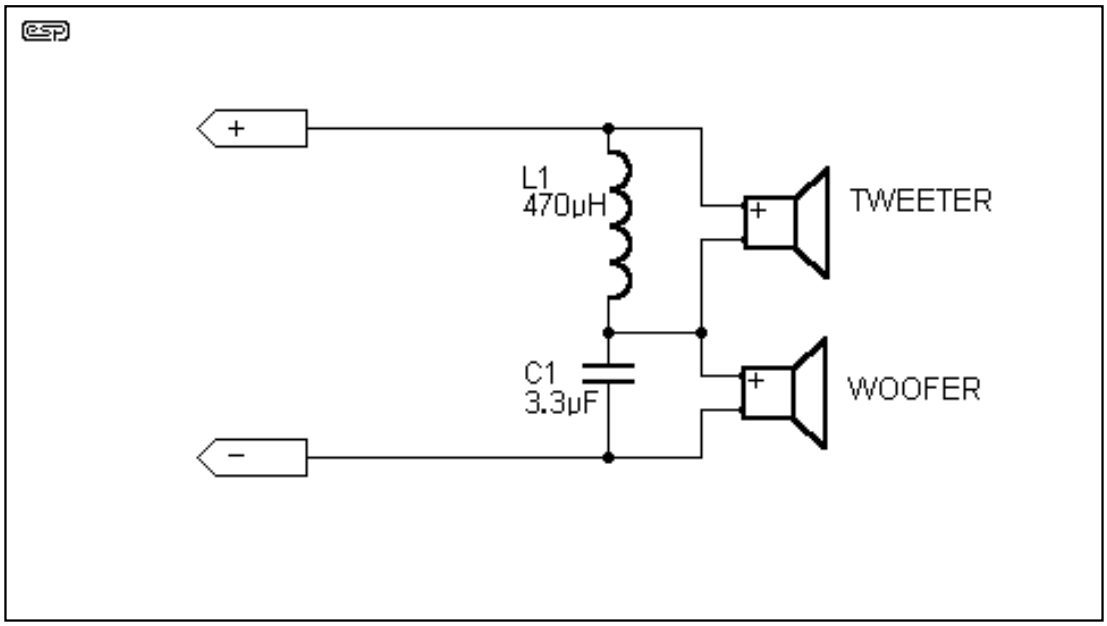

Figure 2 - Crossover Network

Since I have already established (some time ago, actually) that the series connection for a 1st order filter is to be preferred, I have changed the diagram to suit. While it is unlikely that the difference will be immediately audible in many cases, it is no more difficult to make the series version, and it does work better.

The connectors that I used were some I happened to have in my junk box, and are actually the 2-pin microphone connectors that are commonly used on CB radios and the like. They are small, airtight, and cheap (even if you have to buy them), but are a pain to mount, as they are intended for mounting in sheet metal. I recessed the mounting hole using a SpeedBor flat wood drill, and secured the final assembly with hot-melt glue. Feel free to use any connector and mounting that suits you.

Sub-Woofer

This is where all the action is, and I used the following project boards to make the final unit ...

- 1 x P3A dual 60W power amp - connected in bridge-tied-load (BTL) to obtain about 150W continuous
- 1 x P05 +/-15V power supply
- 1 x P09 stereo Linkwitz-Riley crossover, configured for a 200Hz xover frequency
- 1 x P19 dual 50W IC power amp - one amp for each satellite speaker
- 1 x P71 Linkwitz transform circuit

The entire system is powered from a 25-0-25 toroidal transformer. The one I should have used would be rated at 300VA, and I suggest that you don't use less than this or power will be severely restricted. My system is using a 160VA transformer, and this does reduce power considerably. Even so, total system power is around 200W, but can exceed this on transients. This is very loud (as in VERY loud), and may be considered overkill. Feel free to use a lower supply voltage, but the system as described can also be used as a small hi-fi and will give a good account of itself in this role. Reducing the power will limit your

options, and I will be replacing the transformer in my system as soon as I can.

The sub-woofer cabinet needs to be big enough to house the speaker, amplifiers, and the other electronics. For the sub driver, I used a 120W 200mm poly-cone, because it was reasonably close to what I knew would be needed for the job. Selection criteria for the sub are basically ...

- Low Vas - this means that a small box can be used, without raising the resonance too much
- Good efficiency - since the sub is a sealed box, equalisation is needed to get a good low frequency response. A low efficiency means that too much power is needed
- Low Fo - The lower the free air resonance, the better. The small sealed box will raise resonance, and if it's too high, excessive equalisation is needed (and an excessive power requirement results)
- High Xmax - the maximum excursion will be quite high, so the cone needs to be able to move freely
- 8 Ohms impedance - *do not use a 4 ohm driver in this project!*

The above may sound like a tall order, but such drivers exist at reasonable prices - I know, 'cos I bought one. As with the satellite speakers, there is no point getting the best driver you can - it needs to be able to do the job without distorting (too much). Remember that this is a PC speaker system, and makes no pretensions at being audiophile hi-fi.

My sub box has an internal volume of about 22 litres - not accounting for speaker displacement and the volume taken up by the electronics, which is quite small. I used 16mm MDF, which is again very sturdy and shows little or no signs of resonating because of the size. The box measures 480(w) x 280(h) x 230 (d), and again I rounded the edges - not because of diffraction, but I knew I would use the sub box as a footrest, so I wanted comfortable :-)

The box is made with a removable back, secured with lots of screws and sealed with foam tape to prevent air leaks. The back carries all the electronics, with the exception of the power transformer - the latter is mounted in the main case, as far from the electronics as I could get it. This is important (if somewhat inconvenient), because the system has high low frequency gain, and hum and buzz from the transformer is all too easily picked up.

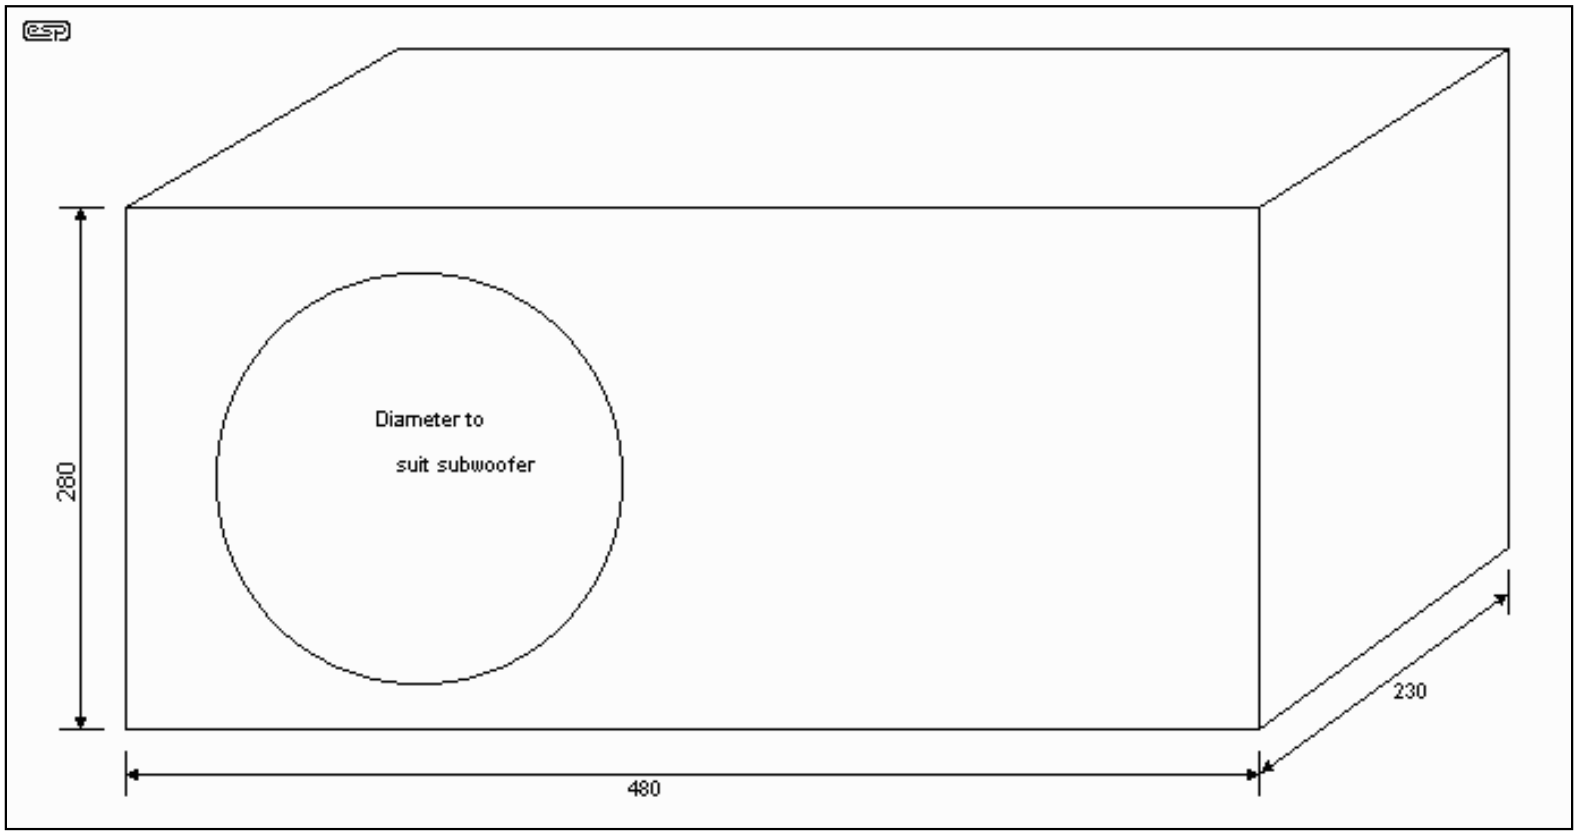

Figure 3 - Sub-Woofer Enclosure

The enclosure is not critical, but you will need to do something before you start hacking holes in the back (removable!) panel. Bolt the speaker in position. You need to do this anyway to make sure that everything fits, but in addition, include the fibreglass or other acoustic damping material, and solder a couple of thin wires to the speaker. Bring them out through a screw hole and screw the back into the box using half the screw holes. Now you can measure the speaker's resonant frequency in the box.

Attach an audio oscillator to the speaker leads. If your oscillator has a low output impedance (such as a sound card sinewave generator), then you will need a resistor in series - about 560 ohms will do fine. Carefully adjust the frequency around the expected resonance frequency (in the vicinity of 50Hz if you chose your woofer wisely). The frequency where the voltage across the speaker terminals is highest is the resonant frequency, and you will need this to double check the figures from the Linkwitz transform spreadsheet. This represents the unequalised -3dB frequency.

Using the spreadsheet, insert your speaker parameters in the "Box" page, and include the internal volume of your cabinet. The spreadsheet will calculate the values you need to properly equalise your box. In the main page of the spreadsheet, select 30Hz as the -3dB frequency, and select a Q of 0.8 for best results. The resistor and capacitor values obtained will be used in the Linkwitz transform circuit board. Have a look at the frequency response graph, and verify that the unequalised -3dB point is within a few hertz of the resonant frequency you measured. If it is not, you may need to "fiddle" the numbers a little until the graph and your loudspeaker measurement agree. Small errors are insignificant, as room acoustics will have a much greater effect than an error of a few hertz.

The Electronics

Finally, all the bits and pieces can be hooked up together. Figure 4 shows the final block diagram of the low level circuitry, and includes a level control so the bottom end can be matched to the satellite speakers. There is a deliberate 6dB extra gain in the low end to allow this, and it will normally be enough to compensate for different speaker driver efficiencies as well.

The low level electronics should be mounted on a piece (or pieces) of un-etched printed circuit board, or some aluminium sheet. The sheet must be connected to the input earth (ground) point, or it will be worse than useless. This provides some shielding, but make sure that whatever you use is securely attached to the rear panel so it can't rattle. If you wanted to, the low level stuff can all be mounted in a diecast aluminium box, but this is not really necessary unless your electrical environment is very noisy.

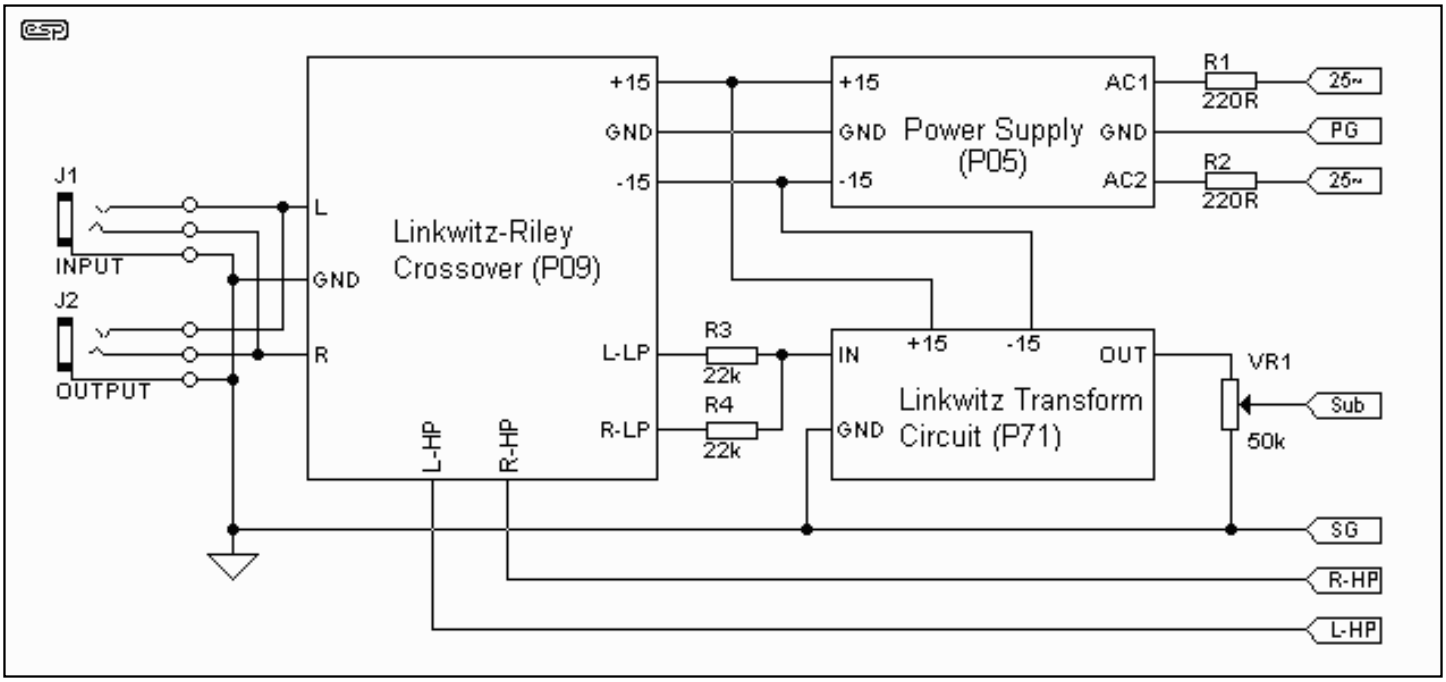

Figure 4 - The Low Level Stages

The input jacks are simply wired in parallel, so you can take an additional feed to other equipment. If you don't want to do this, leave out one of the jacks. The Linkwitz-Riley crossover is configured for a crossover frequency of 200Hz, which is nice and easy - all frequency setting resistors are 10k and caps are 100nF. None of the output buffers and trimpots (etc) are used, so leave out these sections of the circuit. The two low pass outputs are simply summed with the 22k resistors (R3 and R4). These resistors can be mounted on the L-R board, with the signal taken from the topmost trimpot hole. Full details will be supplied as part of the L-R crossover assembly instructions.

Similarly, 100 ohm resistors should be used at the high pass outputs, since shielded cable will be used to connect to the P19 power amp board. Without the resistors, the opamps can oscillate. These too can be easily mounted on the board.

The low pass combined output is connected to the input of the Linkwitz transform circuit, which will equalise the subwoofer to obtain a flat response down to 30Hz. The output of the transform circuit is connected to a pot as shown, and this needs to be accessible from outside the box so the system can be set up properly.

All the low level circuitry is powered from a P05 preamp supply. Note that I included 220 ohm resistors in series with the AC input - these must be 5W wirewound types. Since 35V is the absolute maximum DC input voltage for the 7815 and 7915 regulators, direct connection to the transformer would lead to a potential over-voltage, and the resistors tame that very nicely. The DC input to the regulators will be typically about +/-22V with this arrangement.

NOTE:- Do not operate the supply without a load from a 25-0-25 volt transformer..

Figure 5 shows the power amplifier connections. The P3A (60-100W) amp is wired up using the internal bridging resistor. An insulated wire link is needed between the output of the Right channel and the bridging resistor (R17) on the other. The input of the Left channel should be grounded with a wire link on the board. Note the 10 Ohm resistor and 100nF cap in the ground lead of the P3A power amp. This provides the high frequency ground, but the main earth line is back to the preamp (actually the crossover and equaliser). Likewise, a 1 ohm (1W) resistor is in series with the power ground to the preamp supply. These resistors were used to ensure continuity, but not allow any ground loops which will cause massive hum.

The crossover inputs are the ground reference for the whole amplifier, and the ground is physically connected to this point, where the input connectors are in contact with the input panel. This is shown in Figure 4.

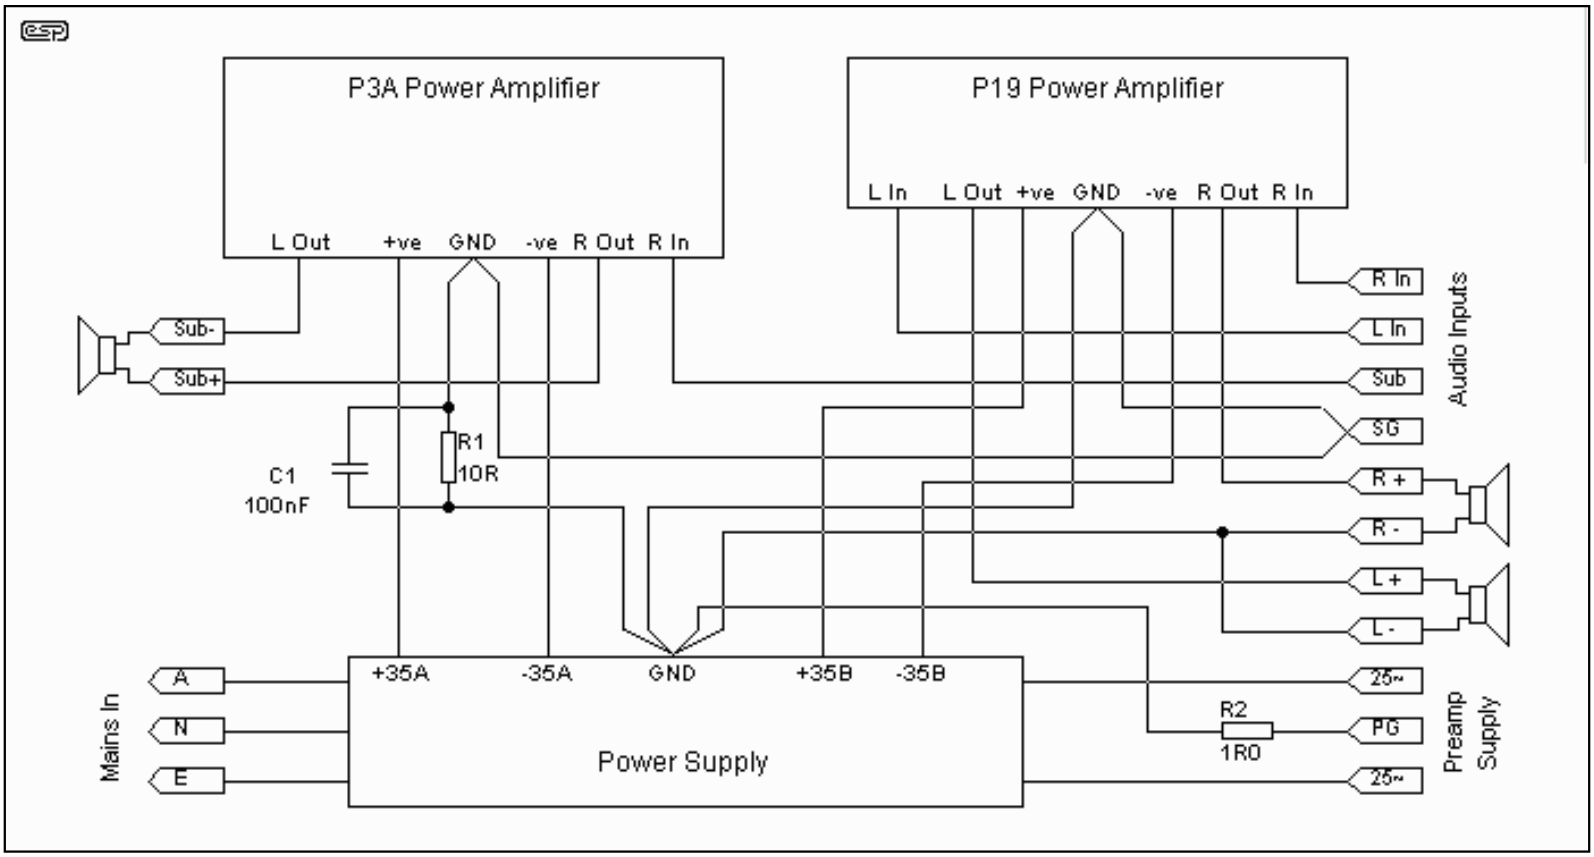

Figure 5 - Power Amplifier Connections

Before you complain, I know that the diagram is a jumble, but it actually does make sense :-) All audio leads should be shielded at the amplifier end only. Do not connect the shields at both ends, or you will create an earth loop, and hum will surely result.

The P19 50W IC power amp board provides the left and right channel feeds for the satellite speakers. These require a connector for the satellite boxes, and although fixed leads can be used, I don't recommend it. All leads should be detachable, as dangling leads are a safety hazard when you are carrying the box - be warned, it is quite heavy when everything is installed.

Heatsink selection is very important. Do not skimp on the heatsinks, as this is a high power system, and needs as much heatsink as you can afford. Use a separate heatsink for each amp module, and each should be no smaller than 1°C/W. Bigger heatsinks mean cooler running and longer life. The amplifier modules must be tested as described in the construction details before you apply power to the finished unit.

The earthing arrangement is very important, and may need some experimentation to get it right. As shown in these diagrams, it should be OK, but your layout will be different from mine, and this can have an influence on the final configuration. Note that the mains earth and signal earth must be joined, but only at one place. This is the classic "star" earthing, and must be used to avoid hum loops and other buzzes and noises. I made the star earth point the common connection between all four filter caps, and this has proved quite satisfactory. This is also the speaker return point for the satellite speakers - the sub-woofer driver is connected to the amp in bridge, so it has no earth return.

All shielded wiring should have the shield earthed at one end only. Do not rely on the shield to complete the earth connection, as noise will almost certainly be injected into the signal lead.

WARNING

Mains wiring should be carried out by qualified persons only. Do not attempt construction unless suitably qualified. Death or serious injury to yourself or others may result from a seemingly insignificant mistake.

Finally, Figure 6 shows the power supply in detail. As you can see, it is a dual supply, with only the transformer as a common point. This is not absolutely necessary, but does improve power output a little, and also prevents any possible interaction between the amps. I used an aluminium bracket fabricated from scrap sheet to secure the filter caps and act as a heatsink for the bridge rectifiers (I used 35A bridges - you don't have to, but they run cooler and are more reliable than smaller ones). The capacitors are mounted to the bracket using double-sided tape, hot-melt glue and a cable tie - I didn't want them to rattle, and you won't either.

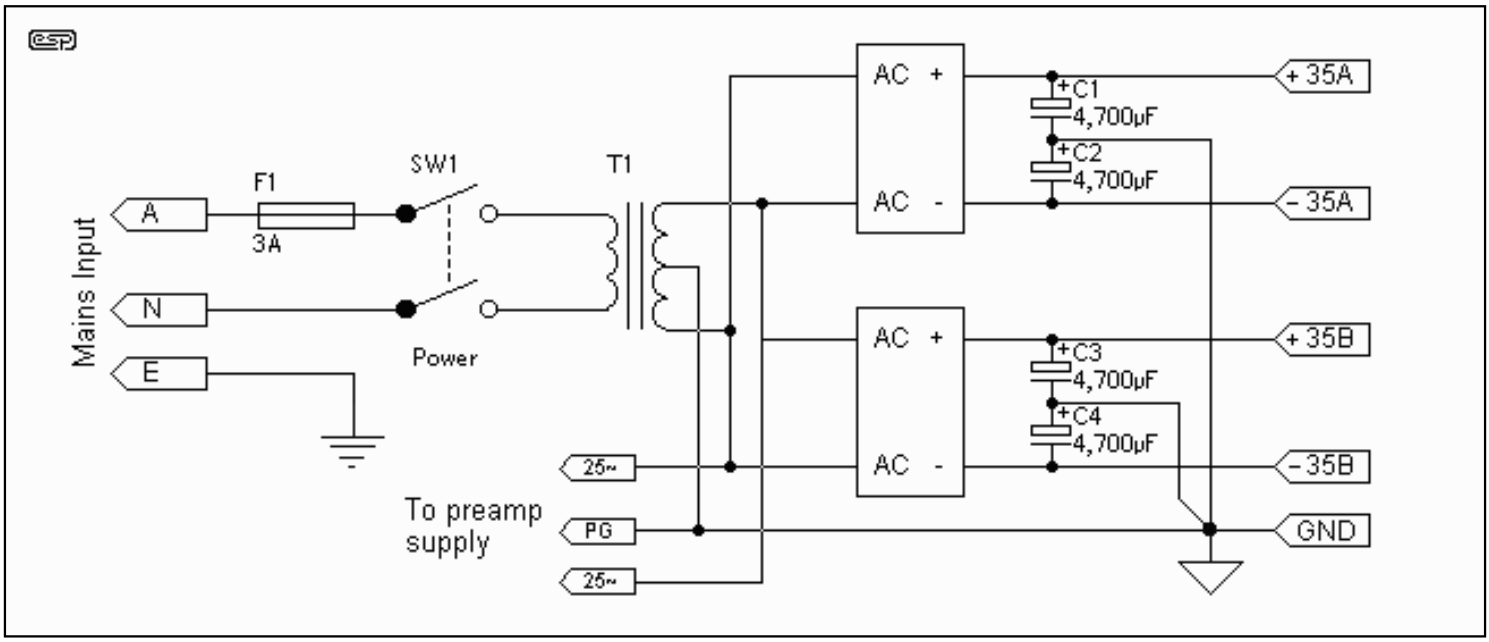

Figure 6 - Power Supply

The power supply mains wiring must be performed by a suitably qualified person, and all connections must be shrouded with heatshrink tubing to prevent accidental contact. The use of a fused IEC mains connector is highly recommended for the mains input. The designators "A", "N" and "E" mean Active (Hot), Neutral (Cold) and Earth (Ground) respectively. If you don't understand this - *don't even try to wire it!*

As previously discussed, I suggest a 25-0-25 volt transformer, preferably rated at 300VA. You will need to use an inline plug and socket (mains rated!) for the incoming AC, since the IEC mains input connector, fuse and power switch will be on the back panel, and the transformer is mounted in the case. The secondary leads should be connected using heavy duty cables, and a terminal block to join the transformer output to the bridge rectifiers and a separate light duty feed to the preamp supply.

Final Assembly

To give you a better idea of how everything fitted together in my system, Figure 7 shows the mechanical layout on the rear panel. Yours will probably be a variation on that shown, since the heatsinks must be accommodated, and yours will be different from mine. Make sure that signal and power leads are well separated, and keep speaker leads well clear of all signal leads, boards and inputs in particular - you don't need an RF oscillator !

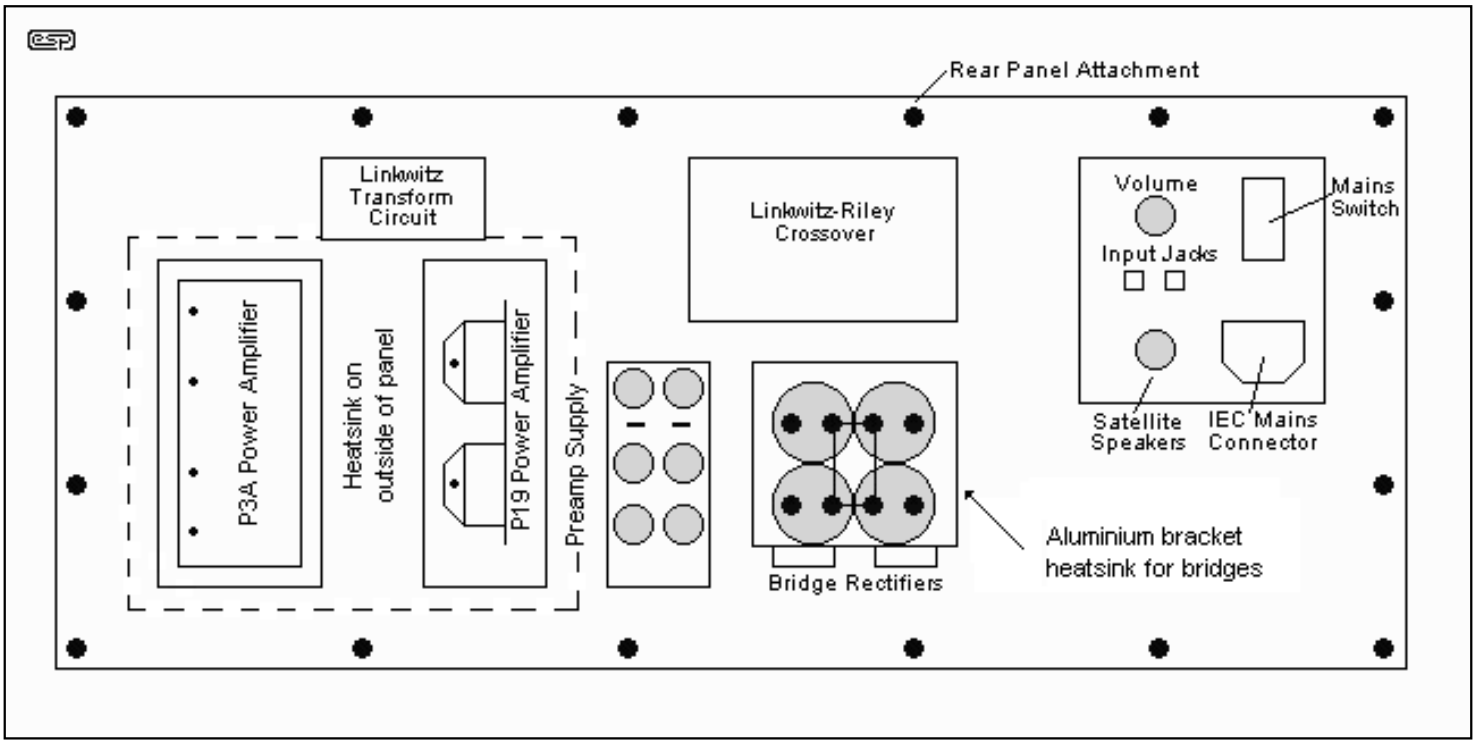

Figure 7 - Rear Panel Assembly Suggestion

The heatsink for the power amplifiers is shown dotted. This mounts on the outside of the rear panel, and must be securely fastened and sealed. The amplifiers are mounted directly to the heatsink through the holes shown (you may only need one hole, depending on your heatsink). The sheet aluminium bracket is used as a convenient mounting point for the power supply filter caps, and is also the heatsink for the bridge rectifiers.

Once everything is tested and operational, you can complete the final assembly. Make sure that nothing on the rear panel rattles before you screw it into position, and ensure that the box is completely sealed. Even a small hole will make noises at low frequencies, because of the large cone excursions and internal pressure. When powered on, the system should be silent after the small initial transient from the amps. Careful listening will reveal a slight hiss from the tweeter - this is quite normal.

Connect the system to your PC and hear your music and games as you have never heard them before. Be prepared to make more than one unit, as your friends will be green with envy after they hear yours!

Subj: Discussion of Group Delay in Loudspeakers

(posted around 1998 to Bass List)

Peter wrote:

> Does anyone know of demanding source material that readily demonstrates the need
> for linear phase/flat group delay?

ANY recorded music will reveal group delay errors if the errors are severe enough. Take the trivial example of a 24 hour delay between the highs and lows. The highs arrive normally but you have to wait until tomorrow to hear the lows. Would this be audible? I think so. Could we all hear it in an A/B test? YES.

The absolute audibility of group delay is not the question. If we make the delay severe enough anybody can hear it. The real question is what are the thresholds where group delay becomes "just audible". One of the most widely referenced reports of the audibility of group delay is:

> Blauert, J. and Laws, P "Group Delay Distortions in Electroacoustical Systems"
> Journal of the Acoustical Society of America
> Volume 63, Number 5, pp. 1478-1483 (May 1978)

Blauert and Laws report approximately the following thresholds for audibility:

Frequency	Threshold of Audibility
8 kHz	2 msec
4 kHz	1.5 msec

2 kHz	1 msec
1 kHz	2 msec
500 Hz	3.2 msec

The real work that needs to be done is to refine these threshold measurements and extend them further into the low frequency region (where the worst delay occurs in speakers).

In summary: Group delay is audible.

The relevant question is: "How much group delay is audible, at what frequency, with what program material."

Does anybody know of more refined measurements of these thresholds that have been reported in the literature?

Regards,

John

Steve wrote:

>To repeat an earlier question that got lost, if I could hear group delay
>in a system, what would it sound like? Can you describe it?

The basic equivalent circuit model of a dynamic speaker system is that of an electrical highpass filter. Such filters have the characteristic of increasing group delay at low frequencies. Thus, in general, our speaker systems tend to delay the lows while allowing the highs to arrive without delay.

Let's consider the trivial case of EXTREME delay at low frequencies. For source material imagine that we use a recording of a single snare drum hit. We know what a snare drum normally sounds like. Now, imagine introducing a delay of 5 seconds on the lows. Play the drum recording through such a delay and you hear the high frequency "snap" of the drum followed 5 seconds later by the lower frequency

"thump" components. So instead of hearing one integrated "pop" sound we instead hear a "snap" followed much later (5 sec) by the "thump". We could all easily hear the delay in this exaggerated "thought experiment".

But real speakers don't add seconds of delay. They only add milliseconds or tens of milliseconds of delay. So the real question comes down to "how much delay is just audible". If we were to gradually reduce the delay in the above experiment to zero there would come a point where the delay was no longer audible as a separate distinct sound. This would probably happen above the Hass limit of 30ms or so. As the delay is reduced further there would come a point where the "delay distorted" or "time smeared" version was indistinguishable from the original recording. This delay would represent the threshold of audibility for this delay curve and source material.

Our mission as speaker designers is to keep our group delays below the threshold of audibility. In order to do this we need to first know what group delay our speakers are imparting on the music, and second, know what degrees of delay are audible.

On the subjective side I suspect that delayed bass or "late" bass is what we experience as "slow" bass. Alternately, I suspect the subjective quality of "fast bass" is likely to be associated with those systems where the bass arrives "on time" within the minimum detectable delay threshold.

For further study: Build a collection of allpass (delay only) filters and introduce stages of delay to your playback chain untill the effect is just audible in comparison with the undelayed program. Note the amount of delay that is just audible in your system. How does this compare to the delay contributed by your speaker system?

<Warning: Blatent Commercial>
Bassers, if you are speaker crazy enough to enjoy my audio ramblings then you can order my new book "Introduction to Loudspeaker Design" at either the True Audio web site or at Amazon.com. :-)

John is correct. group delay is a well defined variation on the concept of "time delay". It is NOT simply the difference in time between the input and output of a system. Rather it is the delay experienced by the signal "envelope" or "packet". Dick Heyser's works are well worth studying to explore these ideas further.

Here is another excellent reference on this subject which discusses phase shift, phase delay, group delay, time delay and defines a "differential time delay".

> "The Differential Time-Delay Distortion and Differential Phase-Shift Distortion as Measures of Phase Linearity" by Marshall Leach,
> JAES, Vol. 37, No.9, September 1989

Leach argues that what matters is the relative delay between the signal waveform and the envelope. He further goes on to argue that bandwidths on the order of 1 Hz (yes, one Hertz) are required in order to keep "phase shift distortion above 20 Hz" below 5%. But leach is discussing amplifiers and makes no comments on audibility of such "phase shift distortion". Generous low end bandwidth is easy to achieve in an amplifier. But with our speaker systems we do not have the luxury of dialing in an extra DECADE of low end bandwidth as a safety margin. Rather, we operate at the threshold of audibility with respect to magnitude and delay anomalies. We would like to know better where the audibility thresholds fall so that we can squeak in under them as we design speakers.

John also wrote:

> I have to backhandedly agree with Phil on the point that phase is the real

Phil, Tom and now John have expressed preferences for "viewing" the "delay" problem in terms of phase. I just wanted to point out that (for a minimum phase system) frequency response, phase response, and group delay response are simply three different views of the same physical 'delay' phenomenon. Change one of these responses an the other will change accordingly (remember, it's a minimum phase system).

For example, given only the frequency response of a system the phase response and group delay response can be calculated. This implies that the frequency response curve contains all the information concerning both phase and group delay. So frequency, phase and group delay are really just different takes on the same information.

My current preference is to interpret this phenomenon in terms of "cycles of delay". This can be calculated from group delay by dividing the group delay by the period of the frequency at each point. I call this "normalizing" the group delay by period. If you do this the frequency dependence gets out of the way of seeing the phenomenon. For example, consider the Blauert and Laws data on audibility thresholds for group delay. Below is a table that shows the data in terms of both delay TIME in ms and normalized delay in cycles.

Frequency (Hz)	Threshold (ms)	Threshold in T (periods or cycles)
8k Hz	2 ms	16 T
4k Hz	1.5 ms	6 T
2k Hz	1 ms	2 T
1k Hz	2 ms	2 T
500 Hz	3.2 ms	1.6 T

Considering only the lower three data points for the moment, I see the Blauert and Laws data suggesting that group delay audibility thresholds appear to fall around 2 cycles. I find this "cycles of delay" view a much more intuitive representation of the data than either the phase or group delay views of the same data.

The essential question remains: what are human audibility thresholds for frequencies below 500 Hz.

Extrapolating the Blauert and Laws data to lower frequencies it could be that "one or two cycles" of delay continues to be the threshold as we move lower in frequency.

One comparison I did recently of a closed vs. a vented enclosure for ACI's SV-12 woofer revealed the following simulated results:

Frequency	Closed Box Delay (T)	Vented Box Delay (T)
100	.070 cycles	.074 cycles
50	.135 cycles	.149 cycles
20	.176 cycles	.338 cycles

Note that the vented system has more delay than the closed system but that both systems would appear to have delay well under my extrapolated B&L threshold of "one or two cycles". At 50 Hz the difference between these two systems is rather slight. But these two systems have very low F(3)'s (about 33 Hz for the closed, and about 23 Hz for the vented system). But a closed box speaker withe f(3) of 50 Hz and Q(tc) = .707 will still experience less than about .25 cycles (or 4.5ms) of delay at 50 Hz. This would SEEM to be well under the extrapolated B&L criteria of "one or two cycles". This would imply that the group delay of a 50 Hz closed box system would be inaudible. Leach's differential delay works

out to be about .475 cycles (or 9.5 ms) for this system at 50 Hz. Using Leach's differential delay makes the delay appear worse than if you consider group delay alone. (.475 cycles for differential delay vs. .25 cycles for group delay)

But what we still don't know is: "How much bass delay is AUDIBLE?"

My current opinion would go something like this: "One cycle or so of delay in the bass range is probably just audible under controlled listening conditions (phones) and with the most challenging program material (clicks and pops). Under less well controlled listening conditions and with less difficult program material the audibility thresholds are somewhat higher."

What do you think? Is the delay (whatever flavor) of a 50 Hz, Q = .707 closed box audible?

Regards,

John

Tom responded (and Philip agreed):

>The statement "given only the frequency response of a system the phase
>response and group delay response can be calculated." is too often not true..

But I was careful to explicitly say that I was talking about "minimum phase systems". So I stand by my original statement as it applies to such systems. For a minimum phase system the frequency and phase responses are Hilbert Transforms of one another and can therefore be calculated from one another. However, I didn't and wouldn't claim that actual speakers are always "minimum phase systems".

To quote Dick Heyser
(from "Loudspeaker Phase Characteristics and Time Delay Distortion: Part 1", JAES, Jan 1969):

"If a network is minimum phase, there exists a unique relationship between
amplitude and phase which allows a complete determination of phase from amplitude"

So there should be no question that phase response can be calculated from frequency response for a minimum phase system.

Now, the real question becomes: 'to what extent are REAL speakers minimum phase?'

If I recall correctly, Dick Heyser expressed the opinion that loudspeaker drivers are 'largely' minimum phase systems. Otherwise why would Dick have spent so much time and energy discussing the Hilbert Transform and its use in acoustic analysis. But I couldn't find a statement to this effect in my brief search of his papers.

But I did see an AES preprint in which the author carefully measured the "excess phase" of a pair of tweeters.

AES Preprint 2118, A Micro-Computer Program for Computing the Phase Response of Dynamic Loudspeaker Systems"

The author measured the response of Dynaudio D-52 and D-21 dome tweeters and concluded: "It is seen that these two drivers are, very accurately, minimum phase devices."

I believe that deviation from minimum phase behavior is an exception for loudspeaker drivers under small signal conditions, and not the rule.

Tom went on to say:

> Zero degrees phase over the entire band (with flat amplitude response) is the
> ONLY condition which a loudspeaker can faithfully reproduce (acoustically) a
> complex non repetitive signal or asymmetric signal, just as in electronics..

This is an example of the "phase view" leading to an erroneous conclusion.

Example: If an audio signal experiences a broadband delay such that all frequencies are delayed equally, the waveform is reproduced EXACTLY in spite of the fact that the delay introduced a "zillion degrees"

of phase shift. The REAL requirement for faithful reproduction of a waveform is that the system have both flat frequency response and flat time delay. That is, all frequency components must arrive with the correct amplitude and time alignment. Flat phase response is just one case where the time alignment criteria is met. But what "delay" are we talking about? Phase delay? Group delay? I think the relevant delay here is Leach's "differential delay".

Does anybody have any measured data on the "excess phase" response of some of our popular drivers?

I am enjoying this "delay" discussion and appreciate that we may have differing opinions. I do hope I have convinced you that minimum phase systems really do have this characteristic that frequency, phase and group delay are just three different views of the same response phenomena.

In any event, do you think these "delay" effects are audible in our speakers?

John

The Subwoofer DIY Page
Measurements

last updated: 15 April 2006

- My home system
- Audio DIY Projects
- Audio DIY Links

- my home page

There are many different ways of measuring the Thiele/Small parameters of a driver. The methods outlined below provide a way of for the beginning DIYer to measure these parameters with the minimum of equipment.

Measuring Re, Fs, Qes, Qms and Qts

To measure these parameters using the method outlined below, you'll need to have the following items:

- One (1) amplifier
- One (1) audiofrequency generator
- One (1) digital multimeter
- One (1) 5 watt resistor (approximately 4 or 8 ohms)
- Two (2) pairs of alligator clip leads

Preferably, the multimeter should be capable of measuring frequency, as well as voltage, resistance and current. The amplifier should be capable of reproducing 20 Hz to 200 Hz with no variation in output and it should be insensitive to the loads above 4 ohms. The frequency generator should also produce a signal whose voltage doesn't vary as the frequency is adjusted.

Method:

- Measure the resistance, Re, across the driver terminals.
- Measure the resistance, Rs, across the resistor.
- Connect the audiofrequency generator to the input terminals for the amplifier
- Connect the multimeter to the speaker terminals of the amplifier
- Set the audiofrequency generator to approximately 100 Hz
- Set the output of the amplifier to Vs, where Vs~0.5V to 1.0V. You may have to experiment with different voltages, depending on the accuracy of your reading for Im.
- Calculate Is, where Is = Vs/(Re+Rs)
- Connect the following circuit (using the alligator clip leads where necessary)
    - Attach one leg of the resistor to the positive speaker terminal on the amplifier
    - Attach the other leg of the resistor to the positive terminal on the driver
    - Attach the negative terminal of the driver to the negative terminal on the amplifier
    - Attach the multimeter's leads to each side of the resistor
- Adjust the frequency until the voltage across the resistor reaches a minimum level.

- Measure the frequency, Fs
- Measure the voltage across the resistor, Vm
- Calculate the current, Im = Vm/Rs, flowing through the circuit
- Calculate the driver's impedance at resonance, Rm = (Vs-Vm)/Im
- Calculate the -3db curent, Ir = (Im*Is)^0.5
- Calculate r0=Is/Im
- Calculate the -3dB voltage, Vr = Ir*Rs
- Measure the frequencies, Fl and Fh, for which the voltage across the resistor is equal to Vr
- Check that (Fl*Fh)^0.5 = Fs
- If the above check out, then Qes, Qms and Qts can be calculated as follows:

Qms = Fs*(r0^0.5)/(Fh-Fl)
Qes = (Qms/(r0-1))*(Re/(Rs+Re))
Qts = Qms*Qes/(Qms+Qes)

You can use the following spreadsheet to perform the calculations automatically for you: TSPARAM.ZIP

Measuring Vas (equivalent air compliance)
To measure Vas, use a good solid enclosure of known volume that's about a cube of the nominal speaker size. Determine the total volume, including the speaker cut-out and that trapped by the cone with the speaker mounted on the outside of the box for easy access. Measure the resonant frequency in this situation as well as the free air space resonant frequency.

Vas = Vb((Fb/Fs)^2 - 1)

where

Vb is the volume trapped by the speaker and box
Fb is the resonance frequency of speaker and box

my thanks to John Straede of the ***BASS and DIY Loudspeakers List*** *for providing this method of measuring the Vas of a driver*

Elliott Sound Products **Project 84**

Eight Band Sub-Woofer Graphic Equaliser

Rod Elliott (ESP) [1]

Updated 02 Feb 2002

PCBs and a set of pots for this project are available. Click the PCB image for details

Introduction

Your sub is installed and set up as best you can, but you can't quite get it to sound right. Some frequencies are too prominent, while others seem subdued. If this sounds familiar, then this equaliser is what you need to fix it. It is not a panacea, and will not cure an impossible room, but the majority of lumps and bumps in the subwoofer response will respond very well to an equaliser as described here.

The unit is an 8 band variation on the expandable equaliser described in the Project Pages, and is dedicated to its task. Boards can be stacked to get more bands if desired, but the arrangement shown will be quite sufficient for most installations.

The equaliser is a constant Q design, so unlike most "ordinary" equalisers, it does not have a very low Q at low settings of boost and cut. This is a major problem with the standard (graphic) equaliser circuit, and is completely avoided by the constant Q version. Using the Multiple Feedback Bandpass design, these filters can be designed for any (reasonable) frequency and Q desired. As a 1/3 Octave equaliser, the filter Q should be 4.3, but I have deliberately lowered this to 4 for this design to allow a little overlap.

While there will always be "that" room which defies all attempts to make anything sound halfway decent, this EQ will dispose of the majority of problems likely to be encountered.

Description

The equaliser is 1/3 Octave band, with centre frequencies at 20, 25, 32, 40, 50, 63, 80 and 100 Hz. The circuit itself uses an opamp as an input buffer (U1A), ensuring a low impedance drive to the following inverting buffer. All filters are driven by an inverted signal from U2B, and the maximum amount of boost or cut is determined by the value of R18.

U1B is a summing amp, and it takes its input from the combination of the input, and the output signal from the CUT bus - this comes from the pots used as the level control for each frequency band. The combined signal is summed again by U2A, this time with the signal from the BOOST bus added. The signal drive to

all filters is performed by U2B, the gain of which determines the maximum boost and cut allowed. As shown, The circuit will provide about +/-14dB, and the response is completely flat with all pots centred. Reduce the range by reducing the value of R18 - a value of 10k gives 6dB of boost and cut.

The actual operation of the circuit relies primarily on the amplitude and phase of the selected frequency, and it is beyond the scope of this article to cover it in great detail. The inverted signal drive is compensation for the fact that a standard multiple feedback filter is inverting at the resonant frequency - I shall leave it to the reader to work out exactly what happens (assuming you care, of course :-) For full details of the circuit topology, see Reference below.

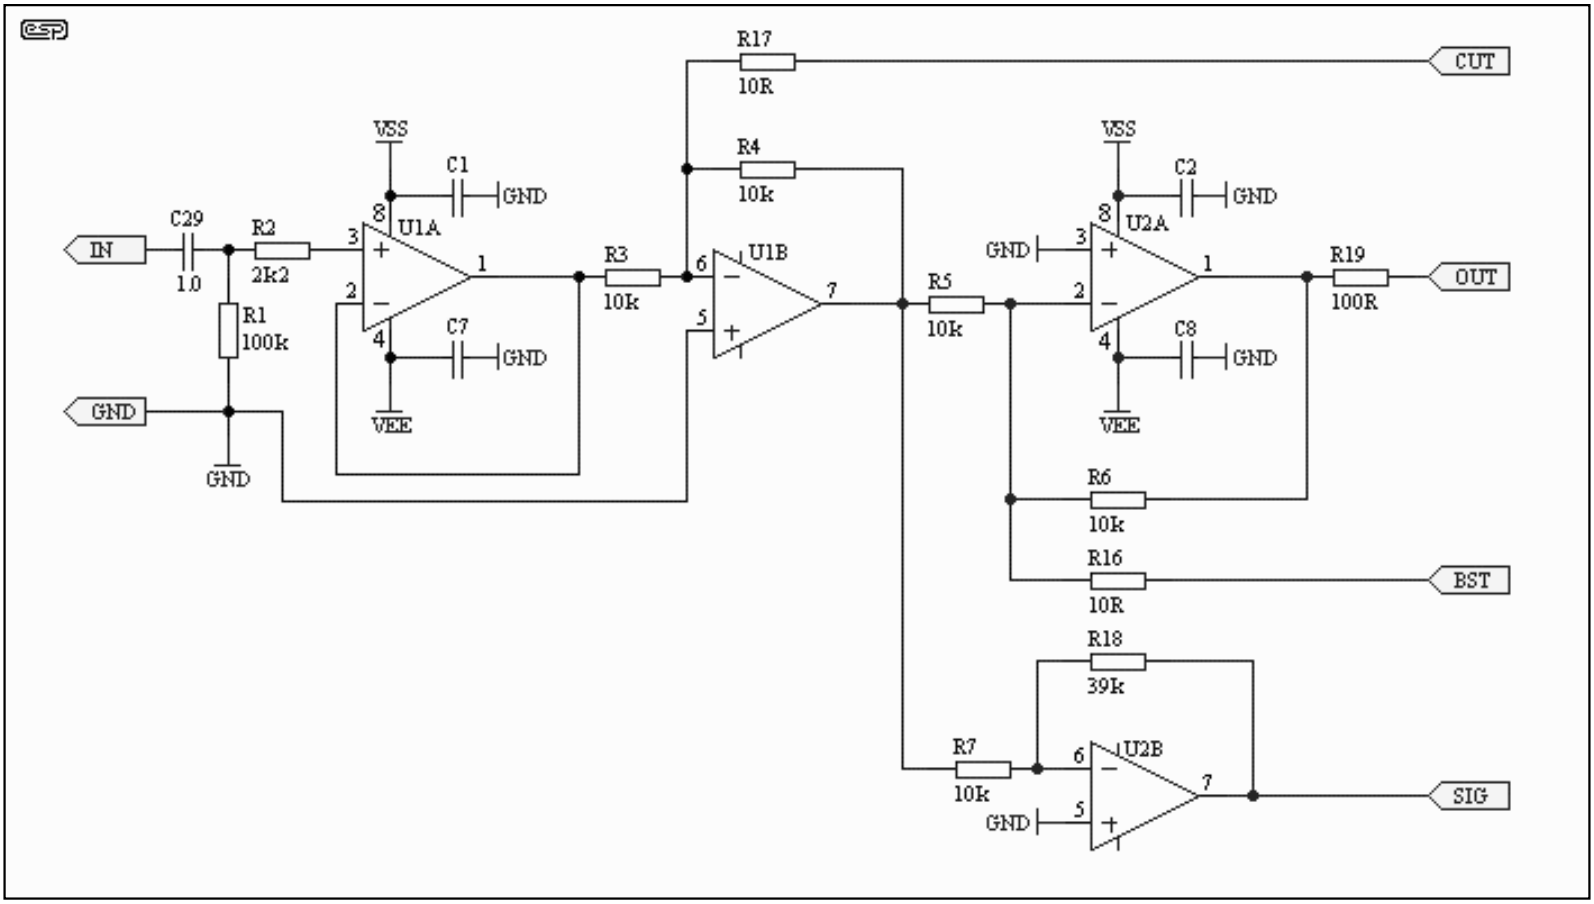

Figure 1 - Input and Output Circuitry

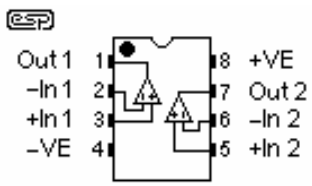
All unmarked capacitors (C1, C2, C7 and C8) are opamp supply bypass caps, and should be 100nF ceramic types for best performance. This is critical if high speed opamps are used, but still important if using the recommended TL072 opamps. There is little or nothing to be gained in using "audiophile" grade opamps for a subwoofer, since the TL072 has more than sufficient bandwidth for the job. Naturally if it makes you feel better, then OPA2134s or similar work beautifully.



The figure on the left (top view) shows the standard pinouts used for the vast majority or basically *all* dual opamps. If the PCB is used for this project (highly recommended, by the way), then only opamps with this pin configuration may be used. This is not a limitation :-) Correct insertion is (as always) essential, or the opamps will die ***!***

The filters are repeated - two are shown in Figure 2, and this functional block is then repeated 4 times to get the eight bands used. Again, unmarked caps C3 and C9 (and those for the additional 4 filter sections)

should be 100nF ceramic bypass types.

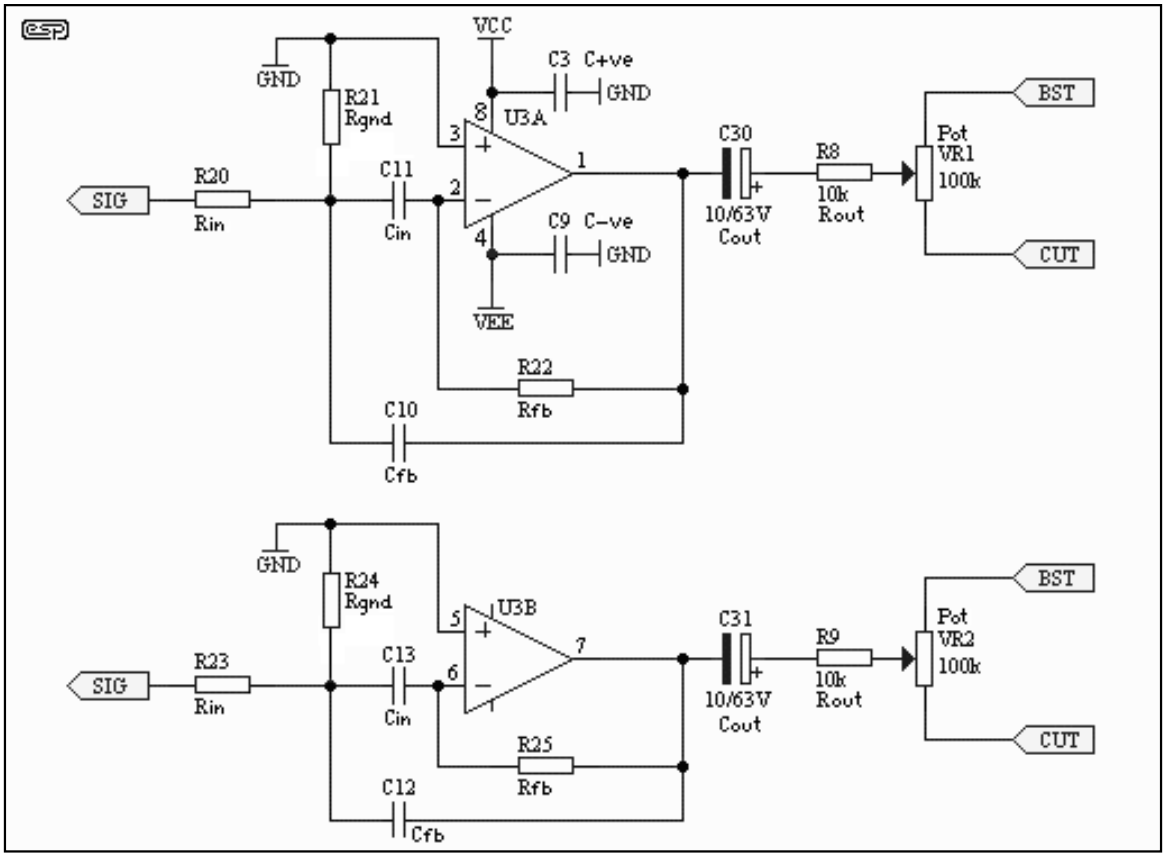


Figure 2 - Multiple Feedback Bandpass Filters

The table below shows the designations for all the filter sections. The output caps (10uF 63V as shown) may also be bipolar electrolytics - film caps would be nice, but are simply too large to fit on a decent sized board. The difference in performance is unlikely to be audible with any system, since the caps are very much bigger than they need to be at even the lowest frequency. The -3dB frequency for all output networks in this section is 1.6Hz worst case - well below anything we can hear.

	Band 1	**Band 2**	**Band 3**	**Band 4**	**Band 5**	**Band 6**	**Band 7**	**Band 8**
Pot	VR1	VR2	VR3	VR4	VR5	VR6	VR7	VR8
IC	U3A	U3B	U4A	U4B	U5A	U5B	U6A	U6B
Rin	R20	R23	R26	R29	R32	R35	R38	R41
Rgnd	R21	R24	R27	R30	R33	R36	R39	R42
Rfb	R22	R25	R28	R31	R34	R37	R40	R43
Rout	R8	R9	R10	R11	R12	R13	R14	R15
Cin	C11	C13	C16	C18	C21	C23	C26	C28
Cfb	C10	C12	C15	C17	C20	C22	C25	C27
C+ve	C3	-	C4	-	C5	-	C6	-
C-ve	C9	-	C14	-	C19	-	C24	-
Cout	C30	C31	C32	C33	C34	C35	C36	C37

The frequency selection components are shown in the following table - these are quite accurate, and will

generally be suitable for all applications. I have included the 125Hz band for those who may want to move the range up slightly - only eight of the frequencies are used for the unit.

Freq Band	Rin	Rgnd	Rfb	Cin, Cfb
20	330k	10k	680k	100nF
25	270k	8k2	510k	100nF
31	270k	8k2	510k	82nF
40	330k	10k	680k	47nF
50	330k	10k	680k	39nF
63	270k	8k2	510k	39nF
80	82k	2k7	160k	100nF
100	82k	2k7	160k	82nF
125	150k	4k7	330k	33nF

Arrrgh! The values are all over the place - this was done to avoid having to use caps in parallel (there is no room on the board), and I have tried to maintain at least passably sensible values. Unfortunately, maintaining the Q and frequency for such closely spaced filters is not easy, and the table above is the result. Feel free to use the MFB Filter calculator program to see if you can do any better - it is available from the Download page.

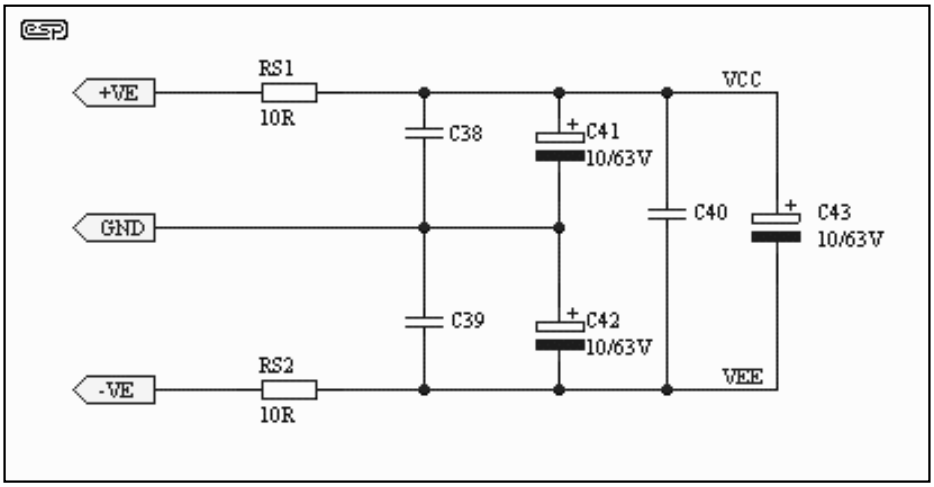

Figure 3 - Supply Conditioning Circuit

Finally, the DC input conditioning section. The 10 ohm series resistors can be omitted, but they do no harm, and help to isolate the supply from other circuitry that shares the same supply module (the P05 Power Supply is recommended for this unit). Small inductors can also be used if interference is a major problem, but these are unlikely to be needed in 99% of cases.

Although C41 and C42 are shown as 10uF 63V caps, I suggest that they be 100uF 25V - this is provided for on the PCB, which is now available.

Note

If you use the PCB for this project, it is designed to use miniature (9mm square) rotary pots, so the term "graphic" equaliser is something of a misnomer. If desired, slide pots may be used, but will have to be

wired to the board. This is not as arduous as may first be thought, since there are only 10 wires needed. If required, the 9mm pots can be obtained from ESP.

Using The Equaliser

Connect the equaliser into the signal path (usually between the source and the subwoofer equalisation and/or power amplifier). Make sure that all pots are centred for an initial flat response. Verify that the sub sounds the same as before, then preferably with a test CD (known music will work too, but is not as predictable), run a frequency sweep (or burst signals) and adjust the equaliser for the smoothest response in the low frequencies. You should be in your normal listening position for this - the sound quality will be different in different parts of the room, and this is part of the problem in the first place.

Make adjustments sparingly - over use of an equaliser is a guaranteed way to ruin the sound, so make adjustments in small increments, one band at a time. It may take a while before you are completely happy, but careful listening and perseverance are the key to getting ot right. Generally, you are more likely to need a reasonable amount of cut than boost, and although possible, it is not really practical to make the circuit asymmetrical.

Once set, the EQ settings will not need to be changed, so the unit should be placed where it is not readily accessible - you ***know*** what will happen if others know that it's there, and what it does.

The settings will need to be changed if the subwoofer is moved, or if furniture is moved, added or removed from the listening area. Large soft furnishings will make the biggest difference, while small (open) shelves will usually make little or no change at all. Book cases are highly unpredictable animals, and only careful evaluation will determine if the settings remain accurate if a bookcase is added or removed.

Reference

The design presented here is based on a paper (Constant Q Graphic Equalisers), written by Dennis A. Bohn of Rane Corporation. The original work can be downloaded from the Rane site ... http://rane.com/pdf/constanq.pdf

Why DIY?

Contrary to popular belief, the main reason for DIY is not (or should not be) about saving money. While this is possible in many cases (and especially against 'top of the line' commercial products), there are other, far better reasons to do it yourself.

The main one is knowledge, new skills, and the enormous feeling of satisfaction that comes from building your own equipment. This is worth far more than money. For younger people, the skills learned will be invaluable as you progress through life, and once started, you should continue to strive for making it yourself wherever possible.

Each and every new skill you learn enables the learning processes to be 'exercised', making it easier to learn other new things that come your way.

Alvin Toffler (the author of Future Shock) wrote:- *"The illiterate of the 21st century will not be those who cannot read and write, but those who cannot learn, unlearn, and relearn."*

This is pretty much an absolute these days, and we hear stories every day about perfectly good people who simply cannot get a new job after having been 'retrenched' (or whatever stupid term the 'human resources' people come up with next). As an aside, I object to being considered a 'resource' for the corporate cretins to use, abuse and dispose of as they see fit.

The skills you learn building an electronics project (especially audio) extend far beyond soldering a few components into a printed circuit board. You must source the components, working your way through a minefield of technical data to figure out if the part you think is right is *actually* right. Understanding the components is a key requirement for understanding electronics.

You will probably need to brush up on your maths - all analogue electronics requires mathematics if you want to understand what is going on. The greater your understanding, the more you have learned in the process. These are not trivial skills, but thankfully, they usually sneak up on you. Before you realise it, you have been working with formulae that a few years ago you would have sneered at, thinking that such things are only for boffins or those really weird guys you recall from school.

Then there is the case to house everything. You will need to learn how to perform basic metalworking skills. Drilling, tapping threads, filing and finishing a case are all tasks that need to be done to complete your masterpiece. These are all skills that may just come in very handy later on.

Should you be making loudspeakers, then you will learn about acoustics. You will also learn woodworking skills, veneering, and using tools that you may never have even known existed had you not ventured into one of the most absorbing and satisfying hobbies around.

Ok, that's fine for the younger generation(s), but what about us 'oldies'? We get all the same benefits, but in some cases, it is even possible to (almost) make up for a lifetime spent in an unrewarding job. As we get older, the new skills are less likely to be used for anything *but* the hobby, but that does not diminish the value of those skills one iota.

However, it's not all about learning, it's also about **doing**. Few people these days have a job where at the end of the day they can look at something they built. Indeed, in a great many cases, one comes home at the end of the day, knowing that one was busy all day with barely time for lunch, yet would be hard pressed to be able to say exactly what was achieved. What would have happened if what you did today wasn't done? Chances are, nothing would have happened at all - whatever it was you did simply wasn't done (if you follow the rather perverse logic in that last statement).

Where is the satisfaction in that? There isn't any - it's a job, you get paid, so are able to pay your bills, buy food and live to do the same thing tomorrow.

When you build something, there is a sense of pride, of *achievement* - there is

something to show for it, something tangible. No, it won't make up for a job you hate (or merely dislike), but at least you have created something. Having done it once, it becomes important to do it again, to be more ambitious, to push your boundaries.

Today, a small preamp. Tomorrow, a complete state of the art 5.1 sound system that you made from raw materials, lovingly finished, and now provides enjoyment that no store-bought system ever will.

The Financial Side

(Advertising slogan ... 'Buy NOW and save!' Translation ... buy now and **spend**)

It has to be considered that no hobby is financially 'viable' as such. People who build model planes or railway layouts or knit jumpers don't do it to save (or make) money, they do it for enjoyment, for the love of creating (or re-creating) something.

For some, it is imagined that by using the DIY approach, they will save money. No, you won't (well, you *might*, but if you do, that's a bonus, not the reason). In general, you will spend money, and if you were to add in the tools that you buy to DIY, plus the book(s) that you figured you needed, plus the costs of the occasional mistake that destroyed an amplifier's output stage, plus a bit of this and a bit of that ... it all adds up.

No. You won't save money. After the first few projects are working and have become part of the furniture, then you realise the real benefits. The gain is just a bit too low - open up the case, change a resistor, and voila! Easy. Cheap. Try getting a major manufacturer to do that with a commercial product - even worse, take it back to the shop and ask them to increase the gain by 6dB ...

- They won't know what you are talking about
- They don't care what you are talking about
- Strangely, they invite you to go away and urinate

Having built a pair of speakers and a preamp, you read an article on the Net that claims that biamping is almost magic! Well, you do have another amp lying about, but can you get everything else you need to try this for a sensible price from a shop? No. Can you make an electronic crossover yourself? Yes. This time, it *will* be cheaper than you can buy one for, because you already built your own preamp, you know what's in it, you can add the board to include a crossover. Your preamp and speakers will be out of service for a couple of days at most, and if you decide for whatever reason that you don't like it,

you can change back. The total cost in real terms is peanuts.

More importantly though, the whole process is one of learning, experimentation and experience. These are all priceless - you can't buy them. By doing it yourself you can only improve yourself. If things go wrong, this is even better (believe it or not).

There is absolutely no doubt that few things are as discouraging as a DIY project that doesn't work. Despite that, there are few things more encouraging than (eventually) finding the problem and fixing it. Don't expect it to be easy, because it almost certainly won't be. Servicing and fault finding are special skills, and are almost impossible to teach (except perhaps for a particular product where common faults are known).

To track down a fault that exists in something that has never worked is particularly difficult, but it can be done - many people do just that on a daily basis. For the DIY enthusiast, it will be harder, because most are amateurs without electronics training. Experience is one of the best forms of education - you rarely forget things you learned the hard way.

There are countless debates on the Web and elsewhere about 'esoteric' components. Some may claim that silver wire (for example) will magically transform your listening experience ... it probably won't, but that's another issue entirely. Others claim that this capacitor or that resistor is so markedly superior that nothing else should ever be used. Again, maybe, maybe not. Only with the DIY approach can these claims be tested unless you have money to burn. Having equipment modified is expensive, and there's no actual guarantee that its technical specifications will be improved - indeed, in some cases the reverse is true. You are forced to believe that it sounds 'better' regardless of technical specs. Yet again, maybe, maybe not.

If you can make the modifications yourself, then the cost is minimal. You only pay for the components, and install them yourself. If there is no improvement (or worse, performance is degraded), then it is easy and cheap to revert to the original circuit.

As a DIY person, you will also be able to make (rather than try to buy) an AB switch box so that you can make direct (blind) comparisons, and find out for yourself if there is any difference between 'ordinary' and 'magic' components. More knowledge to you either way. Should you correctly identify the magic component 70% of the time, then you *know* it really does make a difference. Likewise if you hear no difference - you *know* this because you did the test! Without this first hand knowledge, you are the mercy of the snake-oil vendors and their often very convincing sales banter, or those who say that nothing makes a difference and all amps sound the same.

While I can tell you that neither side is right for the most part, it is only with your own curiosity and test processes that you will ever know the truth. Some things may make a difference in your particular case, but only experimentation will reveal what works and what does not.

Should you simply want to use the best components you can obtain, again, this is your choice. Most of the parts you buy will be no worse (and often much better) than those used in mass-produced commercial equipment anyway, you control the standard of workmanship, and if it fails, you will be able to repair it yourself. These are all major benefits, and to get the same benefits from any commercial product, it will cost you a great deal of money. If looked at from that perspective, then you actually will save by adopting the DIY approach.

Contra-Indications

There are some important factors that you will miss out on if you follow the DIY approach, but in fairness to the hobby, they are only important to some people. Should you be the type who is impressed by the front panel, brand names, image, and fancy advertising, then DIY is **not** for you. You will get none of these things, and the appearance of the finished article will rarely be as fancy as the commercial offering.

Never mind that fact that many commercial products use a plastic front panel that may be dressed up to *look* like solid metal, or the likelihood that the internals are built on phenolic PCB (the cheapest available material). The chassis will be of thin pressed steel or maybe plastic as well as the front panel, and the top cover will almost invariably be thin sheet steel, with a spray coating.

But ... they are dressed up to look great, as long as you never remove the cover. The obviously cheap components in most consumer goods are probably not much worse than the ones you can buy, but the standard of workmanship often leaves a great deal to be desired.

None of this matters if you are only interested in the image. None of it matters if you update your gear regularly whether it still works or not. It definitely doesn't matter if you get the equipment for the right price and it does everything you ever want or need.

Of course, with time, patience and a willingness to pay for specialised work, you can build something that is vastly more impressive than the commercial offering - but if it

lacks the image you are looking for, then your friends will fail to be impressed. This is regardless of performance, which in many cases is secondary to image.

So, if any of the above applies to you and/or your circle of friends, then don't bother. No-one but you will appreciate the effort you put into it, and without the image it might as well be salvaged from the local dump, or <insert local charity here>.

The image from DIY is the one that ***you*** create, and when all is taken in context, you have something of which you can be rightfully proud. If others don't like it, that's their problem, not yours. If it happens to outperform the system they paid $thousands for, then they probably *won't* be impressed, but usually not for any of the reasons they may claim.

Conclusion

People choose DIY for the fun of creation, to learn, or to get something that can't be bought because it is too specialised - even in a seemingly minor respect. Sometimes, all three will be involved at the conscious level, but all three will be usually be involved at the subconscious level.

When you make something (even from a kit), you have the opportunity to customise it so that it does exactly what you want, not what someone else's marketing department told you you want. You will always learn from the experience of building it, even when it seems like a mindless chore stuffing components into a PCB and soldering them in. When it's finished, installed in your system, and doing exactly what you want, then the fun and pride of having made it will always be there - even long after the event.

Do you get any of these things when you buy a product? In a word, no. It is simply a commodity, something that countless others have, exactly the same as yours. If it doesn't do exactly what you want, then you have to live with it - even make excuses to yourself in extreme cases (where you'd like to strangle the salesthing given the chance).

DIY is not for everyone. Some people are forced into it because they *can't* get exactly what they want, and others do it because they think they'll save money. These are not good motives for DIY, although once they get into it, the motives will hopefully change.

The number one reason for DIY is simple - fun. Audio is a hobby for most people, and hobbies are meant to be fun - recreation at its best. In the same way that listening to your system is a recreational activity, so too is building your system yourself. As with all

hobbies, there are new skills to learn, a complete jargon to master (that part is admittedly not so much fun), and something to show for it when it is completed.

Having acquired various tools (and talents) along the way, you may find that you can use them for other DIY activities - especially woodworking tools. Again, don't expect to save money. Many goods are available that are made in China (or perhaps India or some other developing country) for far less than you could build them for. Some are real bargains - well made, and will last well in normal use. Others are terrible - cheap materials, flimsy and with a marginal finish that won't last until next Thursday.

The old saying that 'you get what you pay for' no longer holds relevance - some bargains are real, others are very obviously false. Some highly priced goods are no different from the bargains, many having been made in the same factory (some may even be *identical* to a bargain version).

Again, the DIY approach is more about satisfaction and creation than anything else. If you do happen to save money in the process, then so much the better.

Finally, to get an idea of the reasons people get into DIY for the home itself (and yes, it is relevant), have a look at the UK site Social Issues Research Centre. There are differences of course - a house and a hi-fi system tend to be rather different by their very nature, but the reasons for DIY in any form are often very similar.

Elliott Sound Products **Price List**

Price List Vers 1.21 - 02 Feb 2006

Updated 26 May 2006

This is the latest pricelist. The prices shown are current as of the date shown above and as always, will remain stable for as long as possible. Using a credit card will usually get you the best exchange rate possible at any point in time.

Please see the purchase information for complete purchase details, order forms, warranty information, etc.

ESP implemented a loyalty programme, effective as of 1st July, 2005. Click here for more information about the programme, redeeming discount vouchers, and the terms and conditions for earning 'loyalty points'.

For added peace of mind, your package may be sent as registered mail (within Australia only), or insured (International only) The codes and prices are shown below. Be sure to check the details below first, and if you are still unsure, send me an e-mail. International post can be very frustrating because of the different regulations world-wide.

Order Code	Description	AUD (Aust)	AUD (RoW *)	USD (RoW *)	
REG	Registered Mail to a value of AU$100 (Australia Only)	AU$ 5.50	n/a	n/a	
INS1	Insurance to AU$100 (Overseas Only)	n/a	AU$15.00	US$12.50	
INS2	Insurance to AU$200 (Overseas Only)	n/a	AU$17.00	US$14.20	
INS3	Insurance to AU$300 (Overseas Only)	n/a	AU$19.00	US$16.00	
	Pack & Postage	AU$ 5.50	AU$12.00	US$10.00	

Where registered mail (Australia) or insurance (RoW) is requested, the fee for either is in addition to pack and postage charges.

* RoW - Rest of World

Please note that insurance is not available to all countries. The ones I know that will not accept insurance are ...

> **Canada**(see below), Indonesia, Israel, Malta, Mexico, Philippines, Solomon Islands, Vietnam, Botswana

There may be others, but I have not had to deal with them at this stage. In addition ...

- Germany will accept insurance on letters only - packages may not be insured. Most articles are sent as 'large letter', but some items (notably bulky things like modules, microphone housings) must be sent as packages.
- The US only accepts insured packages - large letters (the majority of my outgoing mail) cannot be insured. Where insurance is requested the goods will be sent as a package (***which costs me a lot more!***).
- Canada has recently been declared an insurance free zone by Australia Post, so Canadians can no longer obtain insurance (don't ask - I have no idea why). The best I can offer is 'delivery confirmation' at AU$5.00 in addition to normal postage charges.
- Switzerland insists you must collect insured items from the Post Office
- Sri Lanka has a AU$60 maximum limit for insurance

If unsure, See the Australia Post web site for more info, or contact ESP for confirmation.

Note Carefully: If you choose not to take out insurance sufficient to cover the full cost of the order, my (official) responsibility stops upon lodgement of the package at the Post Office. Should your package go missing (very rare, but it has happened), then the loss is yours. I will always endeavour to track what happened on your behalf and recover your goods if possible, and in the majority of cases a mutually agreeable solution can be found that minimises both your loss and mine. Please note that if an insurance claim must be made, there is extensive paperwork, and an even more extensive waiting period as Australia Post argues with the destination postal service. This can typically take two *months* or more! (Yes, I know this is stupid beyond belief, but I didn't make the rules.)

Although most people do not have a high opinion of the postal services, it is my experience that international mail is treated by Australia Post and the postal services of all major countries with the highest integrity.

> **Notes:**

- Available only with PCB purchase. *
- RoW - Rest of World (Anywhere outside Australia).
- US$ Prices are for PayPal Purchases *only!*

Unless noted otherwise, all PCBs are sold as a bare board, and *no* components are included.

If your browser does not support Javascript, Right-Click the link, and select "Open in New Window".

The boards listed here represent very good value for money - all boards supplied have very comprehensive documentation available from ESP's secure section of the Web site. A CD-ROM is available for a small extra charge. The CD is provided free for orders over AU$75.00 - note that this specifically *excludes* postage and handling charges, registered mail (in Australia) or insured mail (rest of world).

Your product purchase supports The Audio Pages, and is the ***only*** way that this site can continue. Without your purchase, the articles and projects will cease to exist, as the cost of maintaining the site would be prohibitive without any way to pay for the site and its

maintenance.

My thanks to all those who have bought (or are planning to buy) project PCBs or other products. Without you, The Audio Pages would be no more. Your continued support is greatly appreciated.

Please read this page thoroughly, so that you understand the payment methods and warranty provisions, and any country specific information. To simplify the page, I have separated the major sections into Javascript "popups", making navigation a lot easier because of the large amount of information provided here.

- 1mm Diameter PCB Pins
- Documentation CD

IMPORTANT: If you don't see the board you want here, then it is not available. This page describes all boards currently for sale, and if it is not listed, I don't have it. Also, do not ask for artwork, as refusal is **guaranteed**. In some cases I have been asked because "it is difficult to get boards shipped to [wherever]". While this may well be true, I *will not* supply my original artwork to anyone for any reason.

Boards are supplied as a blank PCB only - no components or other parts are included. Please do not ask about kits, as these are not available, nor are heatsinks, transformers or other components not shown in the pricelist.

ESP Loyalty Programme

ESP has just implemented a loyalty programme. This is effective as of 1st July, 2005, and several discount vouchers have already been delivered. Click the link above for more information about the programme, redeeming discount vouchers, and the terms and conditions for earning 'loyalty points'.

On-Line Construction Info & Terms and Conditions

When boards or other products are ordered, you will be sent a URL, Username and Password to access the board construction articles. The latest information is available on these pages, and you will be able to see the information for the boards you have purchased as well as the other constructional articles. Please click on the header to read the full details.

How to Purchase

There are several options for purchase, and all are quite straightforward. Please click on the section header for the full details. ESP accepts Visa, Mastercard, Bankcard (Australia only), PayPal, Paymate and direct bank deposits.

On-line purchase is not available at this time. When sending your card details, make sure that your details are entered on the order form or the Encrypted Form

Welcome Here

PayPal Info **Paymate Info**

International Customers

Use the GST free board prices listed - you will be billed in Australian Dollars, and the final price that appears on your card statement is determined by the exchange rate prevailing when the card details are processed. Click on the header for more information, currency conversion details, etc..

Australian Customers
For local customers, please note that the GST included price must be used for all orders. A personal or bank cheque is acceptable - but goods will not be shipped until the cheque is cleared. The preferred payment methods are Visa, Mastercard, Bankcard, Australian Post Office money order or Paymate.

Australian residents using PayPal must add GST to the $US price - multiply the price shown by 1.1

Please note that free postage for Australian orders no longer applies - see pricelist form for details

Shipping And Documentation

Boards are normally shipped in a padded postal bag via normal mail, and this is at the rate shown in the pricelist. Where possible, orders are sent as 'large letter' in a padded bag. Customs forms are not required by Australia Post for the padded bags, and are not used unless the package has to be sent as a 'parcel' (anything that is bigger than a large letter). Click on the header for more information.

Order Codes
The order code for each PCB or other product is shown in the price list. Where there is

more than one board for a project, they will have the suffix A, B, (etc.) - for example P27a and P27b (guitar amplifier boards). All boards are made with fibreglass PCB material. Some boards are sold in pairs, please note that paired boards will not be sold individually, nor in odd numbers.

Miscellaneous Info.
All board sizes are in millimetres and are approximate to the nearest millimetre. Board thickness is approx. 1.6mm unless otherwise stated.

Some boards have relatively small tracks and closely spaced components. These require a fine tipped soldering bit (preferably temperature controlled), and careful soldering techniques. If you are new to soldering components into a PCB, please exercise caution during construction, as it is possible to damage the board with excessive or prolonged heat.

Warranty

All goods are checked before shipping, but it is possible that a defective board or disk may be supplied. The boards are warranted to be free from defects that would make them unusable for the intended use. Such boards will be replaced free of charge or a refund given upon receipt of the defective board(s). Click on the header for more information.

Returns

ESP regrets that if you change your mind, returns are only available under some conditions. Full details are available by clicking on the header above.

Package Loss

Package losses are extremely rare, but for shipping to the some countries, insurance is highly recommended. Please see the pricelist for the most up-to-date information I have available. More information is available by clicking on the header.

Order Forms

Load the HTML form, save a copy of the text form, or download the order encryption program. Please fill in all sections. Print a copy of order form to mail or fax, or e-mail the

encrypted order.

Printed order forms can be sent by post or FAX to a secure machine. Please do not send cover sheets or other un-necessary sheets - all needed information is on the order form. The facsimile number is ...

In Australia	**02 9945 1385**
International	**+612 9945 1385**

US Customers please note that +612 is the country and area code, and is not a US domestic area code.

Elliott Sound Products **Application Notes**

Page Last Updated - 03 July 2005

These application notes are presented as a means of making useful circuits and sub-circuits available, along with some information about how they work, test results (where applicable), etc. Some of these are adapted from the projects page, as their application has the potential to be broader than indicated in the project itself. More will be added as time permits.

Few of these (already published or yet to be published) are original, although some have been adapted and changed to the extent that the original may barely be recognisable. As always, if you have a good circuit idea feel free to submit it (along with any reference material).

Manufacturer Application Notes *

No.	Description	Date	Flags
AN-166	Basic Feedback Theory (Philips Semiconductors)	Dec 1988	
AN-1000	Mounting Guidelines for the SUPER-220 - Transistor Mounting Techniques (IR)	Unknown	
AN-72	A Seven-Nanosecond Comparator for Single Supply Operation (Linear Technology)	May 1998	

Each application note may have one or more "flags". These indicate the status of the app. note, and are as follows ...

new	The design (or update) is less than 2 months (or thereabouts) old.
	Mains wiring is involved, and is potentially dangerous - heed all warnings ! Note that other app. notes may also need a power supply which also requires mains wiring.
Date	The page was added or updated on the date shown

* Manufacturer Application Notes will most commonly be links to external sites, although a small number may be included on the ESP site. These remain the intellectual property of the original author/manufacturer in all cases.

Updates

ESP reserves the right to change or update application notes, projects and articles

without notice, so it is important to be aware that a change may have been made. You should always watch for updates of previously published items. Do not build any of the circuits presented here without checking for updates first. A "new" symbol indicates an addition or update within the last two months or so.

Note Carefully

Please see the ESP disclaimer for important information about this site and the contents thereof.

WARNING

Where applicable, mains wiring should be carried out by suitably qualified persons only. Under no circumstances should any reader construct any mains operated equipment unless *absolutely* sure of his/her abilities in this area. The author takes no responsibility for any injury or death resulting from, whether directly or indirectly, the reader's inability to appreciate the hazards of household mains voltages, lack of knowledge of correct wiring practices, etc. Please read the disclaimer now if you have not done so already.

Please note that these application notes are not supported, so do *not* ask for assistance or explanations. All circuits are checked for accuracy, but it is not guaranteed that they will work for your application. In the same way that you might find application notes published by semiconductor (or other) manufacturers, you don't e-mail them for help and the same applies here.

Submissions are welcome, but unlike magazines where they may offer prizes or cash for submissions, all I can offer is wide distribution of your idea. Please ensure that any submission is accompanied by full disclosure of references - do not try to claim the work of others as your own.

Elliott Sound Products **Custom Design and Consulting**

ESP Services

Telecommunications

I will perform contract work for telecommunications systems, especially IVR (Interactive Voice Response) systems, and PABX (PBX) and Call Centre integration of same. This will be by direct negotiation in all cases, and as initial contact please send me an e-mail. The details (including confidentiality agreements and scale of charges) are negotiable, and will not be posted here.

The range of services provided is likewise subject to discussion and negotiation - please use the contact page to send me an e-mail with a brief description of your needs. All contact details (phone, mobile, etc.) will be provided by return e-mail.

Audio & Analogue

Should you have specific requirements for a customised design or something completely new, ESP may be able to help. I have developed many products over the years, both for individual customers and various employers, and during those periods when I was operating my own business (Elliott Sound Products).

Please Note - The availability of my time at the moment is not at all good, as I have been very busy. The chances of a complete design for a product are poor - by all means ask, but don't expect that I will be able to help. Projects for individuals or minor modifications to an existing published design are not possible at this time.

Some examples will show the range and diversity (customer names and specific details will not be disclosed under any circumstances).

- ***Audio circuits.*** (Naturally) some samples are to be seen in my Projects Pages.

These say far more than I can here, and as noted, most are original designs. This is actually a small sample, as there are still some very original ideas that I am unwilling to release to the public domain.

- ***Valve (Tube) Power Amplifier.*** This was one of my most satisfying designs, producing a product that achieved critical acclaim and was deemed by most to be one of (if not the) best sounding amp they (the critics) had ever heard.
- ***Animation Camera controller.*** This was a one-off development to repair an animation camera that was deemed a write off by everyone else. It included all the necessary motor controls for a standard 6 axis (zoom, top peg bar, bottom peg bar, east-west, north-south and rotate) camera, and included movement counters, limit switching and shutter controller.
- ***Printed Circuit Board Design.*** I have been doing this since the days of sticky pads and tapes, and have designed boards for all my own designs (including all the products described here).
- ***Telecommunications System Power Fail Transfer Unit.*** This was designed for my employer at the time, since a new version of the telecommunications system we sold did not have this feature. The unit was so successful that many years later when the system was replaced, it took the installers two hours to work out why the system was still taking calls - even though all the leads to the PABX were disconnected!
- ***Telecommunications Conference Bridge.*** Another special for an employer, this unit can set up automatic (emergency) conferences with up to 64 parties - all in full duplex conference, or operate in "dial up" mode, where up to 64 parties can call a designated number and be connected to the conference. A new feature (not available on any existing conferencing system) is the ability of any conference party to mute their channel (at the bridge, not their phone) if they are in a noisy area that would make the conference difficult for others. This unit has resulted in sales worth a great deal of revenue for my employer. This unit is completely analogue, and is far better than any digital system I have used.
- ***Multi Projector Controller.*** A controller for multiple slide projectors (used for advertising in shopping centres and the like), which controlled the timing for slide changes, controlled turn-on for the lamps to prolong their life, and jamming sensors to prevent the projectors from melting (and yes, this did happen with the original simple controller).
- ***Multi Sector Intruder Alarm System.*** This was (in its time) one of the most sophisticated alarm panels available, and had unique automatic arming and re-arming features that even now (with computer control) are not commonly available.
- ***Sound Recording Studios.*** I have designed two recording studios, one for myself and a business partner, and another on contract. Both were deemed very successful, and had excellent acoustics.

- ***Software.*** I have written various software programs, most for "fun", and one commercial product as well. Various of these are in daily use (world-wide), and the only comments I get are positive. I have also developed computer controlled telecommunications test sets and the software to drive them.
- ***Digital Circuits.*** While I am not a fan of digital audio, I have developed many digital control systems, and several of the products above are based on logic control.

As I said above, a small sample. Please contact me if you have anything that I might be able to help you with.

Terms & Conditions

As can be expected, these are negotiable on a case by case basis. I will generally be happy to operate on a Payment for Service basis, or a royalty based on the number of items sold and my contribution to the product.

I do not expect to have to use the services of lawyers for any contract, unless the value (to you or me) justifies this. A sample contract is available upon request.

Absolute confidentiality is guaranteed for all negotiations, designs and products.

Elliott Sound Products — Privacy and Ethics Statement

The Internet by its very nature is distributed and unregulated. While this is undeniably its greatest asset, it also eliminates many of the tangible cues to a merchant's credibility, which are normally quite obvious in the real world. In the hope of replacing these lost "consumer comfort factors", and preferably without the need for government intervention, Elliott Sound Products (ESP) voluntarily commits to follow a Universal Standard of Ethics when transacting business on the Internet.

As a reputable member of the global Internet commerce community, ESP hereby agrees to ...

Ethics

- Deliver what we promise and promise only what we can deliver.
- Deal honestly and fairly with customers.
- Accurately represent who we are and what we do.
- Fulfill any warranty claim within a reasonable period of time.

Credit Cards *

- Charge only the amount required for the goods ordered and appropriate postage, in accordance with the published prices.
- Never apply any undisclosed charge, repeat charge, or other charge unless specifically requested by the purchaser to do so (for example, add additional items to an order).
- Not apply any surcharge for use of a credit card.

***** ESP reserves the right to correct errors in orders, where the total cost has been incorrectly calculated by the purchaser, the incorrect pricelist was used, or other errors as may occur from time to time. You will *always*be advised of any changes and the reasons for those changes.

Complaints

- Promptly respond to all customer complaints
- Employ our best efforts to fairly resolve all legitimate complaints in a timely fashion

Advertising

- Ensure to the best of our ability that no documents containing false statements are distributed on-line

- Promptly substantiate any statements or advertised claims upon request
- Not undertake any unsolicited electronic advertising or bulk e-mailing of any kind

Disclosure

- Disclose basic features and benefits of products in language that is easily understood by the consumer - bearing in mind that such descriptions are commonly of a technical nature because of the products I sell
- Disclose all terms, conditions, financial and contractual obligations applicable to the transaction including warranties, returns and refunds
- Disclose the price, type of currency and all fees, surcharges, and shipping costs associated with any transaction
- Disclose availability of goods and services, timing of billing, and realistic shipping expectations

Adherence to Laws & Regulations

- Abide by all laws of the Australian Federal and State Governments regarding credit card transactions
- Abide by the rules and regulations pertaining to the Merchant Credit Card Facilities provided by the Commonwealth Bank of Australia or other financial institution as may be used in the future.

Your Privacy

This is one thing that terrifies many potential Internet purchasers, since they are never sure what the merchant will do with their personal information. We know that you are concerned about your privacy and so is ESP. If you provide information about yourself or your business, such as name, postal or e-mail address or other data, this information will be added to our internal data records. Any information received from you (either by mail, fax or in any electronic format) is used internally by ESP alone, and is not shared with *anyone*.

Privacy

- ESP's privacy policy is absolute. Your name, details of purchases and address are absolutely confidential, and will not be disclosed to anyone who does not need this information other than for the authorisation of a credit card purchase, unless I am lawfully obliged to provide such details to a government agency or other statutory body.
- Your credit card details shall not be stored or archived on any computer (unless fully encrypted), and will be kept safely and securely only in the original purchase form and credit card voucher. All card details are destroyed by shredding after the statutory holding period has expired (as established by my bank's policies).
- Used facsimile (fax) developer rolls are cut into small sections and heated to melt the 'ink' before disposal (these otherwise contain a perfect negative image of all pages printed by the fax machine).
- ESP will not send unsolicited e-mail, nor provide your e-mail address to any other party for any reason whatsoever.
- Where your information is supplied in relation to an order for purchases, the information will be used solely for that purpose. ESP will not share personally identifiable information with any third party without your express consent.

On the subject of privacy - because ESP is operated from my home address, I do not advertise or publish the street address or telephone number of the business. This is sometimes seen as evidence of a business that has something to hide - this is not my intention - I am entitled to some privacy as well, and that is the sole reason for this omission. If you have a reason for needing this information, all you have to do is ask.

So far, I have not had one complaint from a customer, nor from my credit card handling facility, PayPal or Paymate. I am determined to keep my reputation - honesty and integrity are the only tools at my disposal to achieve this.

The Lead-Free Solder Directive

The EEC's RoHS (Reduction of Hazardous Substances) directive is due to become mandatory in 2006, and while the overall idea seems reasonable, it is flawed in the extreme. There is little or no evidence to support the claims that lead is 'leached' out of solder by acidic groundwater, and since lead is almost impervious to most acid and alkaline attacks, there is no reason to believe that there is any real hazard. Indeed, high temperature tin-lead solders (those with more than 85% lead) are *exempt* from the directive. So highly leaded solder is less of a problem than the 40% lead solder normally

used? I don't think so!

The costs to manufacturers will be very high, with higher energy usage needed to achieve the higher temperatures needed. Higher temperatures mean greater thermal stress on PCBs and components, potentially reducing their life expectancy. There is a great deal of concern over the RoHS directive worldwide, since any product made after July 2006 cannot be sold in the European Community if it uses lead based solder.

The alternatives are many - so many in fact that all they have achieved is confusion. Some patented lead-free solder formulations are totally incompatible with lead based (and some other lead-free) solder alloys, and a small mistake by a service technician could render a part or an entire PCB assembly unusable because of unreliable solder joints caused by incompatible alloys.

Bismuth in particular is a problem if any lead based solder is inadvertently used, and lead contamination of a tin-bismuth-silver based solder results in joints with very poor thermal properties, and a high probability of faulty joints appearing shortly after repair work. Such lead contamination can result from the use of PCBs or components with lead based solder 'tinned' leads or tracks, or from the application of lead based solder during repairs. If accidentally contaminated, there is a likelihood that an entire PCB may have to be scrapped unless there is a method to de-contaminate the board - as far as I know, no such method exists.

In addition to the problems of the extra heat needed (most lead-free solders require at least 217°C soldering temperature), lead-free solder has poor wetting properties so PCBs and leads must be completely clean, and the solder joints do not have the same appearance as those made with conventional solder, making visual inspection that much harder. Fluxes are not as effective (and burn easily) at the higher temperatures.

A web search for 'lead free solder directive' gives over 6,800 results on Google, so there is plenty of information to allow you to make up your own mind. Although some Japanese manufacturers have already made the switch, there is nothing so far that shows any real advantages, but disadvantages abound.

There is a consensus that the RoHS directive will achieve little that is genuinely useful, and IMO it will create so many problems that it should be rescinded. It is interesting to note that for high reliability applications (computer servers, telecommunications, military, etc) the directive does not apply, or will be postponed for several years, and this in itself is very telling - they *know* that there will be reliability problems with components and the solder joints themselves, and have provided exemptions for those areas where reliability

will cause major problems for industry or military applications. The EEC obviously does not care that consumer goods will be less reliable and cost more, and has shown yet again that there is (or seems to be) almost a conspiracy to either prevent or make it as difficult as possible for 'outsiders' from competing in the European market.

What of the poor hobbyist? Those who are just learning soldering skills will damage PCBs and components, as will many professionals who are unused to the high temperature and comparatively poor looking solder joints. Having used lead free solder for some basic testing, I can confirm that it is difficult to use by comparison, and produces a joint that looks bad. It seems to be strong enough, but I know of no-one who actually likes it.

The 'benefit' of the RoHS Directive is that 0.6% of the world's lead production will be removed from solder, where it appears to do no harm to anyone. For some bizarre reason, the EEC would rather use bismuth (which has not been banned), but the fumes are thought to be toxic (see Material Safety Data Sheet for more information). The effects of contamination are unknown, but it is certainly more likely for bismuth to be leached from solder than lead.

A good idea? I think not.

My Own Little Gripe

There is a natural flow-on effect from this into some (or all) of the other topics I have covered, and I hope that at least a few readers will understand that these editorials are as much an attempt to bring some sanity back into audio as they are an attack on dishonest practices.

People are very often far too trusting of those who will take every advantage, but will brand as a sceptic or fool those who will stand up and shout "*Bullshit*". I know this from past experience with some of my editorials, and I am somewhat saddened that I am accused of being closed-minded or a simple techno-freak who utterly fails to understand the "finer points".

How is it possible that those who are selling something (that is usually outrageously expensive for what it is) are hailed as heroes who have saved the audiophiles from mediocre sound, while those with no hidden agenda, are not selling anything that is technically dubious, and have been dedicated to audio excellence all their lives are castigated, flamed, and accused of (somehow) trying to spoil the enjoyment of the consumer?

This makes no sense to me, and I know I am not alone. Rationality is neither a crime nor a sin, but some of the vested interests would have you believe that it is both. Don't accept it.

Interestingly, the claims against my stance are almost always made in a public forum, and often by the vested interests I am standing against, although regularly "disguised" in some way, typically by not noting their affiliations in their posts. Very few (and I really do mean very few!) people who disagree have sent an e-mail or attempted to contact me directly in any way. There have been exceptions, and these are often reasonable people who have useful information that may well make a difference. I have modified several articles based on proper (substantiated) information that has been supplied over the period this site has been in operation, and will continue to do so whenever such info is made available to me - I cannot test and verify every claim made, so rely on others to provide the details that make my evaluations (and comments, for and against) complete, and as factual as possible.

The Web is littered with outlandish claims, grossly overpriced "accessories", and completely unsubstantiated claims for "products" that you "cannot live without". These are nearly always identifiable by the complete lack of technical information, or pseudo-scientific technobabble, designed specifically to confuse the reader. If you are unsure - try a Web search on the topic to see if there is any technical explanation for the claims made.

The above does not mean that all such products are horse feathers - some may have a genuine value, but beware of the panacea - very few products will work with any system without proper integration. A rock placed on top of an amp or speaker is unlikely to reduce distortion and colouration, and it cannot compensate for room acoustics ... but rocks are cheap, so you can experiment to your heart's content

If it costs a lot of money, and will cure everything from ingrown toenails to poor imaging, then beware - you are about to lose your cash. Eventually you might convince yourself that it has made a difference (no-one likes to be taken for a ride), but careful analysis (with and without the "gizmo") is needed before you can be certain.

Triphaser

Are people being ripped off (again)? The answer appears to be yes ...

There is a device called the Triphazer, that according to its manufacturer will "transform"

your system. Allegedly, it works just as well on top of the line audiophile hi-fi equipment as on a $99 boom box. A truly remarkable device, methinks. I hope the designer is more capable with electronics than writing English - the punctuation is pitiful (I saw one reference that suggested that they should have their apostrophe license revoked :-)

A few quotes (indented text - all are verbatim, including all punctuation and spelling errors, etc.) from the makers of the "Triphazer" (aka Triphasor, Triphaser), followed by my comments.

> Using proprietary circuitry they [Triphazers] improve resolution and lower distortion
>
> All components and cables, have inherent nonlinearities. Amplifiers, preamps in the record and playback chain all contribute to very small distortions that are sometimes called SKEW or SMEAR. Because all designs are limited by this integrated SKEW, Triphazers have been designed to reverse these non - linearity's,
>
> We can repair this skew back into the original shape or condition that it was in when it left the studio mic or concert hall microphones.

For a start, cables do not have non-linearities, other than in frequency response. This is generally only apparent with difficult loudspeaker loads, where there are significant impedance variations, especially at higher frequencies. Response anomalies are very rare in interconnects, at least with normal lengths and within the range from DC to 100kHz. No-one has ever been able to measure distortion introduced by any cable.

No device can remove non-linear distortion of any kind, unless it has the original signal as a reference - this is how negative feedback works, it uses the amplifier to detect differences between the input and output, and make appropriate corrections. The Triphazer does not have this ability, so the claim is blatantly false.

Try this one for a laugh (from the FAQ page) ...

> What will it do for sound reinforcement (public address, rock bands)?
>
> They do a lot! Playing substantially louder and the clip lights never come on! Musicians comment they can hear each other better and request a lower monitor levels, fatigue is reduced tightness improves because the members can hear nuances ..that musicians need to work closely together. Triphazers remove large amounts of distortion that an audio system would normally reproduce and have to be dissipated by the speaker drivers," causing over heating in the voice coil , listening fatigue and confusion. It is this "Removing of Artifacts" that result's in increased efficiency and leaves more energy available for the fundamental musical notes that were at the core of the musical signal before being altered during the record, production and playback process.

This passive device will make a PA system louder, with less power, as well as reduce speaker voice coil dissipation (and again remove distortion!). If this were true, then everyone (and I mean everyone) on the planet who has ever used a PA system would have one. Last I saw, there are but a few references on the Web, not the thousands one would expect. I did find some references on a pro audio forum - all were scathing (to put it mildly).

Another quote ...

> Used in PROFESSIONAL SOUND REINFORCEMENT placing TRIPHAZERS after the mixer provides all inputs with improved clarity and freedom from Feedback! Freedom From Feed back! YOU HEARD ME! FREEDOM from FEEDBACK!

Oh really! Acoustical feedback is always a problem, and there are many solutions that provide some relief. Parametric equalisers, frequency shifters (typically about 3Hz) or a combination will suppress feedback, but according to the above claim, the Triphaser ***eliminates*** it. Bullshit!

Acoustic feedback is the result of sound from the loudspeakers reaching the microphone and being re-amplified. A passive box cannot do this without either attenuating the signal (turning down the volume is a lot cheaper), or introducing one or more notches in the response at exactly the right frequencies (as one would with an equaliser). That it eliminates feedback entirely ("freedom from feedback" implies complete elimination) is again blatantly false. Presumably it takes at least 50 hours to do so, according to the next piece of "wisdom" ...

> What about break-in? What is the deal?
>
> That is a complex question... lucky for you we have the answers that can help you get the most out of your stereo, home theater, PA, or studio. We recommend 50 to 200 hours for preliminary break-in. But we have other technology's that can speed up the breakin time. We will be writing much more on the subject to set the record straight and to show our customers how to obtain the maximum from recording and audio system investments.

Hmmm. The concert will be over by the time the feedback is eliminated, which makes sense, because the PA system will be turned off by then :-) I have since seen claims that your system will sound better, then worse, then much better - sounds just like the claim for the "Magic Lacquer". In the time allowed, your ears and brain will get used to the sound - the sound will not change. No passive circuitry requires break-in, it is completely in the mind of the beholder (belistener ??).

Conclusions

The Triphazer is now patented, and rather than describe it here, I suggest that you look at US Patents and Trademark Office, and search on Patent No 6,486,750. In short, the device **cannot** do what is claimed for it, and is a pure placebo (albeit an expensive one). The claims made in the patent are laughable, and no patent should have been granted IMO.

The Triphazer is not even a Zobel network. It is essentially several pieces of wire of different lengths encapsulated in epoxy, and presumably the inventor has worked out a method to make 3 parallel signal paths act as 3 separate circuits for different frequencies. Unfortunately, none of this is funny, and while it is possible that the inventor really does think it works, he is very much mistaken. If you were to connect anything in parallel with a short piece of wire (for example), the piece of wire will be dominant to the point where the additional circuitry will make zero audible or measurable difference to the signal, regardless of frequency. Different frequencies within the audio range do not 'choose' to travel by different paths - not even if you ask them nicely.

Tritium responded to my request for some technical details by sending a collection of "unsolicited" e-mails saying how good it was. I specifically asked for information, not rubbish. Other responses I have had point to bad reviews, general criticism, and everyone who had tried to get any technical detail has been fobbed off with the same e-mail collection as I received, and no real info at all. I would have serious doubts about having any dealings at all with this company - anyone who has a real product has nothing to hide, and this lot seem to have everything to hide (and no real product).

As of 24 March 2004, I have not had *one* additional response from the manufacturer, and no-one has presented any information whatsoever - for or against - other than the section below, which is actually funnier that the Triphazer nonsense.

---

05 Feb 2002

I did get some information from a reader (a Patent Attorney - amongst other things - as it transpires). Naturally enough, I shall not name the source, but he had this to say (reproduced by permission of the author) ...

> Ahhh, yes, patent procedure. You see, patent applications are generally not published (i.e., available through the databases) until 18 months after the filing date, a practice that has only recently been adopted by the US (it used to be that *nothing* was published until the actual grant of a patent in the US, often many *years* after the filing date - a strange practice much deplored by the rest of the world's patent practitioners). So it is no surprise that your search did not yield the application in question.

> That said, one must understand that the patent system (in the US or anywhere else!) does not require that the invention actually works as claimed! The statutes merely require that the invention is novel, is not obvious to a person skilled in the art, and is industrially applicable (i.e., can be manufactured and sold). The inventor has no burden of proof that his invention has any real benefit.
>
> Sadly, many patents are granted for devices or methods that are absolutely ludicrous, especially in the US. If you want to have a good laugh, look up US Patent 6,025,810, granted(!) for a "Hyper-Light-Speed Antenna". Some quotes: "The present invention has discovered the apparent existence of a new dimension capable of acting as a medium for RF signals ... ***The present invention takes a transmission of energy, and instead of sending it through normal time and space, it pokes a small hole into another dimension, thus, sending the energy through a place which allows transmission of energy to exceed the speed of light ... It has been observed by the inventor and witnesses that accelerated plant growth can occur using the present invention***." One can only speculate what type of plants the inventor was smoking at the time. But yes, this idiocy was worthy of a US patent!! Other examples are legion.

The above is verbatim, and has not been altered in any way (other than the application of bold and italics for emphasis). Methinks the Triphazer is no less silly than the "hyper light-speed antenna", and only misses out on this mysterious "other" dimension ... I suspect that this is planned for the Triphazer Mk II

Please feel free to roll on the floor with laughter at any of the claims made about the Triphazer and the antenna alike, but note that ESP accepts no responsibility for any injury sustained as a consequence of such mirth. If you feel that it is all too much, please stop reading this material immediately, and seek help from a medical professional (either that, or take two aspirin and if symptoms persist, e-mail me in the morning).

You would be well advised to bear the implications of the above in mind when ***any*** manufacturer claims that a patent is pending or has been granted for the "offering" in question. Just because they have a patent does not mean that the product or invention has any merit whatsoever ... "pokes a small hole into another dimension" - I mean, really this is just toooo much - ROFLOL

Dead EAT

Well, the inevitable has happened, and EAT is no more. The magazine is officially bankrupt, and all copyright material has been purchased by the remaining Australian electronics magazine, Silicon Chip. This is a sad time for those who supported

Electronics Australia for so long, but a richly deserved reward for those who caused its demise. It is to be hoped that they never re-enter the world of electronics publishing - may they sweep streets for eternity.

Australia has (had!) the distinction of having what I believe was the second longest running electronics magazine in the world. The magazine began life as Wireless Weekly, and subsequently went through several name changes. These included Radio, Television and Hobbies, then Electronics Australia. The magazine has ceased to be, and the remainder of this section is now redundant and has been removed.

Counterfeit Transistors (and more)

Please note - this section has been moved to a separate page. Click here for the article.

Burn-In - Myth or Magic?

I have managed to bite my tongue on this topic for quite a while, but a passion for common sense finally overcame me, and I had to write something.

First, A Contrary View
After many exhaustive hours of listening tests, I have determined that when a cable is burned-in, it is actually ruined. No cable should be used for more than a few hours, as the stresses on the insulation and the agitation of the copper molecules cause permanent changes to the structure of the cable - these changes are invariably for the worse, and fresh unused cables can be proven by listening tests to be superior in all respects.

The characteristics of the insulation change very subtly as the cable is stressed by signal voltages, and this has an as yet unexplained effect on the stereo imaging, and in particular causes veiling of the high frequencies and a loss of presence in the upper midrange. In extreme cases, the authority of the bass also suffers, with the lower registers lacking speed and power.

All the above defects are rectified by substitution of a new set of cables - the brilliance is restored and the finer details are brought back into startling realism. Bass speed is improved tenfold by a brand new unused mains cable, and new interconnects have a profound effect on the upper frequencies where detail is paramount.

I could say all these things (I just did :-) and I would be lying through my teeth. I could easily expound on this theory, lodge a few posts at some of the audiophile "watering holes", and offer a range of affordable leads in 10-packs (enough to last for a month or more of normal listening) so that fresh leads can be used when the others start to sound "tired". If I did my homework and used all the right words, how many sets of leads do you think I would sell? I already know the answer - "A lot". I am appalled at the rubbish that is fed to the audio fraternity by charlatans and frauds.

Sure, I could do it too (I would certainly make a lot more money than I do from the stance I take at the moment), but I would not enjoy it in the least. The reason I would not enjoy it is simply that it would be dishonest and fraudulent - no-one would actually be able to prove me wrong (as is the current situation), but I would be unable to back up my claims with facts that were in any way meaningful. I would simply throw in a few mathematical terms, a bit of random molecular theory, or perhaps make dire mutterings about resonances and how they become more significant as the cable ages. From reading the postulations of the opposing viewpoint I know that a significant number of people would believe me, and why not? A significant number of people already believe that burn-in makes a good difference, so why would anyone who was disillusioned by a set of recalcitrant cables be unwilling to accept that my idea was either wrong or any more ridiculous than the others "facts" that are out there?

My credibility would suffer badly from such an exercise, and I would do a great deal of harm to the hobby that I (and so many others) enjoy. It is most regrettable (IMHO) that some of the others don't have the same attitude, and are just out to make a quick buck.

We are not talking about facts when the discussion turns to cable burn-in, we are simply digressing into the realms of magic - anything that cannot be explained by the "facts" as they are currently known to exist *is* magic. The concept of a vast machine that can fly through the air is pure magic to a primitive people who have never seen such a thing before. The concept that cables sound better after burn-in (or is that when brand new?) is magic to those who have little knowledge of electrical principles, but love music.

When there is a gaggle of reviewers and manufacturers out there telling them that "something" is so, why would they disbelieve these self proclaimed experts? Who else is there to turn to for help? When the uninitiated think they can't hear a difference, what are they to do? To admit that they hear no difference is liable to have them "cast out" by their peers for the heinous crime of being cloth-eared. A sorry state of affairs indeed, and one that ensures that the unscrupulous will not only survive but prosper.

We keep hearing that cables (some will say *all* audio equipment) should be subjected to various techniques to "stabilise" them. This is generally referred to as burn-in, and after the treatment the item(s) supposedly sound better. To aid this process - of course - many entrepreneurs have slaved away for whole minutes to create CDs with pink noise or some other signal "specially designed" to do the job properly.

So far, I have not seen a shred of evidence that any so-called treatment has any effect whatsoever, other than a psycho-acoustical phenomenon known as "getting used to the sound". This indicates that it is the owner's ears that get burned in, and has nothing to do with the cables.

OK, so I am claiming that there is no change in the cable. I have measured cables (as have many others before me), and normally expect to find three main characteristics and two that are not relevant to audio. These are (respectively) ....

- Resistance - influenced by the length and diameter of the conductors, and to a very much smaller degree by the purity of the copper used
- Capacitance - influenced by the distance between the conductors and the insulation material. The capacitance is also proportional to the length of the cable.
- Inductance - influenced by the cable length, diameter, spacing, and the amount of twist between the conductors
- Self resonance - in any cable suitable for audio this is insignificant, as it is (or should be) so far out from the audio spectrum that it will have no effect whatsoever
- Impedance - all cable has a characteristic impedance, and like self resonance it is meaningless for audio unless interconnects or speaker leads are many kilometres in length - this is unusual.

To some degree, the above comments are tempered a little when radio frequency interference (RFI) is present, but it will ultimately be the way the cable is terminated that makes a difference (rather than the cable itself).

It must be understood from the outset that cables are not very smart. In fact, they are bereft of any knowledge of anything. Indeed, their own existence is unknown to them, and their memory is much shorter even than that of a goldfish. This rather generalised statement applies to the conducting and non-conducting (insulating) materials alike.

A cable has no interest in the current flowing in it (or not) unless it is greater than the current carrying capacity of the conductors, in which case it will get hot (or perhaps only warm). This increases the resistance, but only for as long as the overload lasts, and until

the cable returns to ambient temperature. This will take a few minutes at the most.

As long as the temperature is kept well below the melting point of the insulation (or the copper), no permanent change occurs. This is an extreme example, since in practice most cables are at room temperature, and may gain but a fraction of a degree even at maximum amplifier power. Any current that may have flowed at some time is instantly forgotten.

Likewise, the insulation is not the least interested in the voltage that may have existed between the conductors once it has gone away - again making a valid assumption that the output voltage from the amplifier will not cause the insulation to break down, allowing the signal to arc between the conductors. There are some very minor effects with all insulators (dielectrics), where a short memory effect can be noted, but this is not at all significant for audio, and even less so in the long term.

The end result of this is that cable burn-in is an invalid concept. More than just invalid, it is an attempt to convince you (the buyer) that the reason the expensive cable(s) you just bought don't make any appreciable difference, is that they haven't been given the necessary treatment, so you should buy this CD (or some other overpriced piece of equipment) to rectify the situation.

The simple fact of the matter is that changes in room temperature will cause a far greater variation in the characteristics of a cable than pink noise applied for a minimum of 37.5 hours. At the end of the "treatment" the cable will still exhibit exactly the same resistance, capacitance and inductance as before - so what has changed? And the answer is .... nothing.

There are electrical principles that exist despite any marketing hype. The hype and bullshit does not affect these principles in the least, and there is absolutely nothing you can do to a cable with a normal signal that it will remember or that change its long term characteristics.

What about the other products?

There is no doubt that loudspeakers require some amount of use before they settle down. This is because new speakers will have a stiffer than normal suspension, and it takes some time for this to stabilise. There is no correct time, and no signal that is better than another (as long as there is roughly equal energy in each octave band). Each speaker will be different, and some will have been subjected to test waveforms and will already be optimum (or close to it) when they are purchased.

Over time, the suspensions will "relax" more and more, and will eventually fail - hopefully only after many satisfying years. The sound will change very slowly during the lifetime of the speaker, but largely goes un-noticed because we get used to the subtle changes as we age as well.

Transistor (bipolar or MOSFET) amplifiers generally require a minimal "burn-in" period. This is not really burn-in at all, but a period of time to ensure that polarised capacitors (i. e. electrolytics) have achieved their normal operating state. This varies from one amp to another (even from the same manufacturing run), and as electrolytic capacitors settle down, their leakage falls and capacitance often increases slightly. This process is actually repeated each and every time the amp has been turned off for any period of time.

I do not advocate leaving amplifiers on permanently, as this is a waste of power, and the above effects should not be noticeable in a well designed amplifier.

Valve amplifiers are another matter. Valves change their characteristics quite dramatically in the first few hours of operation. They stabilise after this, and then go into a very gradual decline as they age. Eventually (this can range from weeks to years, depending on how hard the valves are driven), the decline becomes much greater and the valve becomes unusable.

With both speakers and valves, the ageing curve is similar to the discharge curve of a cell or battery. A simple graph as shown in Figure 1 is typical of all three devices - the vertical axis is either stiffness (for a loudspeaker), emission (for a valve) or voltage for a battery.

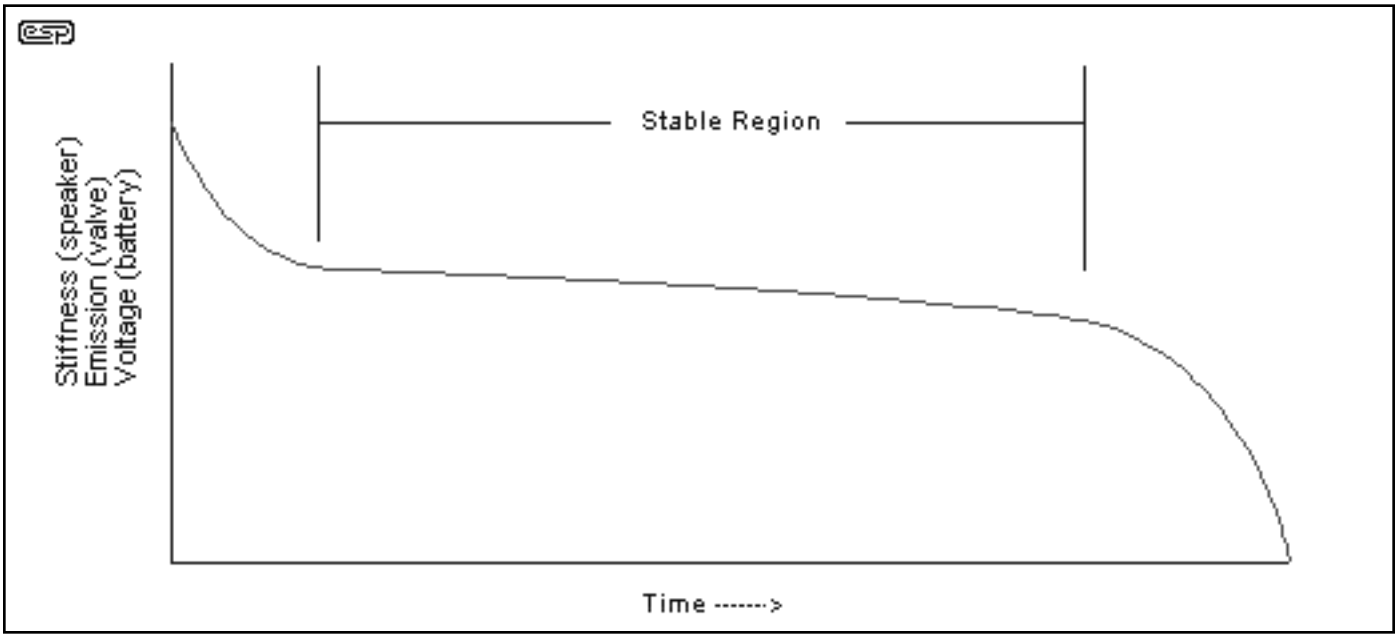

Figure 1 - A Typical Ageing Curve

I really hope that you find this information useful. Unlike some of my other editorials I have not flamed anyone (although there will be some who may claim they have been flamed by inference), but have simply stated a few facts of life. I fear that a few will take this entirely the wrong way and I cannot change this - another fact of life. I fully agree that there are some things that cannot be explained at this time, but cable burn-in is not one of them. There is simply nothing to explain.

Should anyone have some data they would like to share showing a measurable change in the basic characteristics of a cable from its original measurements after a burn-in period, I will be happy to include this information here. My stance on this is that I have not experienced any changes that I could detect - perhaps someone else has (as doubtful as this may be).

Cheers,
Rod Elliott

A Funny Cable Story (And It's True)

This story comes from a reader in the UK and is reproduced verbatim - only the name of his mate has been changed ...

I know that most of what's talked about cables is crap, but how's about this for a story -

A mate of mine decided his system was sounding crap. Since I'm considered (by others,

not me) to be the "authority" on all things hi-fi in my neck of the woods ('cos I own a soldering iron I guess) he wobbled his way towards me one Saturday night in the pub and moaned about how some sales rep in a hi-fi shop in the city had told him that he needed to spend about two hundred quid (GBP) on cables to get the sound he wanted.

To prove this, he trucked all his gear to the shop, the little twerp installed the new cables for him, and Metallica leapt out of the speaker boxes and assaulted my mate about the lugholes. During the course of the conversation, it came out that the twerp had spent ages "pushing" the new cables onto the connectors. Pushing? Never heard of an RCA connector THAT tight. I had a look the next day and what he'd actually done was spend ages twisting the new RCA plugs soldered to the "audiophile" connectors onto heavily-oxidised chassis mounted jacks to get rid of all the crud. We dug out my mate's old cables, stripped all his gear, cleaned the connectors properly and plugged everything back in. Result? His old home made connectors now sound better than the shite sold to him by the twerp.

Interestingly, he's a big lad is my mate Fred, and he's not a fan of being ripped of at all. Last I heard he was taking a day off humping billets of steel round an engineering works to go and see the twerp and have a few words ....

The moral of the story? As always, charlatans beware! Especially when the guy you've just ripped off weighs about eighteen stone (252 pounds or 115kg), and has mates.

(Some time later from a following e-mail) After a bit of foot shuffling and looking at the floor, Fred got his brass back. I suggested that he pushed for recompense for the "damaged" phono connectors on the back of his kit as well. He didn't. I guess he's not an unkind man at heart. Still, when you're that size it's hard to tell - nobody seems inclined to test the theory.

On a serious note, it's just another prime example of the unscrupulous taking advantage of a guy with a bit of brass who wants something decent but doesn't really know what he's talking about. To add insult to injury, the pleb tried to convince him that he had to shove hard as the new connector was stiff. You know what? When the CD player and the connector were both placed on the counter in front of him and he was asked to demonstrate, he had no trouble sliding one smoothly onto the other. Tch! These "audiophile" cables. Loosen up in no time don't they ?

Now he's taking me out for a few beers to celebrate getting his money back and having a great-sounding system for free. Poor lad! He's obviously forgotten about my strange but well-known gastro-financial condition - my capacity for ale and takeaways

spontaneously quadruples when someone else is paying.

My thanks to the reader who submitted this tale. Has anyone else had a similar experience?

A few explanations are in order here, as the story is from the UK, and some of the terms may be unknown elsewhere (in alphabetical order) ....

beer - the stuff most commonly quaffed in pubs :-D
brass - money
GBP - Pounds (as in the currency of Great Britain, not to be confused with "Fred's" weight)
lughole - ear
pleb - plebian, an ordinary person, (also a vulgar person, a boor - probably the intended meaning here)
pub - a place for drinking alcoholic beverages, and generally having a riotous time (or not, as the mood takes one).
shite - I think you can work this one out for yourselves (hint - leave off the 'e')
twerp - a despicable person / a cad (also, a bit of an idiot, a twit)

Copyright Notice. This article, including but not limited to all text and diagrams, is the intellectual property of Rod Elliott, and is Copyright © 2000 except where noted below. Reproduction or re-publication by any means whatsoever, whether electronic, mechanical or electro-mechanical, is strictly prohibited under International Copyright laws. The author (Rod Elliott) grants the reader the right to use this information for personal use only, and further allows that one (1) copy may be made for reference. Commercial use is prohibited without express written authorisation from Rod Elliott.

Page created and Copyright © 14 June 2000 Rod Elliott. Updated Dec 2001 - added triphazer, and additional material, archived GHF, and moved "gripe" column./ 17/29 Jun - clarified a few points, and added some new info.

Elliott Sound Products **Contributions To The Audio Pages**

How to (and why) Contribute

The how to contribute is fairly easy. Send me an e-mail describing the article or project (no attachments please). Provided it fulfils the basic requirements (see below), I will request the full text and any diagrams to be sent as an e-mail attachment.

I will then edit your descriptive text (if and where necessary), insert your diagrams in the places you indicate and advise you of the URL so you can see the finished product before it is indexed. Once we are both happy with the result, I will index the material and your masterpiece is on line.

The why is also simple. I have a page that gets over 2000 visitors a day. This means great exposure for you and your ideas.

Terms and Conditions

These terms and conditions must be read before you fill in the Submission Request document, which is printed from your browser, signed and sent to ESP. All relevant details are on the form.

NOTE: The Submission Request is not mandatory, so you don't have to fill it in if you don't want to. I suggest that you do (and keep a copy for yourself), as this provides you with some degree of copyright protection. Obviously, if someone wants to steal your idea there is not a lot you can do to stop them, but at least you have proof of ownership of the idea, and the date it was submitted. I will also be able to support you if necessary if the form is completed.

The terms and conditions below are not intended to scare you off! The Audio Pages have gained considerable popularity because of the content and value to the readers. Any material that you contribute should have the same intent - to share your ideas, to educate the newcomer and to provide a benefit to the audio community. This is our hobby, our enjoyment (even our passion), so let others benefit from your experiences and help me to establish the best DIY audio web site in the world.

The basis of all of the stuff below is very simple. You don't offer material that is not yours, I don't steal your ideas, and you don't steal mine. We work together to everyone's advantage. I admit that some of the stuff below looks heavy going, but it is actually quite straightforward and in simple terms means that I will not accept responsibility if you try to pass someone else's work off as your own, and get caught out.

Terminology

So you know exactly what I mean by some of the terms, here are my definitions:

Submitted material	this includes any printed material or other hard copy, all software, text files or drawings in any format.
Published Material	includes any or all of the submitted material, and also includes the page format in Hypertext Markup Language (html), the ESP logo, any text or drawings prepared by ESP or others working on behalf of ESP and the final copyright notice.
Relationship	includes any business partnership, memorandum of understanding or other business relationship or any verbal agreement that provides a financial benefit to any person.
Submission Request	the form that declares your ownership of the submitted article, and includes your full name, postal and e-mail addresses.

Ownership

All material submitted must be your own. Reprints of existing articles and/or the work or rework of others is not acceptable without written authorisation from the original copyright holder. Any person submitting material for publication indemnifies Elliott Sound Products and Rod Elliott (hereinafter referred to as ESP) against any legal action that may be taken as a result of the publication of the material either in whole or in part. ESP shall not be held accountable for any breach of copyright, as submitted material is accepted in good faith that no prior claim is held against the published work.

Where the material submitted warrants it, you may be asked to fill in the Submission Request form, and return by post or fax to ESP. The form declares your ownership or other rights to the material. This form is available as an HTML page, and may be submitted with any material if you would like to do so. It is expected that this will not be necessary in the majority of cases, but the choice will generally be yours.

Copyright

The copyright of the original submission of any published material remains your own absolutely, and may be re-used or re-published at your discretion. The final published

material, including but not limited to any drawings or additional text added by ESP shall have joint copyright, and the final published material may not be re-used, sold or re-published either in whole or in part in any form whatsoever without my written consent.

I will not sell, re-use or republish your original submission or the final published material without your written consent, either in whole or in part. Should ESP design a printed circuit board or any other product based on any submission that is subsequently offered for sale, you will be compensated at a rate that will be negotiated beforehand.

As the primary copyright holder, you may request the withdrawal of your published material at any time. I will delete the material from my site completely, within an agreed time period. I reserve the right to retain a copy of the material for my own reference, but will not disclose any part of the material to any other party without your written permission.

All credit for the work will be given to the author, and ESP's only credits will be for editing and additional comment or explanation if necessary.

Content

Material that is offensive, inflammatory or defames other persons or organisations is not acceptable, with the sole exception of exposing fraud or deception. If you choose to do this - make sure you have your facts straight. ESP cannot and will not take any responsibility whatsoever if you are wrong, and will withdraw any article without notice if requested to do so by any Government agency or other authority acting for or on behalf of anyone who claims (rightly or otherwise) that they have been damaged in any way by the published material. You will be named as the author if this information is requested, and such authorities shall be informed of your sole responsibility for the material as set out herein.

Articles or projects should be related (directly or indirectly) to audio, and shall be non-commercial in content. Advertising of any sort is not acceptable. Application Notes are a special case, and may be based on specific manufacturers' data, and do not need to have anything whatsoever to do with audio.

References to commercial component outlets or resellers are only accepted where a specific component is unavailable elsewhere, and where the seller is unrelated in any way whatsoever to the author.

Philosophy

Material does not have to agree with my own published philosophy, but I may have second thoughts if it is diametrically opposed. For example, an article about the "great benefits of super conducting mains leads" (power cords) will probably not be acceptable, since I have grave doubts about such things. However a well constructed article on the differences that can be measured between different power leads is most likely quite OK. Note that differences and benefits should be quantifiable - purely subjective comparisons are useless unless properly conducted double blind testing has revealed that differences do exist. Where possible, any such article should be sufficiently well developed to be able to explain the differences in real (as opposed to imaginary or indefinable) terms.

Editing Rights

Editing shall include spelling and grammatical checking. Australian English spellings will be substituted for others where appropriate (for example, "travelling" versus "traveling"). If any change affects the original meaning or intent, you must advise me of this as soon as the discrepancy is found and it will be corrected.

Drawings that do not fit the standard browser page width, or are of a style that is considered unsuitable for any reason will be redrawn or rejected. If rejected, you may redraw the diagram and resubmit it.

Payment

This is very simple - there is none (with one exception, see below). I do not make money from my pages (other than from the sale of PCBs for my projects), and with no advertising have no means of payment whatsoever, unlike magazines. The Audio Pages are for the enjoyment of everyone, and in the best traditions of the WWW are (with very few exceptions) completely free. By the same standards, I expect no payment from contributors, for exactly the same reasons.

Product Sales

The only exception to the "no payment" policy is where you have boards, kits or other material of any kind that is offered for sale. Since you will get the benefit of the wide circulation of The Audio Pages, I will expect a percentage of the profits of sales made from this site. This is negotiable on a case by case basis, and will generally be based on an honesty system. Any breach of good faith will ensure the immediate withdrawal of the material without notice.

As noted above, the same applies if I make a PCB or kit from your submitted material. I will then pay you a negotiated fee for the right to use your idea. This will again usually be a percentage of the selling price or a single upfront fee based on mutually agreeable terms.

Acceptance of Terms and Conditions

If you submit any material for publication, it is accepted that you agree to the terms and conditions as set out herein. Your failure to read these terms and conditions in no way relieves you of any obligation nor obligates Rod Elliott (including but not limited to his heirs and assigns) to any penalty imposed due to breach of copyright or any other matter whatsoever. You agree with the terms and conditions and accept full responsibility for all published material based on your submitted material.

Format of Submitted Material

The material you submit should be as follows:

Text	An ASCII text file is preferred. Since the risk of computer virus infection is high with document files, I prefer not to have anything submitted in this format. Since I will not open any Microsoft Word or similar file in anything other than a text editor, any formatting you may apply will be lost anyway.
Photos	JPEG is the preferred format for all photographic images. These may be greyscale ("black and white") or full colour. The size must be compatible with the standard web browser page sizes, and should be able to be displayed without scrolling on a standard 1024 x 768 pixel display. File size should be limited to less than 10kB (10,000 bytes) if possible.
Drawings	All line drawings (including schematic diagrams) must be in GIF (Graphic Interchange Format), and should be formatted with black text and lines on a white background. Like photos, they should fit in a standard browser window without scrolling (if possible). File size should be limited to less than 10kB (10,000 bytes) if possible.
References	Where the submitted material contains significant reference(s) to other published or unpublished works of any party, these must be stated if at all possible. Material that obviously uses references that are not acknowledged will be rejected, or placed on hold until the necessary references are supplied.
Printed Material	Any printed material must be in a format that can be scanned and read with basic OCR software or converted into an image file.

Software	Any software, spreadsheet or other computer based material that is submitted should be designed for the Microsoft Windows (98SE or above) operating systems, as I cannot verify operation for any software designed for other operating systems. Software must be certified as virus-free, and 'adware' is absolutely banned. Where this is not possible or available, suitable "screen shots" should be provided to allow me (and other readers) to see what the program is meant to do. (It is unlikely that non-M$ software will be published.)
Completeness	The submitted material should be complete, without any omissions that could make the material unusable to the average reader.
Supporting Material	I need your full name, postal and e-mail addresses, and a brief description of the material. Use of the Submission Request form (see below) ensures that I have all the information I need, and you will have a permanent record of what was sent (and when). This establishes your copyright to the material, and is also for my own records. This information will not be disclosed to any party other than a government body or other authorised agency with a genuine need to know, other than at your request. Should this information be requested (or demanded) from me, I will let you know as soon as possible.

Thank you for taking the time to read this information, and for your interest in submitting material for publication. With your continued input and support, it becomes possible to build the most informative and useful web site in the world for all things audio.

View and fill in the Submission Request form. Use of this form is voluntary but recommended. All instructions are on the form.

The Audio Pages

Elliott Sound Products **Frequently Asked Questions**

Updated 01 Feb 2006

Over the past few years I have answered many, many e-mails. Some ask questions of the circuits and articles presented here, but I also get a lot of general questions as well. The biamp article still creates quite a few questions by itself, and along with the others, I have added this FAQ page. Some of these FAQs used to be located in the Readers' Feedback page, and have been moved to make them more accessible.

Some of these questions are (almost) exactly as asked, while others are a "composite" of many similar questions. I shall leave it to you to decide which is which (assuming you care, that is)

Bi-amping / Tri-amping

Q: Can I get a schematic for your phase-coherent crossover?

A: Yes. The Linkwitz-Riley version is currently the favourite, and is available on the Projects Page

Q: I am thinking of tri-amping. What do I need to look out for?

A:Be very careful of DC power-on transients, which will destroy tweeters. A capacitor (not less than 20uF) in series will prevent damage, but preferably do not use an electrolytic (bi-polar or otherwise) unless you are willing to accept (possibly) compromised sound quality or (more commonly) relatively short life. Note that many amps have a "de-popping" circuit (generally a timed relay), which will eliminate the DC "transient", but usually offers no protection against O/P device failure! (Read the updated section on tri-amping in the Biamp article) You might also want to have a look at the article on Class-A amps, which are ideal for the top end.

It is also worth looking at a DC protection scheme, such as P33 or P111.

Q: I want to bi-amp my system, but don't want to remove the internal crossovers. Will this work ?

A:Yes, but with some caveats. You will not get the same power gains, since both amps will be reproducing the full frequency range, but you will get some degree of benefit in terms of intermodulation distortion, etc. Overall, this is not the ideal solution, since it is almost the same as bi-wiring, but uses more amplifiers. IMHO it is a waste of time and money.

Q: Can I biamp without an electronic crossover?

A: No. All you will be doing is "active bi-wiring". See the previous Q&A

Q: If I disconnect the internal crossovers in my speakers, what should I look out for?

A: First, make sure that your electronic crossover is set for the same frequency. Second, for a 3-way system, you have to keep the mid to high passive crossover section (unless you are going to tri-amp). This will involve determining the circuit of

the existing crossover, and only disconnect the low to mid+high section. If you do not know how to do this, seek help from someone who does. **This is important!**

Q: My passive crossovers use impedance correction circuits. How do I disconnect the crossovers and leave these in place?

A: You don't. These are needed so the passive crossover is not affected by the speaker impedance variation. Electronic crossovers are not affected by impedance changes, so the correction circuits are redundant. Although they waste energy and can be removed, leaving them in place will usually not hurt anything - just don't expect an improvement.

Q: What about (notch) filter circuits? These are often used to remove objectionable tweeter resonances, so these still have to be there, right?

A: Probably not. If you are replacing a 6dB or 12dB passive crossover with a 24dB electronic circuit, you may well find that these are no longer needed. Because of the original crossover slope and the impedance interactions, tweeter resonance effects are common. They are all but eliminated by the steep slope of an electronic crossover. If the tweeter resonance still causes a problem, it is better to remove the offending frequency electronically. Passive notch filters can make the amplifier load "difficult", and may cause instability in some amps.

Q: In thinking about the sound difference between passive and active setups, I have come up with a question that perhaps you would give me your thoughts on.

I am wondering whether the main reason an active crossover sounds so good is the fact that you truly CAN have same-length speaker cables to each driver, whereas in a passive setup you don't?

Just as background, I have a stereo power amp sitting behind each speaker. One channel drives the bass and the other drives the mid+high crossover. With your active crossover in place, an interconnect feeds the power amp and then two, same-length speaker cables connect to the bass and mid drivers.

In the passive setup, the low-pass section for the bass driver has 2 coils in series - which are many metres of wire - whereas the 12dB high-pass slope of the mid-range

driver has a cap in series. Therefore the length of the cable carrying the signal from power amp to bass driver is many times the length of the mid-driver signal cable. I understood the "Audio Rule" was that you must have same-length speaker cables or you screw up the sound stage ... so, by definition, passive crossovers cannot obey this rule due to the coils that they use.

A:Such a long question deserves a long answer (and needs it, too) The difference in path length with passive xovers is large, but the electrical delay is small (other than the phase delay that is common to all crossover networks). I still think that the major benefits of an active crossover are the phase coherence, lack of impedance effects on the crossover, and the fact that each amp has a limited frequency range and you get extra headroom compared to a single amp. The active version is completely unaffected by the driver characteristics (which change with frequency, power level, etc.), and in turn affect a passive crossover's performance.

The equal length cable theory is a bit of a myth really. You can prove this to yourself by running a 10 metre and a 5 metre cable in parallel (or other numbers that remain passably sensible)

If the "rule" were true, then you would hear the difference, but the propagation delay is only nanoseconds, so you won't hear any change. Electric current flows along cables at around 2.25 x 10 ^8 metres/second worst case, so if one had a 1 metre and a 100 metre cable in parallel, this represents a 440ns (nanosecond) delay between the two. This would create a 1 degree phase shift (delay actually, but let's not split hairs) at a little over 6 kHz. Even at over 20 kHz, the shift is only about 4 degrees - you get more than that acoustically by moving your head a few millimetres.

The cancellation caused by a 440 ns delay between parallel conductors is 0.08 dB at 100 kHz (which is negligible), so at normal audio frequencies it may be completely ignored.

Q: I have heard that bipolar electrolytics are commonly used in crossovers. You and just about everyone else don't like them, so why are they still used?

A:Price. They are cheap and have high capacitance in a small volume. However they are not reliable at high power, and will degrade in time. It can be Ok to use them in impedance correction circuits, since they are not in the signal path (they

are in parallel with the driver and amplifier when used like this). However, because of the potentially high current they will be subjected to, their life may be reduced quite dramatically

---

Amplifiers

Q: Can I increase the supply voltage on your amps to get more power?

A:All power amplifiers have limitations on the maximum supply voltage and minimum load impedance. Although you can use parallel output devices, the driver transistors, Class-A driver and input stages also have limitations.

For reasons that remain completely unclear to me, everyone wants to operate P3A (in particular) at above the design voltage rating, which is ±35V (or ±42V into 8 ohms **only**). 32VAC (for example) will give ±45V, and the amplifier will fail. Maybe not today, nor tomorrow, but you will stress many transistors beyond their design limits, so eventual failure is guaranteed.

Power dissipation (and the likelihood of output device failure) is based on many things, and these were taken into account when the amp was designed. As voltage increases, the probability of device failure rises exponentially.

The dissipation into a resistive load must not be used to determine safe operation, and the worst case load is a loudspeaker near resonance, where the voltage and current are 45°out of phase. Instantaneous peak output transistor dissipation is *doubled*under these conditions, and if the transistors are hot and pushed to their limits, then failure is a certainty.

200W transistors will be driven into potential destructive operation with ±42V into a 4 ohm load (peak dissipation is in excess of 200W). ±35V is a safe and 'transistor friendly' voltage, and the amp will give many years of faithful service at that voltage. Even at ±35V, peak dissipation will reach about 150W into 4 ohm loads!

All of my designs are deliberately conservative, since many are built by novices, and it is obviously better if they work reliably. All attempts to obtain more power by increasing supply voltage (and with little or no understanding of the stresses on the transistors) reduce reliability, and place the amp and speakers at risk.

For P3A, ±42V is the **absolute maximum**voltage - not 45V, and not anything that is greater than 42V. Period!

To use a higher voltage, the input transistors, current sink, Class-A driver, drivers and output devices must all be upgraded, then the input device bias will change, and performance may be reduced.

Amplifier design may appear to be 'trivial', but it is not, and any change to any operational parameters should only be done with a full understanding of the ramifications.

It also needs to be understood that seemingly large gains in power are not worth the decrease in reliability. P3A at ±35V will provide an instantaneous peak power (before the supply voltage collapses) of just under 75W (remember too that the supply voltage will normally be higher than expected because of transformer regulation). Also remember that the full +ve to -ve supply voltage can (and does) appear across the transistors, so with a ±42V supply, all driver and output transistors must be able to withstand 84V.

If the supply voltage is increased to ±42V, peak power increases to 110W. It may *look*like a lot more power, but it is only 1.6dB - you need a **10dB**increase for an amp to sound "twice as loud", and that requires going from 75W to **750W**. 1.6dB is barely audible as an increase, and is not worth risking the reliability of the amplifier for.

Q: Would you consider a design for a 1,000W amplifier?

A:No, I would never consider a 1kW amp. No loudspeaker (other than a small number of very expensive professional types) can handle that much power, regardless of claims. Look at a 1000W electric heater - feel how hot it gets and how quickly. Note that the element is thick resistance wire on a ceramic former. The resistance wire glows red hot after only a few seconds.

Since only about 1% of power is converted to sound, the voicecoil has to do the same work as the electric heater. But look at a voicecoil - it is thin wire on a thin aluminium or Kapton former. At 1kW it may last 10 seconds if you are lucky. At low frequencies, the voicecoil will leave the gap, the speaker will distort badly, and quickly fail. In some cases, the spider or surround can be torn, or the voicecoil can suffer impact damage from colliding with the rear pole-piece

Unfortunately, the advertisments and even data sheets lead one to believe that many drivers will take that kind of power. The vast majority will not. I have tested a (claimed) 500W driver that distorted (and would have quickly overheated) with

only 100W input. It was a massive affair, having dual voicecoils, dual spiders, dual magnets and double the distortion.

Although it is useful to have headroom in an amp, it is far better to use smaller amps and an electronic crossover. This makes the requirement for 1kW amps simply go away for all domestic hi-fi systems.

Q: What is power bandwidth and what relationship does it have to overall amplifier sound quality? Does it have some relationship to transient intermodulation distortion, even if indirectly?

A:This remains a contentious question. Power bandwidth is (in amplifier terms) the bandwidth that the amp can provide full power (usually measured at the -3dB frequency). It is closely related to the slew rate of an amp. If any signal is faster than the amplifier can handle, then intermodulation products are generated (TIM). Few modern amplifiers suffer this problem - even if the amp can only provide full power up to 10kHz, this will not cause slew rate limiting, as the signal levels are so low. There is some evidence that such a limited bandwidth creates other audible effects, possibly due to the much lower gain at higher frequencies, meaning less feedback and higher distortion. Just about every designer on the planet will give you a different answer :-(

Q: When an amplifier gets a complex audio source (such as an orchestra soundtrack) does this create greater load conditions at the speaker end and adversely affect damping ratios determined in the normal manner.

A: An amplifier does not care one iota about the complexity of the signal. A single frequency or multiple frequencies all at once make no difference. At any point in time, there is only one voltage present, and the amp will amplify it. This of course is only true if there are no frequencies that cause a rate of change of the signal that is outside the bandwidth of the amplifier. There are two distinct (and separate) things to deal with - the instantaneous value of voltage, and the rate of change of this voltage. If either is outside the amp's capabilities, you will get distortion (of one form or another). Output impedance is (to some extent) frequency dependent, and varies with the feedback ratio - this in turn is reliant on the open loop bandwidth of the amp. After this, it gets complex !

Q: What I mean is does an amplifier's output impedance actually rise during complex musical production or is this all nonsense?

> **A:** This is nonsense. The amplifier's impedance is affected by frequency (so will be different at different frequencies), but the complexity of the music has no direct effect on the impedance.

Q: Does any of the above have anything to do with why valve and solid state amplifiers can sound different?

> **A:** It can. Valve amps usually have a power bandwidth that is almost independent of feedback, and is limited mainly by the valve electrode capacitance(s) and the output transformer construction. Have a read of the article about valve and transistor amps "Valve amps - do they really sound different". There are quite a few other factors (output impedance especially) that have a greater influence on the perceived sound quality.

Q: I suspect that many or all of the above potential problems are greatly reduced by bi-amping or tri-amping.

> **A:** There is no doubt on this score. Anything that reduces the demands on an amp helps, but it helps even more when the speakers are driven from a defined and constant impedance - this does not happen with most passive crossovers. Biamping is more about the speakers than the amps. Very few (if any) modern amplifiers are stressed by the full range signal, although impedance dips caused by passive crossovers may be responsible for some subtle (or not so subtle) effects on the sound. This has not been proven (to my knowledge).

Q: Can I operate the 60W amplifier (or any of the others) into a 4 ohm or 2 ohm load for more power?

> **A:** Four ohm loads will often be acceptable, but I strongly recommend using paralleled (or more powerful) output transistors. It may also be necessary to use a small heatsink on the drivers, as their dissipation is usually more than doubled. Two ohm loads are very difficult for any amp not designed specifically for this impedance. I do not recommend using any of the published circuits for 2 ohm loads.

Q: Is is better to use transistors or op-amps for amplifiers built today?

A: It depends on what you want to achieve - a well designed discrete power amp still outperforms any power opamp, but good opamps outperform (technically, at least) any discrete circuit for preamps. However, the P37 (DoZ preamp) circuit is a good indicator of what can be done with only a few parts, and that measures well and sounds very good.

There is no simple answer.

Q: I don't have an oscilloscope, so how can I know if my amp has crossover distortion?

A: A reader sent me his idea for this, and it is both simple and ingenious. You need a very clean sinewave source of between 100 and 150Hz. Set up the amplifier providing some power into a resistor load - about 1V RMS into 8 ohms is usually enough. A cheap piezo tweeter connected across the load will make harsh clicking noises if crossover distortion is present. Adjust the level to zero to make sure that it is not spurious noise.

If you are adjusting the quiescent current on an unknown amplifier, set it so that the clicking noise just goes away (or stops decreasing). You must check that all transistors remain at a sensible temperature. (Thanks to Raymond Quan for the idea.)

Q: As far as I can tell, there is next to nothing on PWM amplifiers at your site, despite the fact that recently there seems to have been some dramatic improvements in chip(set)s that enable truly amazing compact (size of a credit card) amplifiers. I find it curious that you don't seem to have addressed PWM amplification at all.

A: You are (almost) correct - there is not a lot, but there *is* a very comprehensive article that discusses PWM/ Class-D amps.

There are many problems with DIY Class-D amps, and the possible need for surface mount components is only a small part of it. Making/debugging something like that requires considerable expertise in digital signal (or switchmode) analysis, and absolutely requires the use of an oscilloscope. The required parts are also hard to get and relatively expensive, especially in small quantities.

There is nothing curious about it - many people have problems getting a simple discrete amplifier to work, and I don't even want to contemplate the questions I'd get if I had a PWM amp project. I agree that it is interesting, and in a few years most high power amps will be PWM, but at this stage I would be a fool to develop and publish one !

When PWM amps do become available from me, they will be fully built and tested.

For more information on the design of amplifiers, see the various articles (and references) I have published.

Mobile (Car) Audio

Q: i have a 1200watt car amp and 2 600watt car speakers with no car. witch brings me to the problem how do i hook it all up in the house. if you have any advice e-mail me at e-mail@address.com. tanks!

A: In case you were wondering, that was an actual e-mail I received (some are a lot worse!). You will need a big power supply, probably with a 12V car battery (situated outside the house, please!) for backup and to provide for surge currents. A battery charger will not be helpful, because there will be excessive noise on the 13.8V supply (that's the actual charge voltage for a 12V battery, and **all**car amps are power rated at 13.8V).

I get quite a few of these questions, and quite frankly, I'm sick of them. This is not a trivial undertaking - one person even suggested that he already had a wall transformer, and wondered if that would work - it wouldn't. To those who may be thinking of asking ... don't. There are many forum sites that deal exclusively with car audio systems, and you should ask them, not me.

Q: Do you have a design for a car power amplifier. I want to use your 60W amp from the 12V supply, what do I need to do?

A: For useful power from conventional hi-fi amplifiers, you need to increase the supply voltage. This requires a switch mode power supply.

Q: Are you planning to publish a suitable switching supply suitable for any of your

amplifier designs?

A: Yes, a 300W supply design is available on the Projects Pages. However ... there is a fundamental problem with switch mode supplies - the ferrite transformer core. Unless you can get one that is quite similar (and achieve the same primary inductance), the supply will just blow up. Unfortunately, these cores are not readily available to hobbyists, but they can be obtained. In addition you need high speed (Fast or Ultra-Fast) diodes, and again, these are not easy to get. The layout and construction of switching supplies is such that they are difficult for the home constructor inexperienced in building them.

Q: About the Project 89 Switchmode power supply for car audio ... Can it be modified to work (step-down of course) from 220VAC (120, 240, etc.) rectified to 300VDC? If not, where can I find a design for a +30/-30 SMPS rated at 500W or more?

A: The SMPS is not suitable for 220V (or any other mains voltage) operation without major re-design. It is an entirely different matter to make a high voltage step-down system, and apart from PC type supplies, I have not seen a schematic anywhere on the web for an off-line switcher. As a DIY project they become rather daunting (and dangerous), and it is highly unlikely that I will ever attempt a design for publication.

Q: Can I use your preamp or crossover in my car system? I am especially interested in the Linkwitz-Riley crossover / sub-woofer controller / quasi parametric equaliser.

A: Yes you can. You need to establish an "artificial" earth (ground), at 1/2 the supply voltage, and input / output capacitors must be used (make sure you check the polarity of electrolytics). There is a project for a simple preamp and artificial earth in theProject Pages. This can be adapted to your needs. Alternatively, you can use Project 69 (Switchmode power supply for preamps) to obtain ±12V at up to 45mA

Printed Circuit Boards

Q: Can I get a copy of the PCB artwork for any of the projects?

A: No. I do not supply artwork to anyone. The PCB layouts take considerable time

to develop, and I must not only recoup the time spent, but I also need to be able to pay the costs of operating the website. This is my primary source of income, so I don't think it is reasonable to expect me to give away my intellectual property. No-one else who sells products will give you their design information either.

Q: With all of your boards, I have to run wires for the pots. This is a real pain. Why don't you use PCB mounting pots?

A: I dislike running wires as much (or more) than anyone, but if I have the pots on the board, you are limited to using the same type of pot (some are not readily available in other parts of the world). In addition, you would be limited to using the same layout as I designed for - the pots would be the distance apart that I designed the board for, and the PCBs would be considerably larger (and therefore more expensive). You would be much more restricted, and would not be able to use the layout you want.

Q: I sent a faxed order, but I didn't receive any confirmation. The first I knew that it was received correctly was when the boards arrived. Why didn't you let me know?

A: I normally only contact you if there is a problem with the card details, if I am temporarily out of stock (rare, but it has happened), or if I can't determine what you want. If the fax is clear, and I can validate it properly, then the order is processed and despatched, usually within 2 (±2) days of receipt (i.e. it may be immediate, or could take up to four days, depending on my workload).

Q: Can you give me an estimate on the cost of assembling Project (insert any project number)

A:No. The cost of parts varies from one supplier to another, and even more energetically between different countries. It is simply not possible for me to try to maintain any sort of price list, as there are too many projects, too many suppliers, and too many countries and currencies. This is your job, mine is to produce the projects

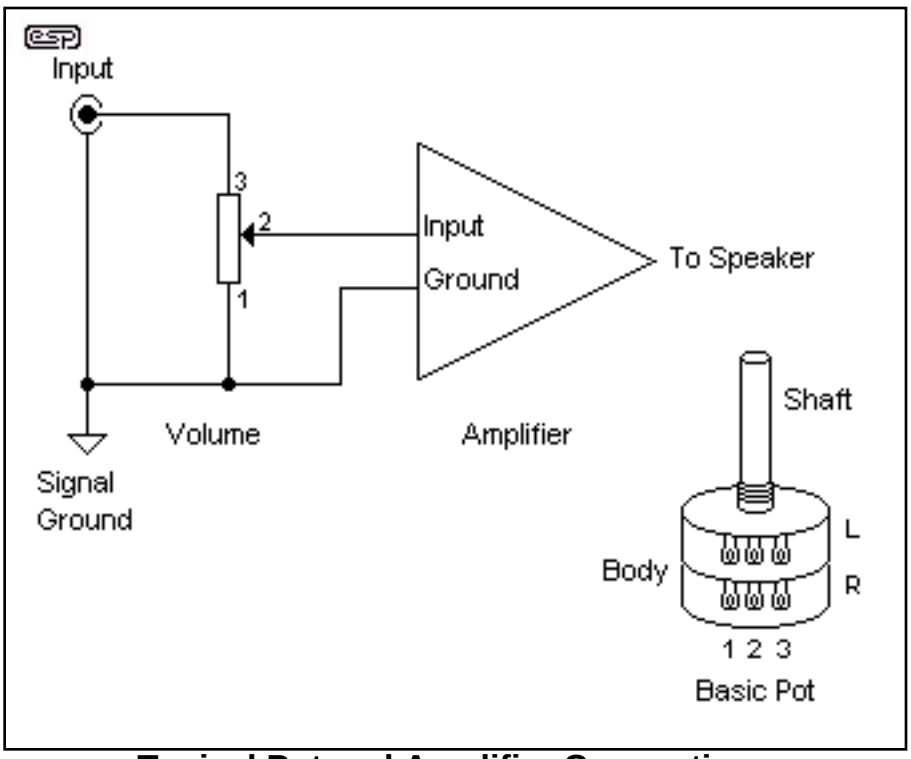
For power amplifiers, a reasonable estimate can be made by pricing the power transistors and doubling it to cover the cost of the smaller devices and passive components. The heatsink, power transformer, filter capacitors and case will normally exceed the cost of the amplifier itself by a wide margin. The availability (and cost) of these varies widely from one country/ supplier to the next.

Q: Do you have power supply boards for any power amplifiers ?

A:No. The power supply for power amps consists of a transformer (too large to mount on a PCB) a bridge rectifier (which needs to be chassis mounted for cooling) and filter capacitors. If I designed a board for filter caps, it would cost a ridiculous amount of money because of its size, and you would have to use caps of the same physical size as I designed for. This would be extremely restricting, and would make component selection much harder than it should be. Power supplies are best hard wired using thick wiring and you have far greater flexibility for mounting.

Q: How can I add a volume control to your Project "XX" power amplifier? (XX is any amp project number)

A: This is a *very*common question, and is fully explained in the article about potentiometers (pots). However, I will also cover it here, as I might save some e-mails. The basic schematic for a volume control and a drawing of a pot are shown below ...



Typical Pot and Amplifier Connections

For more information, see the article Beginners Guide to Potentiometers. Generally, a value of between 10k and 25k (or thereabouts) is fine, and log pots are "traditional". The above article shows how to make a linear pot behave more

logarithmically than a "real" log pot, and this is usually very much better than cheap to medium priced log alternatives. Expect to pay fairly serious money for well matched conductive plastic log pots, or get the same performance from a budget carbon pot suitably modified.

Miscellaneous

Q: I have been doing some research into what my next hi-fi upgrade might be and i have been reading about how vast am improvement can be made with the filtering of AC power.

According to 'everyone' such a device can lower noise floors on a system so that all you hear is the music and no longer the system. It makes sense that the cleaner the ac signal the cleaner the output signal will be although i have been unable to find any really hard evidence that this is the case (in terms of graphs or whatever).

What do you know or think about this? I have heard of several types of filtering methods, ranging from some product called a ***** to battery banks to run amps from cleaner DC.

A: First, with no music, place an ear next to the speaker drivers. If the noise you hear is just a gentle hiss, then you are already at the system noise floor, and there is not much you can do to improve this. Hums and buzzes are probably due to wiring, and re-routing the leads keeping power separate from interconnects (etc) may improve matters.

Unless you have recognisable evidence of mains interference, external filters and conditioners serve no purpose. I'd steer well clear of anything that claims to be a 'magic bullet', and batteries may be noisier than a good mains supply in some cases (the chemical reactions create electrical noise). Mains filtering is only effective and useful if the system's background noise is audible from the listening position, and is the result of mains interference.

If there is no interference and the system noise is inaudible from the listening position, then nothing needs to be done, as you do not seem to have a problem.

Q: Can we obtain tremendously high voltage gain using a FET or valve (vacuum tube) with a current source load or bootstrap circuit

A: Using a current source (or bootstrap) load with valves or MOSFETs will make

them more linear, but does not increase the voltage gain by anywhere near as much as with bipolar transistors. The voltage gain is almost an illusion, largely because the bipolar transistor is a current device (output current is determined by input *current*, not voltage).

Q: What is the reason that bipolar transistors have such a high voltage gain when used with a current source load versus valves or MOSFETs

A: Transistors are current controlled current sources, and the others are voltage controlled current sources. Because the current is controlled by a voltage, valves and MOSFETs have a much lower voltage gain, and high impedance loading (however applied) will not cause a huge change in the transfer characteristics. (This *is*the simple explanation, by the way)

Q: What is your opinion on using an "off-line" power supply, using a capacitor to drop the mains voltage, then regulating using zener diodes. Will it affect the sound? For better or worse?

A: DON'T DO IT !These supplies are extremely dangerous, and are intended only for equipment that is not connected to anything else (for example, stand-alone mains appliances). This method must never be used for audio equipment, since there are always connections to the outside world.

Q: Will an amp that is built with film caps will be better than with ceramic caps? Can you advise any sources on the Net about how caps affect sound and what ones are better for using in audio projects?

A: Film caps versus ceramics is no contest. Ceramics are not particularly stable, and their capacitance varies with voltage, temperature and whim. They are by far the best for bypass applications, but should never be used for coupling or in filter circuits and the like. For coupling and any filter application, always use film or "metallised" types. There are claims that some film caps sound better than others, but I know of no definitive test that has ever proven this (for listening tests - many measurements will show differences, but these have never been proven to be significant in an blind test).

Q: I am thinking of using Brand X amplifiers, and Brand Y cables. What do you think?

A: I will (generally) not endorse any brand of amp,cable or other product in these

pages, although the occasional comment may be in order. Basically, my response is to try it and listen to how it sounds.

Q: I want to build one of your published projects. Are there kits or circuit boards available?

A: I currently have PCBs available for quite a few of the more popular projects, and eventually hope to be able to offer complete kits as well. This remains some way off at the moment because of the cost of purchasing large quantities of expensive devices. Check the Purchase PCBspage for the latest information.

Q: I am confused about transformer voltages and VA ratings, and I want to build a power supply for an amp I am building. What do I need?

A: This is a very common question, and the answer is different in nearly every case. The article on Amplifier Design has a few details, but there are extensive answers in the Linear Power Supply article, as well as the beginners' articles on transformers.

The VA rating is simply the product of volts and amps (hence VA) - it is not called "Watts" since the VA rating and Wattage are very different due to the rectifier and filter caps. A rule of thumb for Class-AB amps is that the transformer should be rated at a minimum of 1.5 times the maximum power from the amplifier(s). For Class-A, the ideal is that the transformer is rated at a minimum of 4 or 5 times the RMS amplifier power rating. It must be remembered that the load in Class-A is continuous, and a transformer that is too small will overheat and be ruined.

Q: Which of the amplifiers in your projects pages sounds the best?

A: Perhaps surprisingly (perhaps ??), I don't recommend any one of them over any other. The Audio Pages are about experimenting, learning and building. All the amps (and preamps) work well and sound good, and it is up to you to decide which one you want to build.

Q: Do you do custom design work?

A: Yes. Send me an e-mail, and I will see what can be done. I do not have the time (and you don't have the money) for development of projects for personal use. My time is very limited at the moment, so I may not be able to help at all.

Q: Do you plan to produce a project for an AM/FM hi-fi tuner?

A: No. These are quite reasonably priced as commercial offerings, and are too hard (i.e. almost impossible) to align for the home constructor with no RF test equipment and specific skills in this area.

Q: What does 4k7 (100R, 2n2, etc) mean? Does this mean 47k (100 ohms, 2.2nF, etc)?

A: 4k7 means 4.7k - this is basically a European standard and is used to ensure that the decimal point is not missed. 100R means 100 ohms, and is used so the omega symbol does not have to be inserted all the time. 2n2 (and similar) means 2.2nF, and the same logic applies as with resistors.

Q: What does 0R47 mean?

A: 0R47 means 0.47 Ohms - another variation to the European standard and again used to ensure that the decimal point is not missed.

Q: What does 2.2nF mean" What is "nF"?

A: A nanofarad is $1x10^{-9}$Farad, and is equal to 0.001uF. This is the preferred nomenclature for capacitors between 1000pF (1nF or 0.001uF) and 1uF (1000nF).

Q: Do you have time to even answer one of these pain in the butt questions?

A: It would seem so

Q: On a different subject altogether, I heard that you helped set up the SAE (School of Audio Engineering). Is this true?

A: Yes. Along with John Burnett and Tom Misner. I was only there for a short while, until I became aware that the operation was not (IMO) above board. Without going into detail, it transpired that I couldn't work with Tom Misner for a number of reasons, not the least being his (self acknowledged) lack of ethics. As a result, I quit on the spot, and John (Burnett) followed a few months later.

For more information on the topic, have a look at John's education FAQ page - Lenard Audio FAQ.

coldamp	coldamp - Class-D audio power amplifiers, switchmode power supplies and other innovative audio products. coldamp is a company dedicated to design and manufacture high efficiency audio amplifiers and other complementary elements for audio systems.
GUITAR Tips Online	**Discover the fastest way to learn the electric or acoustic guitar - online.** Learn from the best - Chris shows you how to play the guitar in exactly 30 days, and you can bypass traditional guitar lessons and achieve real results! This is a very good course, and is genuinely recommended.
SSS	Stones Sound Studio - Artisan audio art series speakers, speaker design, plans, drawings, pcb & crossover design, components, active filter design, speaker driver t/s measurements. Russell Storey, senior design engineer, acoustical consultant, high end audio products sales and service.
NOT GOOD ENOUGH .ORG	What can I say about this site? It is everything that the government "watchdogs" are not, and is probably one of the best consumer action sites around. NotGoodEnough is an Australian operation that does everything it can to get consumer problems sorted out with manufacturers, retailers, banks, airlines, etc. **Highly Recommended** (International membership is available!).
LENARD	The Lenard Audio site has an excellent educational section, and belongs to a friend of many years. You can see some of the commercial products I worked on in the past (and/or am working on at present) with John, and browse through the education sections to understand some of the fundamentals of audio and its application.
Class-A Amps	Geoff Moss (my defacto editor and contributor) now has re-instated his page, primarily devoted to Class-A amplifiers. Geoff has all the details on the John Linsley Hood classic (both versions) plus a lot more Class-A amps and a great deal more helpful information on various amp topics.

RANE	Rane Corporation - probably one of the most open and informative pro audio manufacturer websites ever. There is a wealth of excellent design information, covering a wide range of topics. Not only for professionals, it is just as applicable to hi-fi. Check out the PDF library - I hope you have lots of disk space :-)
The Self Site	Douglas Self - well known designer of amplifiers and audio equipment generally, published many times in Wireless World (now Electronics World) - This is an excellent reference site for design information.
Audio Myths	Many of the things that are taken for granted in audio are myths, and on good days have the credibility of alien abductions or miracle cures. The rest of the time ... well, find out what someone else has to say.
Steve Ekblad	Audio Related Internet WWW and FTP sites. One of the all-time great links pages
True Audio	TrueAudio - Info on speakers and their design + loads of other stuff
ThieleSmall	ThieleSmall dot com has a driver database that is second to none. Jan has put a lot of work into this, and for the speaker builders it will become a very useful resource as it gets known
ValvesUnlimited	For those who just love FETs with pilot lights - I am one of them, does that say something?
CyberTracker	Singapore's Unofficial Audio/Visual Technology Pages
DIYaudio	The name says it all, really. Also some more good links
Linkwitz Labs	Siegfried Linkwitz (of Linkwitz-Riley crossover fame) has some extremely useful information, especially on the design of bipolar loudspeakers and other speaker topics. Some of this information will change the way you think about reproduction of audio.
AudioXpress	AudioXpress is the home of the renowned Speaker Builder and Audio Amateur magazines. Subscription info and sample articles are available, plus a lot of other info.
eCoustics	Easily find the latest news, articles, and reviews on thousands of consumer electronics and hi-fi audio/video products from the most popular, informative, and reliable A/V web sites.
morrison	Don Morrison Audio - Creator of the E.L.A.D. (Electronic Line Amplifying Device) which has had rave reviews, as well as some interesting articles and nice speakers.
Musical Fun!	One of my link exceptions! This page has a collection of very funny stuff - mostly orchestra musician jokes (pity the poor viola player!), but much more, too. Don't miss the first story: "The Bangkok Piano Recital Review"
GMArts	Another excellent Australian site, this one for guitar players. Lots of info about guitars, amps (etc).
Electronics Calculators	Online electronics calculators - work out resonance, capacitance, inductance, resistance and time constants on-line.
Audio Calculators	Audio calculators for all occasions. There is a huge range here - something for everyone

SatCure	Satellite equipment, MacIntosh computers, and (of course) audio make up Martin Pickering's site. Well worth investigation.
Decibel Dungeon	Nick Whetstone has another audio site that is worth a look, especially if you are interested in turntables and other DIY activities.
SSC Electronics	DC converters for portable or car applications, SSM2017 mic preamp ICs (yes, they have them), plus many other useful items.
AUDIOHOLICS.COM	Audio equipment, reviews and thoughtful articles and home theatre setup hints. Includes a forum, FAQs, and more.
Phase Linear	The official Phase Linear site - Owners' manuals, service information, photos, schematics, history and general information
GedLee	Loudspeakers, home theatre, acoustics & noise control and sound quality are the main areas of expertise, and GedLee is the home of *SPEAK* loudspeaker design and modelling software, and the book 'Audio Transducers'.
Bill Collison	Vented Subwoofer information, showing that it *can* be done, if you are willing to make the effort. There is quite a lot of useful information, allowing you to make a high performance vented system and avoid the pitfalls.
CATENA SIMETRIX	An absolutely top notch simulator. The free version has a limited number of nodes (connections), but is still sufficient for nearly all your simulation needs..

delabs	***delabs*** has around 200 electronic circuits in pdf document format or png image format.

More Links - The Audio Miscellaneous Collection

As of March 2000, I have suspended further additions to what is now the "Miscellaneous Links" page. I will only include links here to those sites that (a) satisfy my criteria for content and accuracy of information, and (b) include a reciprocal link to my home page (there are some exceptions, but they are rare for any new links).

Last Update - 30 Apr 2005

Humour Index

It is so often beneficial to have something to laugh at (other than management and the antics of our elected representatives), that I have this humour collection - expect it to grow. Contributions from readers are most welcome.

Please Note: I don't want to offend other readers, although the Joke Collections already have some risque offerings - please, if you don't like "off colour" jokes, don't go there.

ESP Index

Satcure UNIQUE Audio Products

ESP's Humour Collection

Dynamic Range Versus Ambient Noise	By George Izzard O'Veering - some light hearted reading for the technical types
Waltzing Matilda	An "interpretation" of Australia's most famous song
HAL9000	Stanley Kubrick, eat your heart out
OS Airlines	If Your Operating System were an airline (perish the thought)
Monty Python	A trio of the more famous (and suitably bizarre) sketches from those well known lunatics
Murphy's Laws (and Others)	A collection of laws by the likes of Murphy, and joined by various others. If you ever wanted to know what rules your life - here are a few answers.
Joke Collection - 1	An array of jokes to appeal to (or otherwise) just about anyone - Please note that some of these offerings may contain language that could offend.

Joke Collection - 2	More jokes for your enjoyment. This also contains amusing news headlines, hospital emergency room anecdotes and .... jokes!

Please note that Murphy's Laws and the joke collections (1 and 2) may be considered "public domain" - feel free to copy

Elliott Sound Products **Reader Feedback**

Some of the responses I have had from readers. It is most gratifying that so many of you have taken the time to respond. While all e-mails are answered, the answers to the offerings here are not reproduced, as they are basically my personal thanks to the sender. These letters are reproduced verbatim - no editing has been done at all, except to remove the writer's name (and in some cases additional info or questions).

Please note that I have basically stopped updating these reader response pages, as the task was becoming overwhelming. If you have something you *really want* others to see, ask me to publish it (rather than the other way 'round as it was before).

For more readers' responses (and my answers), please see Readers Letters

Website Feedback

This is a small sample of the comments I get from readers. These are reproduced verbatim, with no modification to the text at all (hence some interesting spellings and typos :-)

Thanks for such a comprehensive treatise on bi-amp.

First of all i must congratulate you for your page, it's far the best i've visit on the net, because the didactics, the projects and the humour.

First of all I want to congratulate you for this great web-side. It's really the best audio/ hobby side I've encounterd. The first time I saw it, I printed out all interesting articles and projects and I could not sleep that nigth till 6:30 because I had to read them all!!! Twice

or three times cause I learned a lot while reading. Everything is indeed well written and has a beautiful style.

Impressive website - finally an engineer/audiophile who hasn't lost touch with reality. I thoroughly enjoyed reading everything!

Nice site. Informative and easy to navigate. I'm interted in seeing some pcb layouts when you get around to it.

Hello, I read your articles on the net and it is so interesting.

Thanks for this very informative overview on bi-amping.

Since I was browsing during office hours I didn't sign your guestbook, but felt I should compliment you on your site - easy to browse and full of sensible advice...

I enjoy your page very much! Please present an article on a digital delay circuit!

I have seen your website but I am not sure what business you are in. I absolutely agree with you about biamping. I have had many arguments with people over biwiring. I very much enjoy your article and feel it has more truth than most articles I have read on audio.

Hello, thanks for the very good article and caveats for the unwary.

Let me say, first of all, how much I enjoyed reading the articles on the ESP website. I found myself agreeing with almost everything you have written.

I have really enjoyed reading your project pages. I do wish that pcb's for the 60 watt amp were available.

Thanks for your splendid guidelines about amplifiers on your website. I didn't know about the nonlineairity of darlingtons and mosfets because of all the designs with them, till I had read your website, so I asked friends of me working in the electronic "scene" and they comfirmed it.

Thank you for a very good article.

I think you have an excellent site. It is one of the best I have found. I wish it were around 3 years ago. I find the articles to be very informative - I hope to see more and perhaps contribute to your site.

Hi .. my name is (name supplied) i,m from egypt , and my age is 21 year I very happy to contact your site and thanks for you to add this site in the internet.

I made your surround decoder, and works well.

Loved your website and the effort that you have put into it. Congratulations and my best wishes.

I surfed over to your site for the first time in a while. All the DoZ information was interesting. Some of it was over my head, and all of it is beyond my current skills and resources. But it was entertaining. Some "audiophiles" should be fairly irritated with the death of their misconceptions regarding their beloved Zen components.

It was great pleasure for me to read your articles of amplification theory and amplifier desigh particularly.
While I am not totally agree with your conception of FETs and MOSFETs usage in HI-FI, your approach to schematics is very reasonable and "classical". The same as mine.

Thanks for good web site. The capacitance multiplier is a great circuit! I have made a Pass zen-amp. Now I am making "death of zen"-amp. The things you have said about the Zen are true. I am not fanatic about any topology, though class-A is most interesting to me. I expect to get better definition and precision with your amp.

I just finished the Linkwitz-Riley cross-over. I built a pair of mid/tweeter bins with two mid-range and two tweeters (4 ohms) crossed over at 3000Hz. Then I built the L-R cross-over at 650Hz (34uF & 5K1 ohms). The bass driver is 97dB while the M/Ts are 94dB each. The Amps are a 125w into 8 ohms for the bass and 108w into 4 ohms for the M/T bins. It is a little top heavy, but when I build a 200w into 8 ohms amp, coupled with the 175w into 4 ohms amp currently driving the bass speaker I think it should be fine. I must say it is very "loud" and very clear in the voice and instrument range, without loosing any of the bottom end. It is an excellent result.

I just read your editorial, and I must say that it is very refreshing to hear someone finally talk some sense! It has always been my experience that audiophiles tend to subscribe to mystical cures to phantom problems they didn't even know they had! Thank you for your wisdom and straight forward approach.

I´m very interested in your "projekt 30" and I think I´m going to build it myself one. I´m recording on my computer and therefore I need a little outside mixer. I also saw that you had one chapter unfinished so I wonder if it´s possible that you can e-mail me some info about this when done? :)

Thanks for the very interesting web site. I look forward to visiting it often. It is nice to see valuable information given for free.

As ussual, your page is great stuff. ABout your Termal-fan cooling and the upcomming Termal Shutdown project. Please only use disctgrete devices (no Op-amp), so the circuit can be integrated into an Power-amp circuit, WITHOUT having to go to low-level PSU (like 12 V).

I am very pleased to have found your web site. I am an EE (Electronic Engineer) working as embedded designer/software developer and have developed a strong interest in professional music electronics since I started running my church's sound system . To my dismay I find that my formal education didn't really equip me for high quality audio equipment design. Over the last few months I have been searching the web for useful design information and practices. To my further dismay, I have found lots of "cookbook" type data but very little in the way of rigorous design. Most of what I have found so far is either based on component vendors application briefs or else the circuits presented don't appear to agree with what is claimed about them.

I find your articles interesting, well written and very informative. I especially like the fact that you lay out the pro's and con's of each design choice as you make it and don't try to hide the mistakes you have made. Too many of the "experts" I have read try to make you think their favorite scheme was handed down to them from on high and is the ultimate solution to all of life's problem. Real life is a lot messier than they allow for, especially since a solution that is a good fit for one problem may end up making a different one worse.
...
I encourage you to keep on disseminating sound (no pun intended, well maybe a little bit) audio circuits, exposing meaningless marketing hype in audio gear and the preaching the importance of testing (instrumenting) what you do.

You rock. I am so happy there are people like you in the world, preachin' the truth and laying it out clearly and plainly. Too many things i've been reading lately are written by people who i suspect don't really understand exactly what they are waving their hands at, and I know because all of a sudden things get too "complicated".

You have given me several enjoyable hours in my favorite coffeehouse so far. I'm slowly going to swallow the entire site, burp, and sit back with a complacent, enlightened grin on my face. What a relief that there's no magic where there shouldn't be, and all you gotta do is ask the right question and think a little.

Keep it up. Pass it on. Thank you.

I stopped by your site after someone posted a link to it from a guitar effects makers forum - so you probably know where I'm coming from here. Just like to say after reading through your reviews or the dodgy amps and spray etc, I was really surprised that at what crap people would believe.

I'm an electronics engineer, so I see and hear a lot of what you're talking about. Glad to see someone showing up these morons and exposing them for what they really are - frauds.

Great articles, keep it up

Elliott Sound Products — About The Audio Pages

This site was initially created some time in late 1998, and has progressed from a single page (a somewhat shorter version of the bi-amping article) to what you see today. I have gradually built up the content, and the overall site "map" has changed several times as I have tried to incorporate all the new stuff in a reasonably sensible manner.

As the site continues to grow, you will see more changes, but I will always keep the user interface as simple as possible to maximise loading speed. This is one reason that you won't see fancy mapped graphics, frames or other frills that might make the site look really cool, but at the expense of download times.

The overall philosophy of the site has never changed - keep to the facts, stay away from the constant efforts of the subjectivist camp to ever "improve" on what they have (almost always with expensive "tweaks" whose performance cannot be measured, only heard by people with "finely tuned ears" :-). Music is to listen to. Recordings are rarely perfect, the concept of reproduction ever matching a live performance is a myth. Listen to the music, not the equipment.

This is not to say that good equipment is not something to strive for, since the enjoyment is greater when it sounds good. I love to experiment, and many of the designs are experimental - in some cases just to prove a point (the DoZ is a perfect example). Sometimes these experiments backfire (the DoZ is a perfect example!), and I get a whole bunch of e-mail telling me how great it sounds.

How much of the great sound is purely the result of the reader having built it himself/herself? I honestly have no idea, but it doesn't matter. If people can get double the enjoyment from building and then listening to equipment then so much the better. In the long run it is all about enjoyment; of music, of making something and of life.

May you all enjoy building my projects as much as I enjoy bringing them to you.

Images

I have been asked many times about the way I create the circuit diagrams (or schematics, if you insist), and over the time the pages have been running this has changed. I currently use Protel to draw the diagrams (although I have used other methods in some of the earlier drawings). These are simply captured and pasted into Paintbrush for some minor touch-ups, and the final image is then exported as a GIF file. This method is a little time consuming, but I have found that the images are very clear, and I get consistent results.

Articles & Projects

The content of all the articles and projects is entirely my own unless otherwise stated. This extends to the philosophy of the site itself, which is mine and mine alone. This (of course) does not mean that others will not have similar ideas (many do), nor that I automatically disagree with the opinions of others who might have a slightly different opinion on the same subject. I have been corrected many, many times - for anything from spelling mistakes to errors in diagrams (I have even managed to get a few electrolytics backwards - oops!), and various people have assisted with additional information on a number of occasions.

I do not (knowingly) steal the ideas, drawings or other content of others, and any information from others is reproduced with permission and full credit is given to the original author. Contributions are encouraged, as I am determined to make the best audio web site around, and I cannot do it alone.

There is a very small number of images on these pages that seem to be in the public domain, and I have used some of these where appropriate. If any reader out there sees their image on my pages and is offended that I purloined it, let me know and I will remove it.

Sometimes you see an image that is just too wonderful to ignore - the picture here falls into that category. It was sent to be by a friend, and I am sorry to say that I know not where it came from. I just loved it on sight!

I do not use (or condone the use of) spam (the web kind or the canned variety), so you will never get bulk e-mail or cans of fake "meat-like substance" from me for any reason, so that image is appropriate in it's own silly way :-)

I just wish I knew where it came from so I could thank its creator. Whoever you are - my thanks and apologies for "borrowing" this image.

Cheers,

Rod Elliott

Elliott Sound Products **Meet The Author**

I (Rod Elliott / aka "the author" / aka "rode") am based in Sydney (Australia), where I have lived for the majority of my life. I was in a small country town in my early childhood, and having revisited it not long ago, I am immensely pleased that I no longer live there. I have travelled extensively, both for work and pleasure, and this helps to balance one's view of the world. Australia is still my favourite place to live though :-)

I am a QbE (Qualified by Experience) engineer - I do have some formal qualifications, but they are relatively meaningless without experience and background - I consider them to be "unimportant". I have worked in the electronics, audio and of late the telecommunications industries for over 30 years, and have developed a number of products which in their time received critical acclaim. At this stage of my career (Definition: to rush or hurtle with much speed but little or no control) I have no real desire to re-enter the rush and bustle of commercial enterprise, but one cannot still a lifelong passion.

As a result, I have produced these pages which have stimulated some interest in the subject and hopefully introduce some new thinking and ideas into what is rapidly becoming a tired old brain (Oy! Who put that bit in? I never said that!).

In case anyone was wondering, I am not an "audiophile" in the true sense of the term. I enjoy music immensely, and quality reproduction is naturally very important to me. Will I go off and spend hours, days or weeks testing different tweaks, cables or boxes of sand to "damp vibrations" - no. I will spend a considerable amount of time experimenting with ideas or building something new to play with, and every so often I actually get a chance to just listen. This does not happen often enough, unfortunately, since I have a web page to feed and actual work to be done - these things take their toll on available time.

When I do get the chance to "just listen", I do what a lot of audiophiles should do. I listen to the music. The reproducing system must be open, clean and transparent enough so that I don't hear it, only what comes from it. The extraordinary amounts of money that some people spend on systems is beyond my means, but what I listen to is what I have built myself, and I figure that a considerable sum has been saved in doing so. This is the major reason for the existence of The Audio Pages - to encourage others to do the same.

Apart from anything else, there is great satisfaction in building equipment. It may not have the glamorous appearance and prestige name of some of the "finest equipment", but if it sounds great (to me and my friends - some of whom *are* audiophiles), then it is great. I don't need the brand names and fancy looks, I want good sound at a respectable price. This is something that is attainable for everyone who has the interest, and who decides to build their own equipment. Reading these pages won't hurt either ;-)

Anyway, enough drivel ...

History

For many years I had my own business, which was predominantly involved with musical instrument amps, PA systems and the like. During this period I also worked with a friend in a recording studio I designed and built,

called "Fly-By-Night Recordings". We did a fair bit of advertising work (bleccht) and recorded a bunch of bands. One of the recordings we made has recently been re-mastered and released on CD, so the quality must have been there.

I played in a few bands for a while (guitar, then bass), but soon realised that I was much better at the technical side than the musical. I still play for the fun of it, but alas, don't get as much time as I would like for that, either. I spent quite a while mixing for live bands, and toured Australia a few times - life on the road with a rock band has to be experienced to be believed!

I worked for a spell with (and helped to start) the SAE (School of Audio Engineering) - one of the most recognisable of the audio engineering schools, and was teaching students the basics of recording - how to mic a drum kit, mixing techniques and that sort of stuff. See the FAQ page for a bit more (and a useful link) on that topic. After that was a school that taught electronics (a privately run affair called The School of Electronics), where I taught the basics (and not so basics) of electronics, primarily analogue of course - digital was still in the future at the time. I still see some of my former students, and a great many of them are still involved in the electronics industry.

I then spent some years at a computer company, initially in the repair centre (this was when it was still worthwhile to repair computer boards), then into a Research and Development role (as its sole team member!) designing telecommunications products. I then moved to a telecommunications company, where after a while, I was back to teaching again - don't you just hate when that happens?

I have become my own boss again, so ESP is now a full time business - this is something I have been hankering for, and it has now happened - not without some trepidation of course, but I will be able to devote more time to the things I enjoy the most.

My System

My personal system has been through many changes (as you would expect), but in its present form it was fairly stable for about 4 years (up until September '99, when some major changes were introduced).

I am using a modified fairly standard type CD player (premium Burr-Brown opamps instead of the originals), and also a direct drive turntable with a fairly old but still magnificent moving coil pickup cartridge. There is the mandatory cassette tape machine (rarely used except for some of my old live recordings), and an FM tuner. A DVD player is a stable part of the system - just don't assume that because they can play CDs that you should use one for this. They do it, but not as well as the 'real thing' (this depends on the DVD player, of course - some are outstanding!)

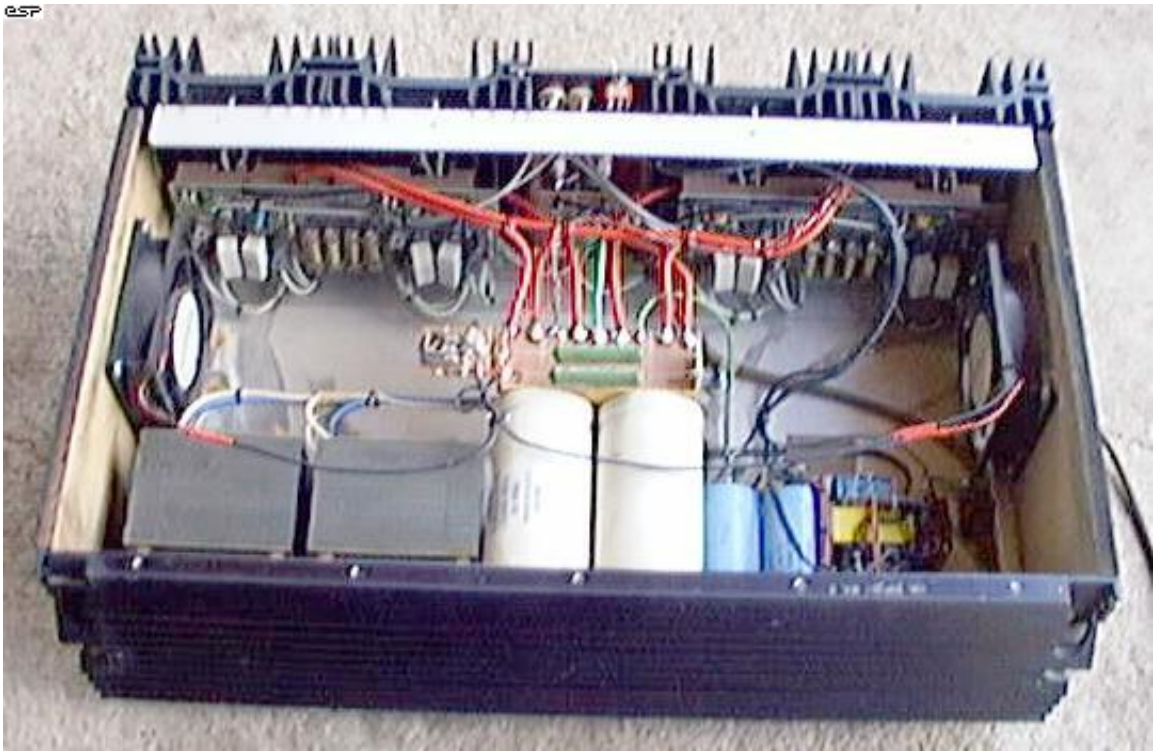
Nothing really special in the source department, but the preamp and control unit are of my own design, and the system has an inbuilt phase-coherent crossover network (at 300Hz and 3000Hz), feeding a triamped system using four of the 60W (P3A) amps (modified) described in the Project Pages. The Control Unit shown below does the following ...

- Provides tweeter amplification (20W per channel)
- Contains the 3-way Linkwitz Riley electronic crossover
- Houses the phono preamp (Fully shielded - bottom left corner)
- Signal shorting relays and DC protection relay for the tweeters
- Switched power for all power amplifiers in the system (controlled from the preamp)

I was using my valve preamp, but now use the Project 88 preamp, which I think actually sounds better! This feeds directly into the crossover. It also allows me to use the phono preamp (the preamp unit does not have its own), and now everything is there.

As you can see from the photo, almost all of the circuitry uses the PCBs I offer for sale (the power amp is an early prototype of the P3A amp board). If you want to know what the valve preamp looks like (because this is what I used to use) have a look at the VP103 page.

The main power amp is something else again. I had actually forgotten how much work I put into the thing, and the insides surprised me when I took it apart to replace the input and output connectors.



As you can see, the power supply is a fairly robust affair. The two large transformers (there are two little ones for the preamp too) are 200VA each (400VA total) and were specially made to my design quite a few years ago. The amps are as described in my projects pages (the P3A amp), but have been upgraded, using 200W TO3 power transistors and run a +/- 40V supply, with 18,000uF of capacitance per side. The smaller electrolytics you can see on the right were for the preamp, but are no longer used. The amp can happily supply 70W into 8 Ohms from each of the 4 amps, and will do about 80W peak on normal program material.

The fans are thermostatically controlled, and only ever run when we get one of the famous Australian hot days. Because the power amp runs a fairly high quiescent current (around 80mA per amplifier), it gets rather warm even when idle, and the safety margin for temperature was not large enough for my liking.

All input sources (including the turntable, using the phono preamp in the new control unit), now go through my P88 preamp before the crossover, and that has all the characteristics one would desire - dead quiet, excellent imaging, etc.

The speakers and control unit are described in the My New Speaker Project article. This tells just about anything that you might want to know about them, so I shall not ramble on here. All electronics in the control unit (crossover, tweeter amp and phono preamplifier) are as described in the various published projects.

To combat the lack of low bass (< 50Hz with the new boxes), I am using an EAS (Electronically Assisted Sub-woofer) of my own design (seeProject 48 for details) which has extended the bottom end dramatically. Powered by a 400W Class-D amplifier, I can get -3dB at 15Hz or less, but raised this to 25Hz to prevent excessive cone excursions caused by assymmetrical signal waveforms (these shift the effective DC operating point). There is very little that is audible (or recorded) below 25Hz, and not being a great fan of pipe organ music, I don't think that I am missing much in the frequency range. The sub is now equalised with the P84 Subwoofer Equaliser, and is flat to 20Hz in my listening room.

Test Gear

The photo below shows the bench mount gear. There is also the mandatory collection of hand held meters - both analogue and digital, capacitance and inductance, etc. (not shown, 'cos they are boring :-)

From left to right, you can see my distortion meter (the large black box with big meter), and on top of that is an arbitrary waveform generator, frequency counter and tone-burst generator perched at the summit. Next is an audio generator (now well over 25 years old, and still going strong), then my digital oscilloscope. My ancient transistor tester is next, with a function generator on top of that. At the top of that stack is my quasi-parametric equaliser (with its back rudely turned!). Next in the line is a dual tracking power supply, with a combination test

unit on top of it (audio generator, small power amp, monitor speaker, and triple power supply). At the top of that pile is a 10 band spectrum analyser. At the extreme right is my test amplifier, with 3-way variable crossover, phase correction and impedance control on two of the three amps. An old tuner (now retired and replaced by another no quite as old) sits atop that. (Sorry, that was boring too.)

The inevitable (for me) bits of "stuff" are occupying any remaining space. I don't know why, but any time I get a clear flat surface (regardless of size), it seems to be covered with things within minutes. I suspect that I may be the cause, but this cannot be proven :-)

Me, And Some of My Toys

This is not a particularly good photo, but I am reluctantly forced to accept that I do look more or less like the photo suggests. Given my location (Australia) the DownUnder sweat shirt is fairly appropriate.

A couple of my favourite toys are visible - the pantograph engraving machine in front, and radial arm saw behind. There are obviously others, but I won't bore you further with the details.

I hope you enjoy my offerings, and those of my growing list of contributors. I wish you happy reading.

Cheers, Rod

1. - Introduction

In as far as it is possible, the articles presented on the ESP site are aimed at one thing - the truth. To be more exact, it is really my version of the truth, since truth is neither absolute nor tangible. There will be areas where it is later proven that I am (or was) wrong - I accept and welcome this.

At various times, I have been berated because I do not 'trust my ears', or that I have claimed that a product is fraudulent without having tested it at all. Guilty as charged - there are simply too many products that should be tested, and in a lot of cases the

claims are so preposterous that testing is clearly unnecessary. While my ears remain a much used and relied upon test instrument, this is true only for my own tests - to be able to say anything with authority, I need hard evidence, not just add to the confusion by making unsubstantiated claims based on what I think I hear.

There are many products that claim *massive* improvements over and above the standard offerings, without offering one single shred of evidence to show that the claim has any basis in reality. While it is apparently perfectly acceptable for the vendors of such products to make their claims unhindered, for some reason it is not alright for me to debunk these claims without having listened to the product myself (indeed, testing is often claimed *not* to be needed, or should be avoided!). In many cases, it really is not necessary to do so - the claims made have no relationship with reality, and wasting any time at all on such products is pointless.

Most commonly, magic component claims are riddled with pseudo-science, gobbledygook 'technical' specifications or references to proven characteristics of materials that, while passably interesting, have nothing to do with that material's performance in a piece of electronic equipment. This is a popular technique to convince the non-technical reader that there is real science involved, when in fact nothing could be further from the truth.

I cannot change the way that people think, and I have no desire to even attempt to do so - I present my material as is, and by virtue of the fact that I wrote most of the material, it comes with my own prejudices built in. To some readers, this is unacceptable (mainly because I don't agree with them), and is seen as a perfectly good reason to launch an attack ... most commonly in forum and bulletin board sites, and rarely by anyone who has ever bothered to send me an e-mail to discuss their point of view (or offer some real data to prove their point). There have been several cases over the years where I *have* been challenged, real data *has* been offered, and I have done further testing or investigation and made changes to the affected page(s) as a result.

There are great differences in the hearing ability of different people. This changes from day to day, and is affected by mood, alcohol and other substances, minor illnesses and many other factors. That some people will hear things others cannot is a given, but no-one can hear sounds that are well below the general ambient noise floor, except under well controlled conditions and perhaps with specific sounds. A signal at 1dB SPL cannot be audible in the presence of another sound of similar frequency (range) at 110dB SPL, yet it is not uncommon to find claims that some individuals can hear sounds that would relate to -10dB SPL or less relative to the overall sound pressure. For example, if a 0dBV signal produces sound (via a power amplifier and loudspeaker) at 100dB SPL,

then -100dBV is 0dB SPL - the threshold of hearing. Anything below -100dBV will be inaudible in *absolute* terms, and completely inaudible relative to the overall SPL.

Please Note: It is very important that one thing be made perfectly clear. No individual person or specific group of people is referenced herein by inference or deed, although it is possible that some readers may think that there is an oblique reference to them, their behaviour or their beliefs. This is not the case - this article refers only to generalised examples of particular behaviour, and no specific or individual person or group is stated or implied. There is one exception, which follows ...

---

2. - What is Truth?

Krishnamurti said in 1929 (in a speech where he disbanded the Order of the Star - of which he was the head) ...

> **I maintain that Truth is a pathless land, and you cannot approach it by any path whatsoever, by any religion, by any sect. That is my point of view, and I adhere to that absolutely and unconditionally. Truth, being limitless, unconditioned, unapproachable by any path whatsoever, cannot be organised; nor should any organisation be formed to lead or to coerce people along any particular path. If you first understand that, then you will see how impossible it is to organise a belief. A belief is purely an individual matter, and you cannot and must not organise it. If you do, it becomes dead, crystallised; it becomes a creed, a sect, a religion, to be imposed on others. This is what everyone throughout the world is attempting to do. Truth is narrowed down and made a plaything for those who are weak, for those who are only momentarily discontented. Truth cannot be brought down, rather the individual must make the effort to ascend to it. You cannot bring the mountain-top to the valley. If you would attain to the mountain-top you must pass through the valley, climb the steeps, unafraid of the dangerous precipices.**
>
> Reproduced with the kind permission of the Krishnamurti Foundation of America [1]

This is such an eloquent description of truth that it almost certainly cannot be bettered. It is just as relevant to the pursuit of excellence in audio as anything else, although I'm sure Krishnamurti would have considered this to be rather trivial compared to the spiritual context he referred to. Trivial or not, the fact remains that the essential principles of which he spoke are just as valid in the field of audio as spirituality, and indeed anywhere that several competing versions of 'truth' exist side by side. This is rarely a peaceful coexistence - examples abound in the world around us, and we have seen the terrible destruction of life (and property) in the name of one truth or another.

We have also seen the almost religious fervour with which some people will defend their point of view or favourite piece of sound equipment. Likewise, we see attacks (sometimes very vicious) on those who do *not* believe in pseudo-science, magic components or rocks (special or otherwise). To criticise is seen as heresy by some, and pity he who has the gall and audacity to openly state that $10,000 speaker cables (for example) are not the path to Nirvana.

Such extravagances may make their owners think their system is something Heaven-sent, however it is completely unreasonable and unacceptable that they will attack someone else who claims that the cable had nothing to do with the sound, or for another to claim that such sound is impossible to achieve *without* the 'special' (or magic) cables/ components used. It is simply impossible for either party to win such an argument, and it is best for all if they could agree to disagree and leave it at that.

Much of what is at issue is based on the oft-repeated claim that there are many things that simply cannot be measured, and only our ears will be able to pick the subtle improvements offered by the product. There is no point asking anyone making that claim to prove it, nor is there any point trying to convince the person otherwise. It is their belief, and to them it is true.

However ... How much of their belief has come from elsewhere? To what extent is the belief something that has been formed after years of listening to music on different systems and taking detailed measurements, versus listening to the proclamations of the Black Knight 'gurus' whose belief system was built on an unknown premise? Does the cable vendor (for example) genuinely believe that his product is as good as he claims, or it the whole exercise a cynical ploy to separate the buyer from his hard earned cash? We simply do not know the answers to these questions, and further probing for the answer will only infuriate the persons involved. The net gain is zero - to all parties.

---

3. - Truth Versus Belief

The problem is that each of us has our own truth, and this is arrived at by many and various means. In some cases it is nothing more than a belief, and it must be accepted by others that this is valid for the person who believes. Although we may challenge the belief, it is rare (to the point of being virtually unheard of) for people to simply drop one belief system for another.

In other cases, our truth is the result of research, testing and measuring. Should we find no evidence that a particular type of cable or component makes an audible difference,

then that becomes our truth. This must also include pure analysis, without measurement or listening test. For example, if it is suggested that demagnetising plastic materials makes a difference to the sound of an audio system, there is little point in anyone with an analytical mind testing this. Since it is well known that no commonly used plastic can be magnetised, there is no point 'demagnetising' it. Simple analysis indicates that demagnetisation and a resultant improvement in sound quality are impossible, when the base material *cannot* be magnetised in the first place. Perhaps there is some other mechanism at work, but it is certainly not magnetism.

But, what of the beliefs of those who have demagnetised non-magnetic materials, and say that the difference is astonishing? Are they demented, or have they succumbed to the placebo effect? Could they be right? I can't answer this, and nor can anyone else. To me, they are the unknowing victims of a fraud, and have chosen to believe that their hard earned money was indeed well spent, and not wasted making the fraudster rich. It is important to understand that despite this, *their experience is real to them!*

Neither you nor I can convince them that they are wrong, any more than they will be able to convince me that the effects are real. If it cannot be measured (bearing in mind that the digital signal can be analysed byte-by-byte) then I shall remain unconvinced, since there is zero proof to support the contention. Billions of characters of electronic and conventional (paper) storage are devoted to arguments between the different 'camps', be it religion, politics, audio, cars, 'free' energy, conspiracy theorists etc., etc.

No-one wins these arguments - ***ever***. They are un-winnable in any forum, since no-one can convince anyone against their will. All that anyone can do is to explain in a reasoned and (hopefully) rational manner that *they* believe that the claims are false, giving sound reasoning and clear details of the facts as they are understood. In any case, the 'true believer' will not be swayed by any argument, however rational or well reasoned - and lest you may think that I am approaching this from my own perspective, this applies both ways.

A cable believer will be just as incapable of persuading me to change my mind as I will be incapable of changing his - we each have our own truth, and it is completely true - but only to the one person. I base my beliefs on what I can measure, since I believe that measuring equipment can resolve details that cannot be heard under any conditions. For example, although I know that I can measure the microphony of a cable (i.e. it's ability to act as a microphone when vibrated), I also know that the signal level is infinitesimally small when the same cable is loaded with the typical impedances of the source and load. Some claim that this is in fact audible, and to them, this may be true. It may also be true that they *think* they can hear it, and a double blind test (DBT) would show that they

can't. We cannot force anyone to perform a DBT, exacting measurements, or anything else against their will.

There is no answer - people will continue to believe what they want to believe, and all anyone can do is to present the facts as they know (or believe) them to be. One can do no more.

---

4. - What is Science and Belief?

Two excellent articles that explain the concepts of beliefs are "What is Science, anyway?" [2] and The Belief Engine [3]. These two articles are recommended reading, but there is a great deal of other information available from any search engine.

What is Science?

"Science is the systematic enterprise of gathering knowledge about the world, and organising and condensing that knowledge into testable laws and principles." This rather elegant description is from biologist E.O. Wilson's book "Consilience" [4]. That laws and principles will change over time is a given, since we are always learning. Very little science (none that I can think of) has grown from pure belief - the gathering of evidence is hard work.

In short, science is knowledge based - all scientific principles are based on what we *know* rather than what we may believe. Science is a process of assembling knowledge, correlating that with other knowledge, and testing the outcomes to determine a set of rules (or 'laws') that govern the interactions between materials and/or energy. Without the testing and verification, there is no science. If the tests are not repeatable by others, there is no science. Anything that cannot be verified or measured, relies on opinion or subjective reports (hearsay) falls into the following category ...

What is Belief?

Simply stated, a belief is based on something that we cannot prove, and requires *faith*. We do not 'believe' in the existence of air or water, for example, since we *know* that they exist. Some may *believe* that they can live on air or water with no other sustenance, and this belief will stay with them until they either die of malnutrition or come to their senses. Thus, it may be demonstrated that faith is not enough, and that we cannot live on air or water alone - such beliefs are not real to the majority of people. Other beliefs that are not so easily disproved are much harder to deal with. The longer a belief has been held, the harder it will be to convince the believer that s/he is mistaken.

What of God or magic components? These are beliefs - neither can be proven to the satisfaction of any observer, so there will be those who believe in God and those who do not. Some will believe that God is different from the (false) God of other believers, that S/He has different rules, is benevolent, fearsome, omnipotent, or just 'there'. Others (agnostics) may take the wait and see approach, which according to some believers guarantees the agnostics will suffer eternal damnation. There are no facts either way, so no-one can actually be right *or* wrong - they simply have different beliefs, and will not change readily.

Likewise in audio (and indeed many other pursuits) - some believe in magic components, others do not. The non-believers may be agnostic or full-bodied non-believers, but the end result is much the same. Although it is possible to prove that a great many of the magic component claims are false, this proof will only affect those who are already non-believers or agnostics. The believers will claim that the proof is bogus, just as the non-believers will claim that the reasons given that the magic *works* is bogus.

I like to think of the believers in magic components as 'naysayers', since (to me) they refuse to see reality. To them, I am the naysayer, since I refuse to believe that there is any magic in components, and I believe that all audible effects can be measured.

There are some that fall into a special category I call the 'Black Knights' - as in the Black Knight of Monty Python fame, who refuses to accept that he can no longer fight, even after he has lost both arms and legs. Some of the Black Knights of the audio world have been brutalised and scorned by many, and some observers might say with considerable justification. Their beliefs are so strongly held that no argument, no rational discussion of the facts, no possible reason, will sway them from their often ludicrous postulations. Rarely (if ever) does the Black Knight have a website with detailed diagrams, test results and measurements. Often (if they *do* exist), the data will be lacking certain critical information, without which it is essentially meaningless. There will nearly always be other people who agree with the Black Knights for reasons of their own, and who believe that the claims are reasonable and rational. They will leap to the defence of a downed Knight regardless of the rationality of the detractor's claims, and most often also without a shred of hard evidence to back up their position.

To me, this behaviour is denial - they deny that there is anything wrong with their claims, they deny that any proof to the contrary is valid, (regardless of the qualifications or reputation of the person providing the proof), and they will deny that there is anything to deny. The arguments used are usually ad-hoc, often (ever so slightly) off-topic, and almost always emotional rather than rational. In exactly the same way, a creationist will deny that the proof of evolution is valid, or a conspiracy theorist will deny that any proof

of man's moon-walk is valid.

To take it to an extreme, the Flat-Earth Society (and yes, it does exist) refuses to believe or accept that the photos taken from space prove anything (they will typically claim they are all faked), and despite the fact that not one of them has ever fallen off the edge of the world, it is still flat - regardless of the awful paradox that creates with air travel, the existence of the horizon, etc. These are the ultimate Black Knights - are they completely mad? I don't know, and I don't much care either, the truth be known.

Naturally, some of the claims made by (some of) the Black Knights will be valid and may be proved easily, and this makes it much harder for the layman to separate fact from fiction. Only by experimentation and education will people be able to see what is (or is likely to be) true, and what is based on faith or is complete fabrication. In some cases, a claim can easily appear to be completely rational and have scientific validity, but without evidence and repeatable test results it should be treated with suspicion.

---

5. - Perpetual Motion in a Different Form?

The proponents of 'overunity' or Perpetual Motion Machines (PMMs) have a similar philosophy of life to that of the magic component proponents and/ or vendors. Essentially, they feel that their discoveries are so important that *no-one* should overlook them, yet both groups will reveal nothing tangible about how their creations actually do what is claimed.

Any information that is provided requires that you must take it at face value, and only after a purchase will you discover the truth - namely that it does not work, or at least, does not work as claimed. These people seem to have a disconnect with reality, and believe that established science fails to see the importance of their work, is blind to the benefits, or even deliberately withholding the truth.

Having purchased the magic component or plans for the PMM, in many cases the buyer may convince himself that it works, for to do otherwise is to admit to having been duped.

The claims in both cases are very similar - you will get benefits that are way beyond what simple physics would indicate, and these people will protest that established science simply does not understand the principles involved. No amount of mathematical or measured performance proof will ever make a difference to their beliefs, and will be simply deemed wrong, inappropriate or misguided. They will vehemently deny that their own claims are wrong, inappropriate or misguided, and will reject any proffered proof out

of hand.

In many cases, the PMM brigade will defend their position with words alone, and would rather continue with endless debate than spend some time in the lab or workshop fabricating their invention (and thus proving the claims), and rendering all further words superfluous.

The magic component believers will do exactly the same thing, but with a twist. They do build equipment and test their inventions, but refuse to perform meaningful measurements, double-blind tests or anything else that would prove or disprove the claimed benefits once and for all.

Both groups are rather like the alchemists of old, and think that all they need is sufficient faith and purity of thought to achieve things that are in fact virtually impossible. The scientific approach is considered 'defective', because it does not embrace their beliefs.

There are many examples that will be brought up where science has been proven wrong in the past. Splitting the atom or exceeding the speed of sound are two classic examples, since everyone used to consider both to be impossible. Now that they have been shown to be perfectly possible, the same logic is applied to their own creations ... "*Since the scientists were proven wrong then, so shall they be in the future when my claims are examined properly.*" The flaw (from their perspective) is in current thinking, which disallows the proof that their PMM, cable or 'universal distortion and noise canceller' (etcetera) will actually do what they think it does.

Then there is the 'undiscovered law of physics' that can be brought to bear if a detractor is particularly persistent. While it is quite possible that there really is an undiscovered law, it will not negate the current and well proven concepts of conservation of energy, thermodynamics, or any other basic principles. Any such new law (should it exist in the future) will add greater understanding of existing principles rather than make the currently used physical laws obsolete.

To these people, Einstein's special law of relativity should read ...

$$E = mc^2 \pm 3dB$$

... and the uncertainly factor allows them the latitude needed to enable their process to function as claimed. Sadly for them, this is not the case.

In a similar vein, there are many who believe that everything is black or white, true or

false. There is no grey (which translates to uncertainty). In fact, the grey area is usually where the real truth is to be found, this is the area that should be examined most closely, for in doing so one will learn a great deal about himself, and potentially a great deal about the way the world works.

In this context, there used to be a claim that "you can't have trees and grass too" - this was the common cry of early sheep farmers in Australia. This belief resulted in the wholesale removal of trees, and the result is now decimation of the land - massive soil erosion, rising salt tables that threaten (or make useless) more and more land each year. The claim in itself is true, but without examining the grey area, the actual *reasons* were not seen, and trees were simply cut down.

So, what are the reasons? I present one possible reason that is potentially quite simple, although I *do not* claim this to be the final answer - just one of many possibilities that will only be seen when the grey area is explored ...

- Sheep are cold climate animals.
- Australia (especially inland) gets very hot.
- The sheep will head for the coolest areas they can find. Under ... trees.
- While there, in the relative cool, they will eat!
- Before long, there will be no grass under the trees.

Now, it is not *because* of the trees there is no grass underneath, but because the sheep have eaten it all while trying to keep cool. In addition, sheep are hard hoofed animals, and Australian native grasses evolved with only the native mammals - none of which is hoofed!

Removing the trees was obviously a big mistake, and the real reason for no grass beneath the trees was neglected in the rush to 'solve' the 'problem'. In fact, trees may allow grass to grow better, especially in the areas shaded from the morning sun - I can see this in my own backyard! I can likewise lament this when I have to mow the very thick grass thus shaded, which grows like crazy during summer. In the areas that get full morning sun, the grass growth is much more subdued.

Ok, but what on earth does this have to do with electronics, audio, PMMs or anything else?

Good question, simple answer, but with complex understanding. The grey area of all things is that which is unknown. There is no immediate right or wrong, true or false, real or unreal. To get to the answers is difficult, time consuming, and in some cases

expensive. It requires one to think, long and hard, to discuss and to examine and reject theories. It is not the easy path.

On the other hand, to accept someone else's theory (e.g. "Oh, don't even *try* to understand it - it's magic!") is easy, but you then fall into the very trap that Krishnamurti warned against. 'Truth' is packaged, sanitised and instutionalised, you are warned that you must never question that which is 'written in stone'. This applies to politics, religion, finance, hi-fi and almost anything else you can think of. To accept the 'word' is the easy way - you no longer *need* to question, examine or experiment, or to search further for enlightenment. You have been told - it must be true because so many others also believe, and anyone who questions this truth is an heretic.

This principle was used to great effect by the Spanish Inquisition, and is used today to push the current fiscal policy, someone's belief in 'world order', and at the trivial end of the scale, to attempt to silence those who criticise the high end cable vendors.

A new belief can come about so easily that it is scary ...

> Someone thinks they hear a difference between two components. At first, they may be unsure, so will ask someone else. The second listener may say "I do believe you're right - I'm *sure*I hear a difference too." At this stage, they may (or may not) actually hear a difference, and it is more likely that they have fallen victim to the 'experimenter expectancy' effect.
>
> Along comes another - he may be unsure, but it's two against one now, so he may well bow to the pressure and *think*that he too hears a difference (this is called self-delusion, and is far more common that most people realise). Anyone who comes along after that either goes with the flow, or admits he has 'tin ears' and is ostracised from the new clique.
>
> Advance a few years, and this vague belief has become the truth!

Those who refuse to believe this (new) truth are naysayers, have tin ears and are deluded! **Of course** they are! The truth has been laid before them, and they refuse to see it. They are blind to the truth, and insist on trying to explain away the magic with mere science! By now, the clique has grown to cult status, it brandishes its truth as fact, and the heretics who refuse to believe are ostracised, categorised, criticised, and put aside - until they come to their senses. This is identical to the old tale of "The Emperor's New Clothes" [5], where everyone claimed to behold fine garments that never existed.

Does any of this sound familiar?

---

6. - Definition of Proof

Despite the reservations some may have, proof is not difficult to explain. Simply stated ...

> Proof may be defined as an experiment or test result whose outcome is demonstrably different from that predicted by random variations as may be found in similar devices or processes (i.e. the results must be statistically significant). To be valid, the experiment or test procedure mustbe repeatable, using equipment that need not be identical but has similar specifications, is not modified in any way that will produce the outcome independently of the characteristics of the device under test, and does not rely on guesswork in any form.

From Dictionary.com [6] we get the following ...

1. The evidence or argument that compels the mind to accept an assertion as true.
2. a The validation of a proposition by application of specified rules, as of induction or deduction, to assumptions, axioms, and sequentially derived conclusions.
   b. A statement or argument used in such a validation.
3. a. Convincing or persuasive demonstration: (*was asked for proof of his identity; an employment history that was proof of her dependability*.)
   b. The state of being convinced or persuaded by consideration of evidence.
4 Determination of the quality of something by testing; trial: put one's beliefs to the proof.
5 Law. The result or effect of evidence; the establishment or denial of a fact by evidence.

In other words, if anyone takes a measurement that shows a particular behaviour (positive or negative) with a particular component, then anyone else with similar equipment should be able to duplicate the results. Proof of any behavioural characteristic does not imply anything else. For example, if I were to prove that certain component leads were magnetic, then that (and *only* that) is relevant. If I then postulate that this degrades the sound quality, there is no proof of this, merely speculation or guesswork based on the original finding. It is necessary to then *prove* that there is a degradation, and if I cannot (or will not) do so then my postulation remains an opinion only - it is not a fact, it has not been proven, and may or may not be true.

Most people who attempt any form of proof will make mistakes. They may overlook something, or be unaware of a characteristic of one or more of the components. Their

proof will be flawed, and will almost certainly be challenged.

Those who take a scientific approach will (usually) re-examine the new data, and may decide that it is irrelevant or important. If the latter, they will usually look more closely at the claim and their proof, and often find that they were indeed wrong. They may well be miffed (I have been on several occasions), but will generally publish a correction once the new data is correlated and the experimental processes are repeatable.

By contrast, there are those who rely on postulation (or proclamation) alone, and do not even attempt to prove their claims. Given the lack of evidence the claims must therefore be viewed with suspicion, since without any offered proof, there are no facts to work with. Emotive comments, unsubstantiated 'evidence', and hearsay don't amount to a hill of beans in the real world, and any complaint that modern equipment is not sensitive enough to measure the difference is simply bollocks.

"I heard a difference" is not evidence, merely a claim or hearsay, unless the test was performed using a properly conducted Double-Blind Test methodology, with a statistically significant outcome. The majority of magic component vendors and proponents eschew the DBT, and will use all manner of (usually ridiculous) arguments to support their position, such as "the DBT equipment degrades the sound so much that the test is meaningless" or "DB Testing is too stressful, so you never get the correct result". This is simply rubbish, and should be seen in every case as a priori evidence that the claims made are grossly exaggerated or simply balderdash.

A proposition is knowable 'a priori' if it is knowable independently of experience [7]

In some cases, it is entirely possible that a test methodology really does not exist to prove or disprove the claim, but the proponents of magic components will never, *ever* attempt to devise a method to prove that what they say is true, for to do so would almost certainly amount to shooting themselves in the foot. They know that they are talking through their hats much of the time, but they certainly don't want you to know that - especially if they want you to buy their product.

In some cases, the vendor may genuinely believe that his magic component works. He may be passionate about it to the point of being fanatical, and have such faith in the benefits that he is blind to all reason. He *cannot* accept any proof that the device simply doesn't work. The only 'proof' needed is letters of commendation (no, not condemnation) from users or reviewers, but there will be no technical information, no graphs or charts showing the before and after effects. No test equipment will ever be brought to bear, for this may shake the faith when it is demonstrated that no change can be found. It is

important to understand that this is still technically fraud, regardless of the beliefs of the vendor. A device must actually perform the described functions, and this should be based on evidence, not hearsay.

---

7. - Conclusion

So, to summarise the general philosophy of The Audio Pages and myself, I can safely state that ...

- I do *not* believe in magic components, fantastic 'capabilities' of certain interconnects, speaker or mains cables, magic lacquers, overunity or perpetual motion machines, or other amazing claims that are made regularly on the Web.
- If a component makes an audible difference, then I believe that it will be possible to measure the difference between the standard and improved component. It is unlikely (IMO) that any non-measurable differences are audible, but it is possible that a measurement technique may not have been thought of to quantify some subjective differences. This is an area that I am looking at closely in a number of areas (mainly loudspeakers).
- There is considerable evidence that a great many measurable differences in components exist that are not audible, but virtually nothing to support the opposing viewpoint.
- It is highly unlikely that there is a flaw in current science or thinking that prevents PMMs or 'magic components' from working. Note that it is the flaw in *thinking* that causes the problem - not the 'undiscovered mechanism', which is presumably somehow obscured by current thinking, thus preventing its discovery by the many followers of such theories. Hmmm. I'm not sure that **I** even follow that one
- The opinions expressed on these pages are primarily my own, and although some articles have been contributed, the content is substantially in agreement with my own ideas and beliefs.
- Contrary to what some people may claim, I do not automatically denounce the theories of others when they do not agree with my own. Indeed, there have been cases where I set out to prove that something made no difference, only to find that it is important, and does have audible consequences (time alignment, for example).
- As a matter of course, I keep an open mind on a great deal of material, and just

because I cannot disprove it does not make it 'wrong'. There are, however, some claims that are just too outrageous or stupid to even consider, and it is no more being 'closed minded' to scoff at such claims than it is to scoff at the Flat-Earth Society's beliefs.

There are a great many things that I don't know, and as I grow older and (hopefully) wiser, I realise that the more I know, the more there remains to know - this will no doubt continue until the day I die. The primary aim of the ESP site is to educate and enlighten - and I have had so many e-mails of thanks that I can only conclude that a lot of people have found benefit and knowledge from the articles and projects.

This was always my aim, and it is hoped that the majority of readers will appreciate and welcome the information presented. For those who think that the site is biased and does not fit with their beliefs, then I can only suggest that you go elsewhere - I will no more change my beliefs than you will yours. Argument is futile, wastes a great deal of time, and rarely if ever achieves anything worthwhile.

Just because you disagree with one or more of the things said on the site does not mean that nothing is valid. All are welcome to browse, and to join and participate in the ESP Forum (whilst abiding by the rules). The greater the participation, the greater benefit to all who visit - this is not a place for 'I win, you lose' arguments - it is intended to be a place where everyone can win.

It must be remembered at all times that *any claim that seems too good to be true, almost certainly is!* There is no appeal against the laws of physics, and any claim to the contrary is false, and should be an instant warning that something is seriously wrong. While it is more than possible that there are still things that have not been discovered, they are unlikely to be of such massive importance that our listening habits will be forever changed - i.e. they will be evolutionary rather than revolutionary. Any such discoveries are far more likely to be made by well equipped laboratories than backyard tinkerers or 'magic component' suppliers.

The Audiophile Webring

Join this Ring

Instructions

- **Step 1**
  Fill Out Ring Application
- **Step 2**
  Review & Submit Application

New to WebRing?
Read important information about what joining a WebRing Ring means here.

Step 1: Fill Out Ring Application

Enter the website address, title and description of the site you would like to add to this Ring and click **Next**. You should click on the **Help** link above to review what joining a Ring involves.
Not sure about "navigation code"? Click here for more information.

Enter Your Site Address (URL)

http://

Note: If accepted, you must place the Ring's navigation bar on this website.

Title Your Site (50 characters or less)

Describe Your Site (400 characters or less)

We need some additional information to make it easier for you to manage your WebRing site information. You appear to be **new to WebRing**, or you are not logged in.

If you're an existing member, Log In now (Remember, you only need **one** User ID even if you want to join more than one Ring).

Don't have a WebRing User ID yet? - No problem, signing up for your User ID is fast, easy and **FREE**. We collect almost no personal information, the User ID is to help you manage your WebRing sites easily and securely. You only need to do this once, and then you can join as many Rings as you'd like using the same User ID. Then when you want to manage anything to do with any site you'll have them all in one convenient location! And don't worry about security, all the information

you enter below will be kept confidential by WebRing and **not** passed on to the Ring's manager (except the User ID of course, so they can communicate with you!).

Required fields:

WebRing USER ID:		Choose an ID using letters, digits or underscores '_' only (32 maximum).
Password:		Choose a password that is hard to guess. Capitalization matters!
Password (repeat):		Now type it again so we can verify it.
Email:	1	Enter the email address where WebRing **correspondence** should be sent. PLEASE ensure your email address is valid. We do **not** share your address with any individuals and we do **not** share your email address with third party companies, and we **only** use your email for WebRing operations.
Retype email:		
Birthday:	[select one] ,	Enter your birth date.

Optional fields:

If you forget your password, we can use the security question you enter below to verify your identity.

Question: Enter a simple question that others cannot answer easily.

Answer: Enter an answer that you can remember ***easily***.

Website host?: ☐ Would you like to learn more about letting SimpleNet host your website? Check here and we'll have them contact you.

By submitting your registration information, you indicate that you agree to the Terms of Service and have read and understand the Privacy Policy. Your submission of this form will constitute your consent to the collection and use of this information by WebRing and its affiliates.
