1.0 - Introduction

A class of electronic crossover is variously described as a 'derived' or 'subtractive' filter is hailed by some users as the ideal. They have (apparently) perfect transient response, in that the summed output is not only flat, but a squarewave is also passed intact. This implies that they are the Holy Grail of electronic crossover networks. Almost by definition, no other crossover network should even be considered.

So, are they any good? Why aren't they used everywhere?

These questions are best answered by a full examination of the network, so that all the facts are available.

2.0 - Basic Subtractive Crossover

The general idea of the subtractive crossover is quite simple. If we have a filter, and subtract the filtered signal from the input, the result is a filter with the opposite effect (i.e. a low pass filter is 'derived' from a high pass filter and vice versa). Because of the subtraction process, the result must be perfectly in phase, and the sum must (by definition) be flat response.

There have been many variations on the general theme, some of which are claimed to provide better performance than others. Subtractive filters have been discussed in Elektor magazine [1] and some I have seen are quite complex. While the added complexities may suit a particular arrangement of specific loudspeakers, they generally don't add anything that changes the overall performance.

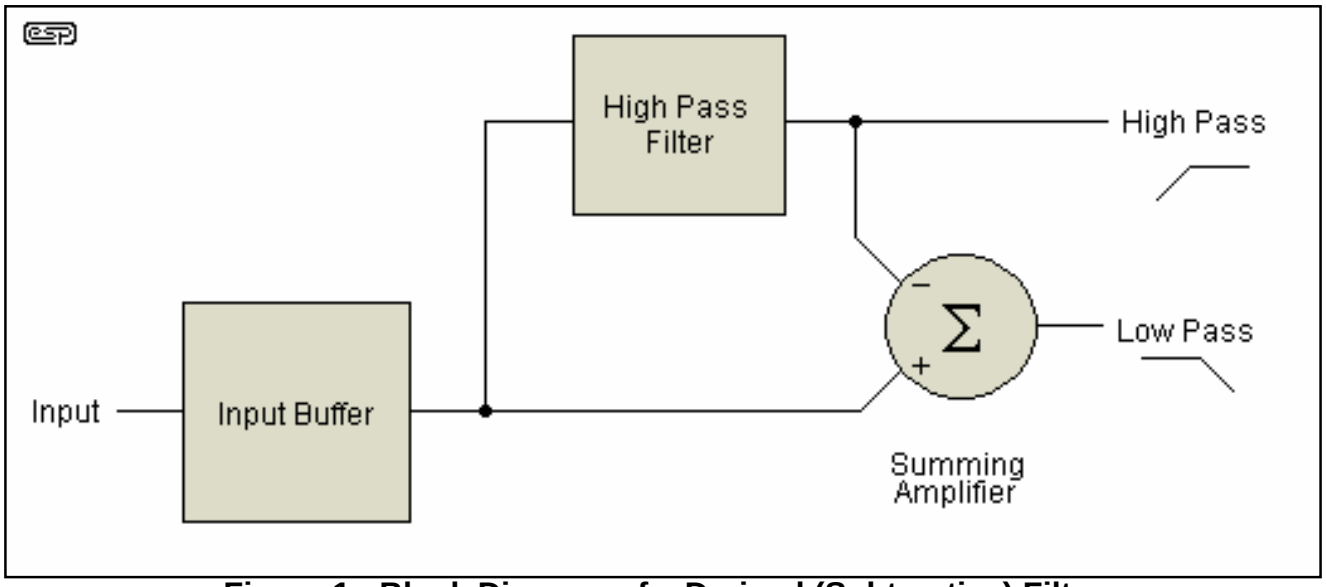

Figure 1 - Block Diagram of a Derived (Subtractive) Filter

While all circuits shown in this article are configured as shown in Figure 1, the filter itself can be a low pass section. No other changes are needed, but this connection may give rise to performance limitations that at the very least must be classified as undesirable (see below for more information).

In the circuit diagrams below, all buffers are unity gain, and all circuits are driven from a low impedance (voltage) source. This is a requirement for all filters, so the input buffer is not shown for clarity. The voltage source shown is an ideal voltage source - zero ohms output impedance.

Likewise, for clarity, the power supplies are not shown. All the results below are from the SIMetrix simulator, and while somewhat idealised, are representative of reality with any reasonable opamp in a real world circuit - especially within the audio band.

Within this article and for the simulations used to get the graphs shown, the same values were used for filter tuning, regardless of the filter order. While this does change the crossover frequency, as you will see it is actually of little consequence.

2.1 - First Order Filters

While there is little point looking at a first order (6dB/octave) network, it *is* the simplest to examine, and this will make it easier to follow the more complex filters. A first order crossover is already 'phase perfect', so making a subtractive version should give an identical result.

As shown below, this is the case. The only advantage of the subtractive method is that only one reactive element (the capacitor) is used, and this is highly debatable as an 'advantage'. This is especially true with the increase of overall complexity of the circuit.

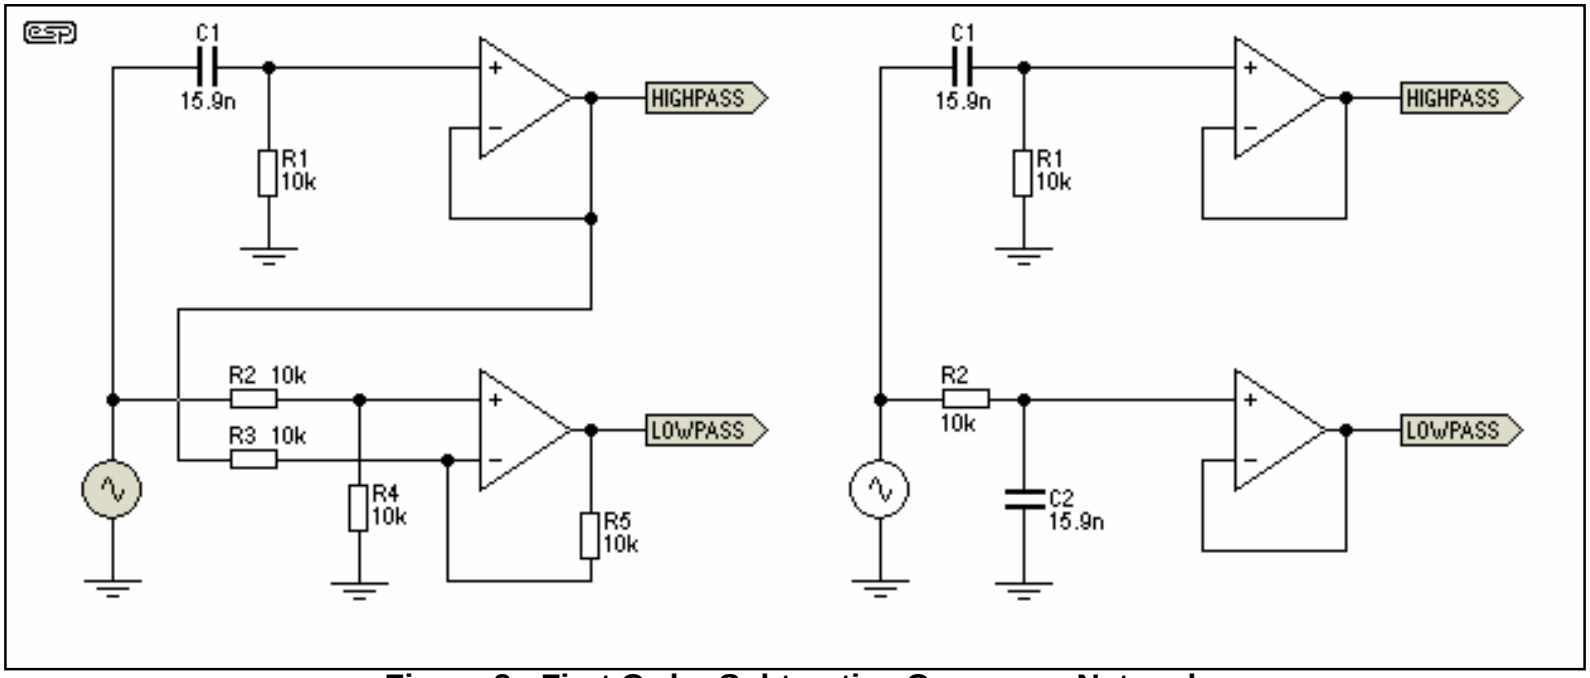

Figure 2 - First Order Subtractive Crossover Network

Figure 2 shows the schematic of the subtractive filter, and for comparative purposes, a conventional filter is also shown. A conventional high pass first order filter is used, although a low pass filter can also be used and gives identical overall results. The subtraction circuit is simply a common balanced amplifier, which only amplifies the difference between its two inputs. The frequency and phase responses are shown below, and they are identical to a 'normal' 6dB filter response. The summed output is flat, having no peaks or dips at the crossover frequency. Since a straight line is hardly inspiring to look at, this has not been included for this or any of the graphs that follow.

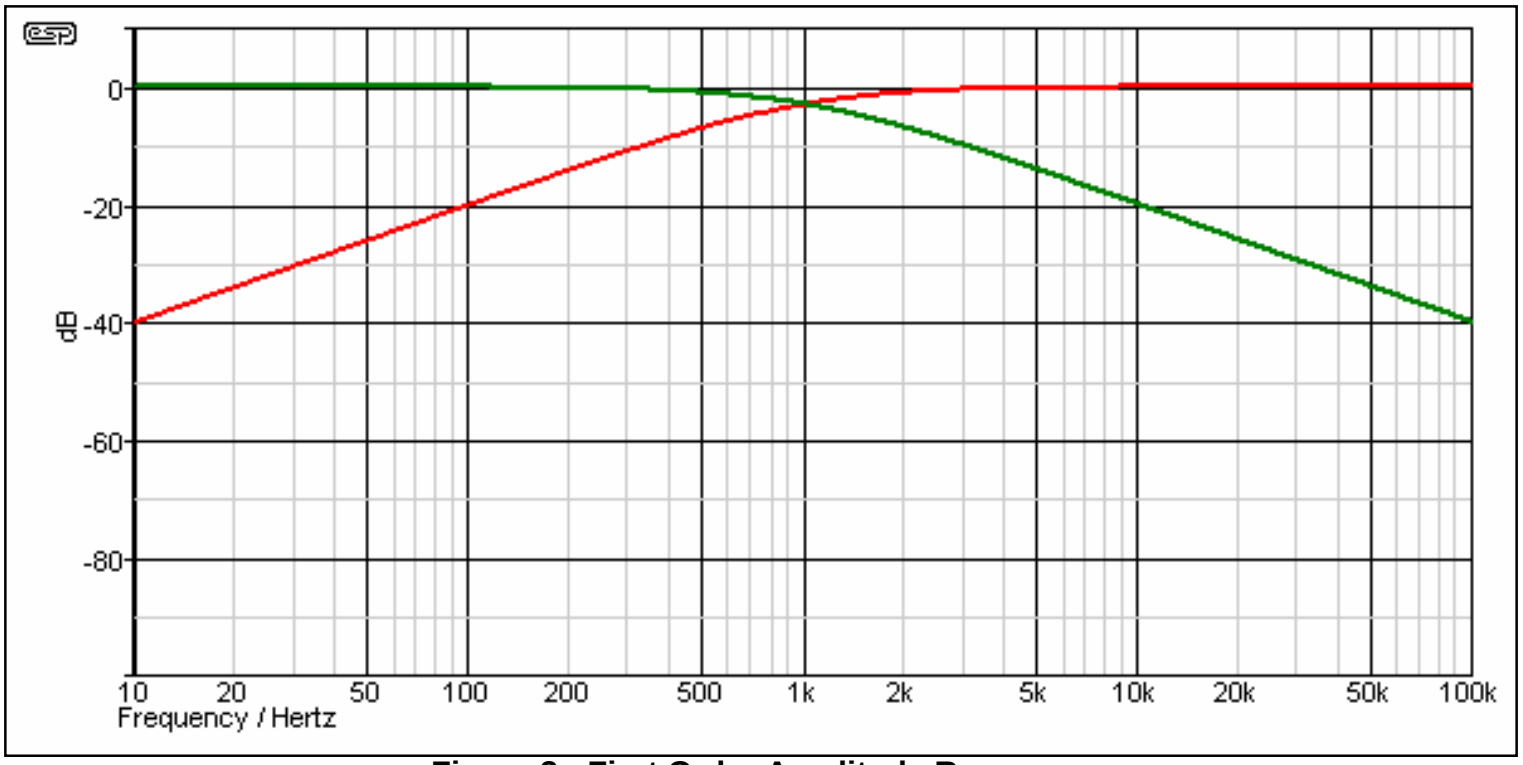

Figure 3 - First Order Amplitude Response

The amplitude response is as one would expect, and requires little or no further comment. As stated above, this is identical to a conventional first order filter response.

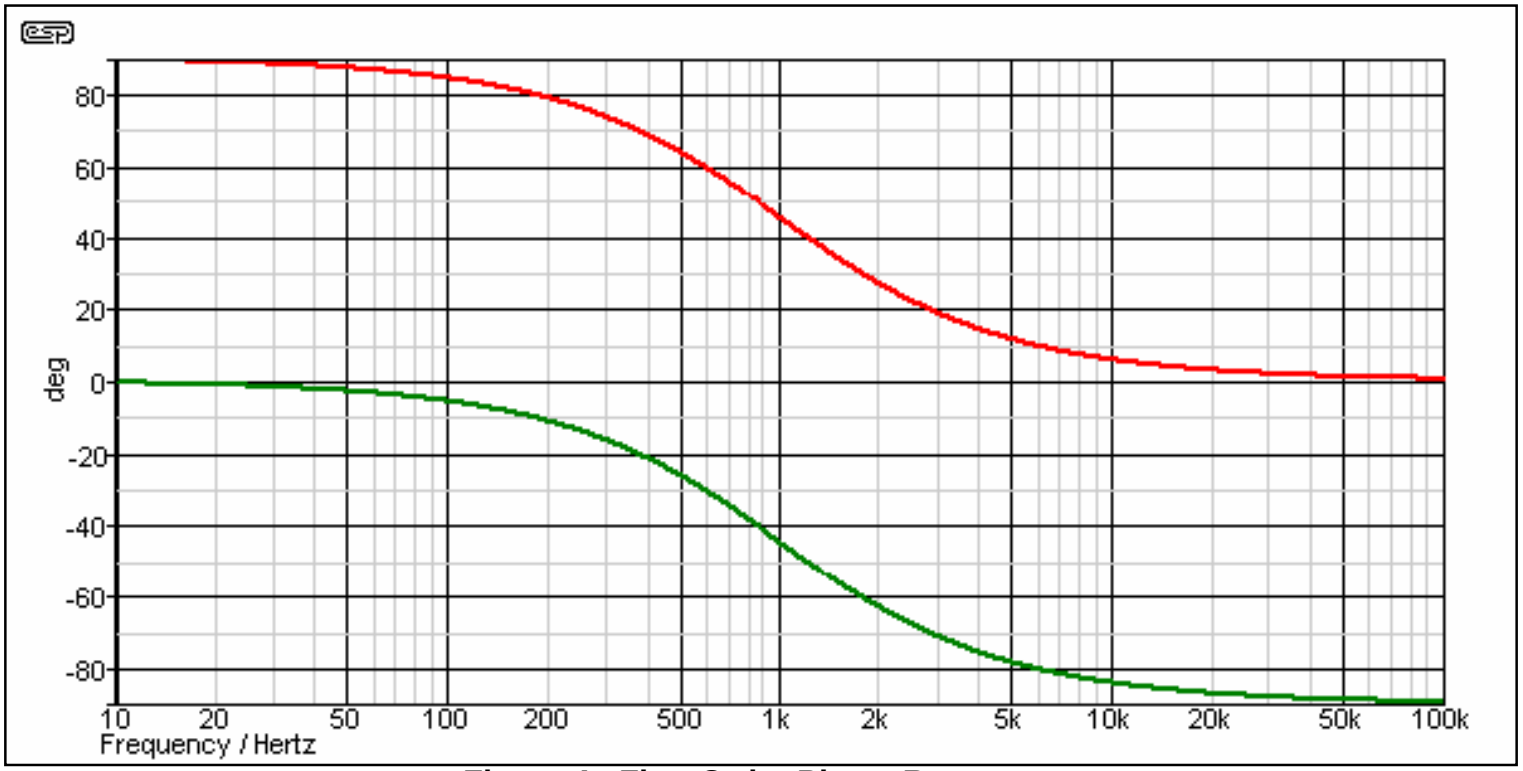

Figure 4 - First Order Phase Response

Phase response again shows the normal behaviour for a first order filter. In all cases in this article, the red curve is for the high pass filter, and the green curve is the low pass. As noted

earlier, there is no point using the subtractive method for a 6dB/octave crossover - the above is by way of example only.

2.2 - Second Order Filters

When we look at second and higher orders, we start to see real difference between the subtractive filter and other more conventional crossover networks. Figure 5 shows the schematic, and it must be admitted that it is a little simpler than a standard Linkwitz Riley filter (for example). While the difference in complexity is not great, the summed response is better, and unlike nearly all filter networks above first order, it is not only phase coherent, but the summed signal reproduces a perfect squarewave.

It is at this point that some people get excited - any filter that can pass a squarewave *must* be better than one that cannot, and in truth, virtually no conventional filter above first order can reconstruct a squarewave. The subtractive versions therefore must be better.

As we will see later on, this is not necessarily true, and the ability to reproduce a true squarewave is vastly overrated. Apart from anything else, we rarely listen to any audio signal that even approaches a squarewave, but there are other relevant factors that will wait until the conclusion of this article.

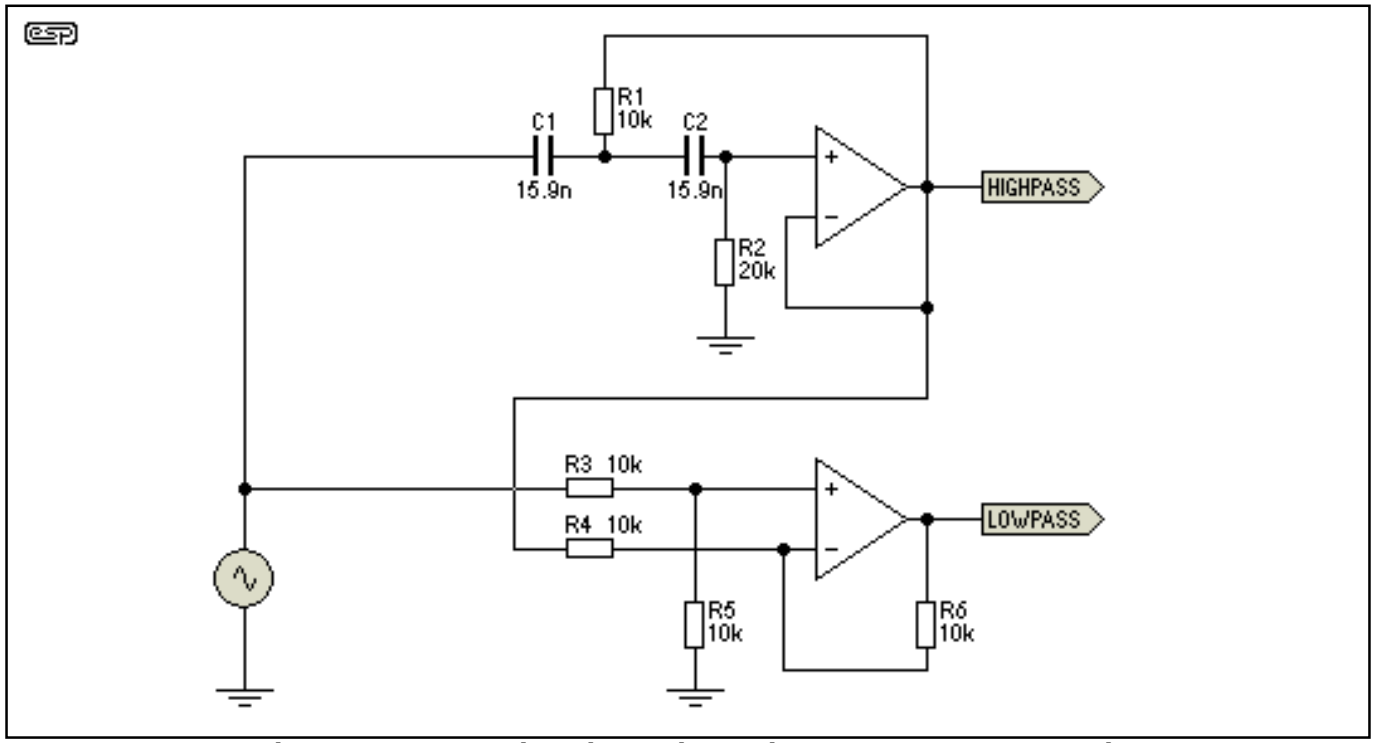

Figure 5 - Second Order Subtractive Crossover Network

Above, we see the schematic for a second order (12dB/octave) derived crossover. A single second order Butterworth highpass section is used, with the difference amplifier subtracting

the filter's response from the input signal. One would think that by doing this, the derived filter would match the rolloff characteristics of the filter, but this is thwarted by phase shift. It is phase shift that causes the derived rolloff slope to remain at 6dB/octave, and although it is possible to include a phase shift network to equalise the slopes, this will no longer allow the filter to recreate a squarewave, and it will behave the same as any other filter network.

In fact, various magazines (Elektor being one that I know of - thanks to a reader) have published projects that use a combination of a standard subtractive crossover with a phase shift (all pass) network. This does equalise the rolloff slopes, but the network behaves in the same way as a conventional crossover network.

The 'saving' is two capacitors, but you need more resistors and one additional opamp (not much of a saving). The circuit complexity is greater than a conventional filter because the repetition is replaced by a relatively complex phase shift network plus a summing amp. This makes it more likely that a mistake will be made while wiring the circuit. IMO there is absolutely no benefit, and it is far easier to build a conventional Sallen-Key based filter network such as that shown in Project 09.

Unless there is significant demand, no further details will be provided for this design. It is interesting from an acedemic perspective, but contributes very little in real terms.

Look carefully at the graph below ... as explained above, while the high pass section certainly rolls off at 12dB/octave, the derived low pass section is indeed only 6dB/octave. This is one of the greatest disadvantages of the subtractive crossover. The derived filter is *always* 6dB/octave, regardless of the rolloff slope of the filter itself. (However, see note above.)

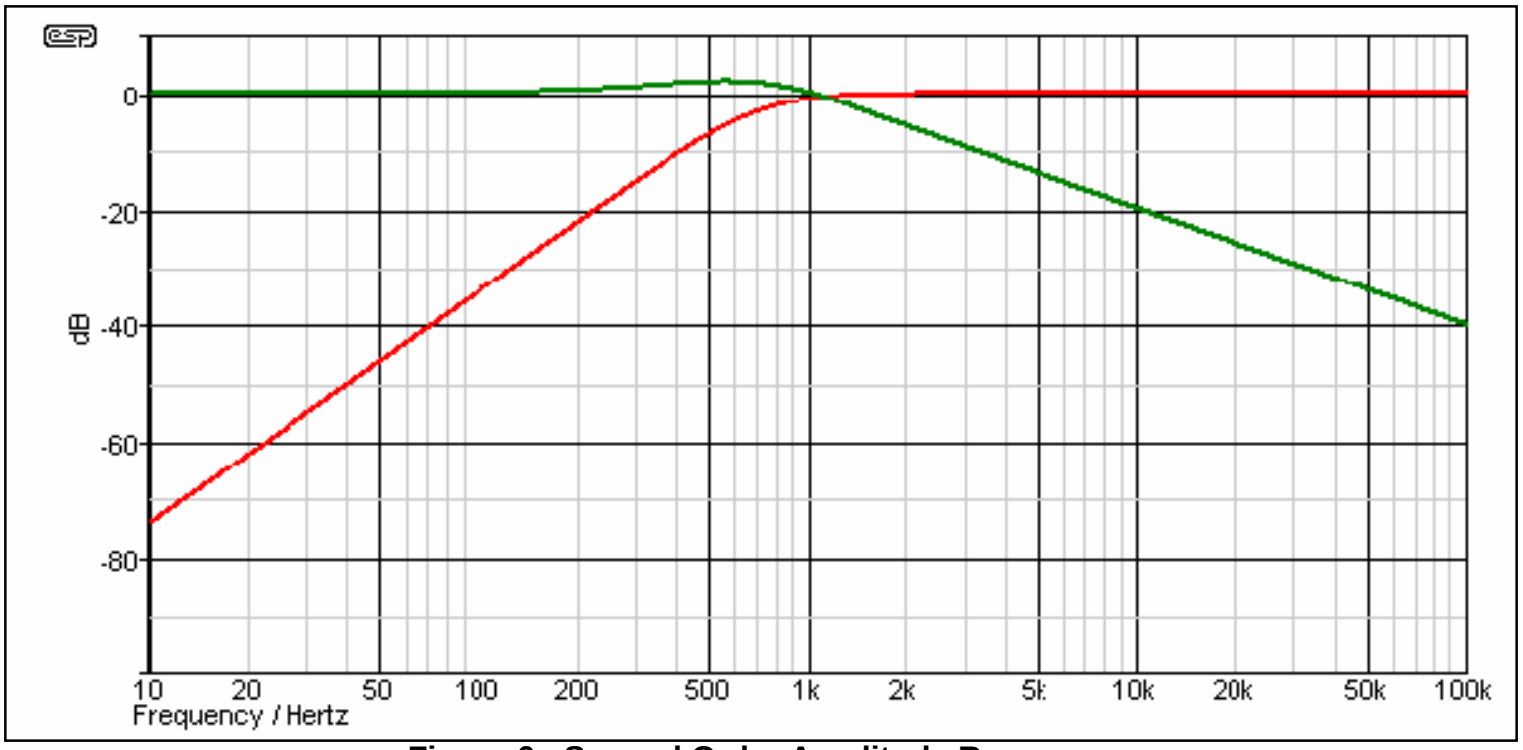

Figure 6 - Second Order Amplitude Response

Potentially of some concern is the peak in the low pass response, just before it starts to roll off. This can be reduced by reducing the Q of the filter. While it is not serious, the expectation is that the tweeter will have sufficient output at this frequency to cancel the acoustic peak, thus restoring flat response. As discussed in greater detail below, this may be wishful thinking.

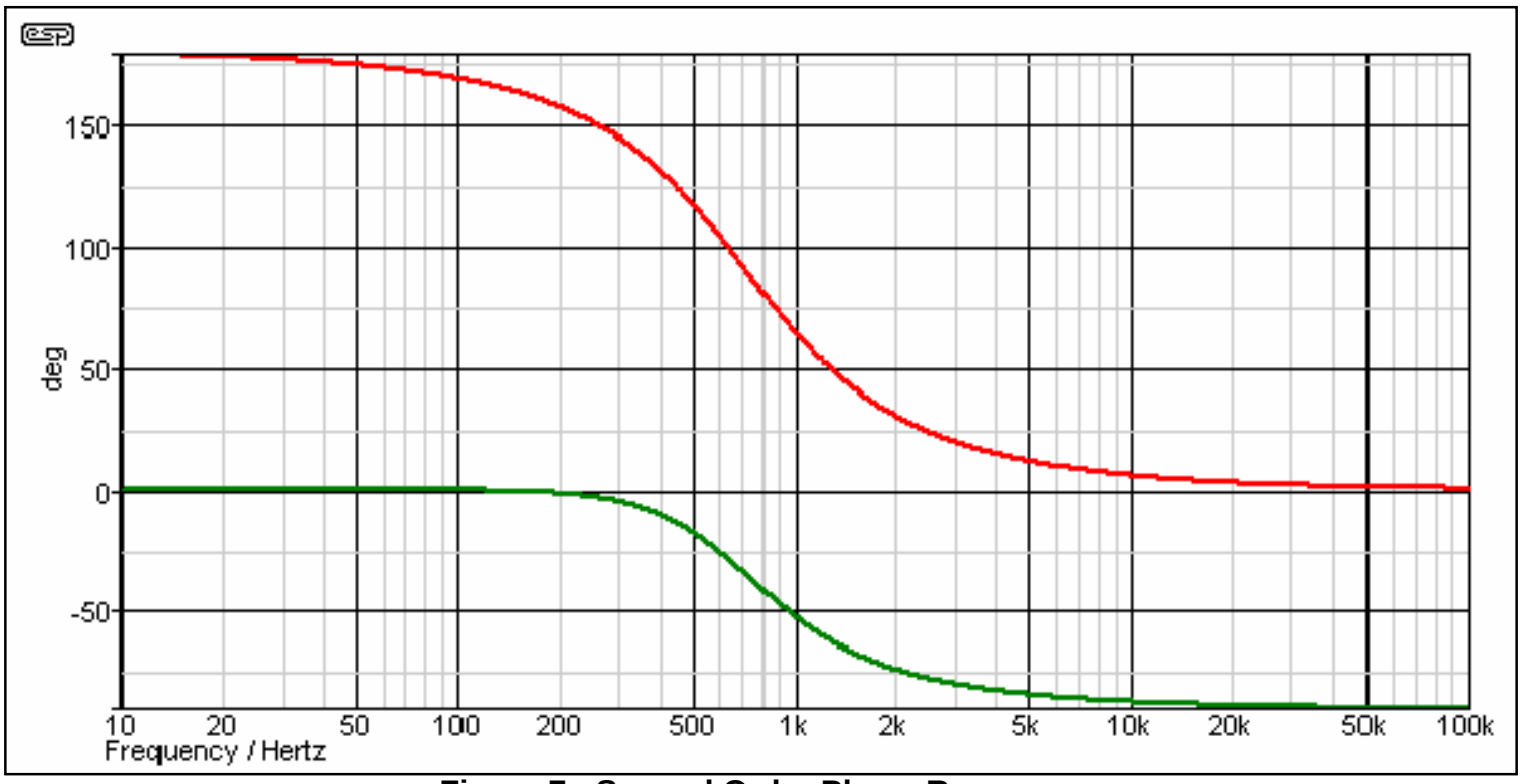

Figure 7 - Second Order Phase Response

The phase response is shown above. It is seemingly impossible that two outputs with such frequency and phase responses could possibly be summed to a flat response, but they do, and this filter (just like the first order network) can pass a perfect squarewave when the outputs are summed. Likewise, the summed response is completely flat, with no peaks or dips.

It is rather unlikely that the acoustic outputs from the drivers will be able to match an electrical summing network, so it is less likely that the acoustic output will be flat. Electrical and acoustic summing are not the same thing, and although electrical summing is an effective way to find out the ideal response of the system, what happens in reality is likely to be altogether different.

2.3 - Fourth Order Filters

Finally, the circuit diagram below shows a derived 24dB/octave (fourth order) network. Where this should offer the best response, in fact it is the worst of the three shown.

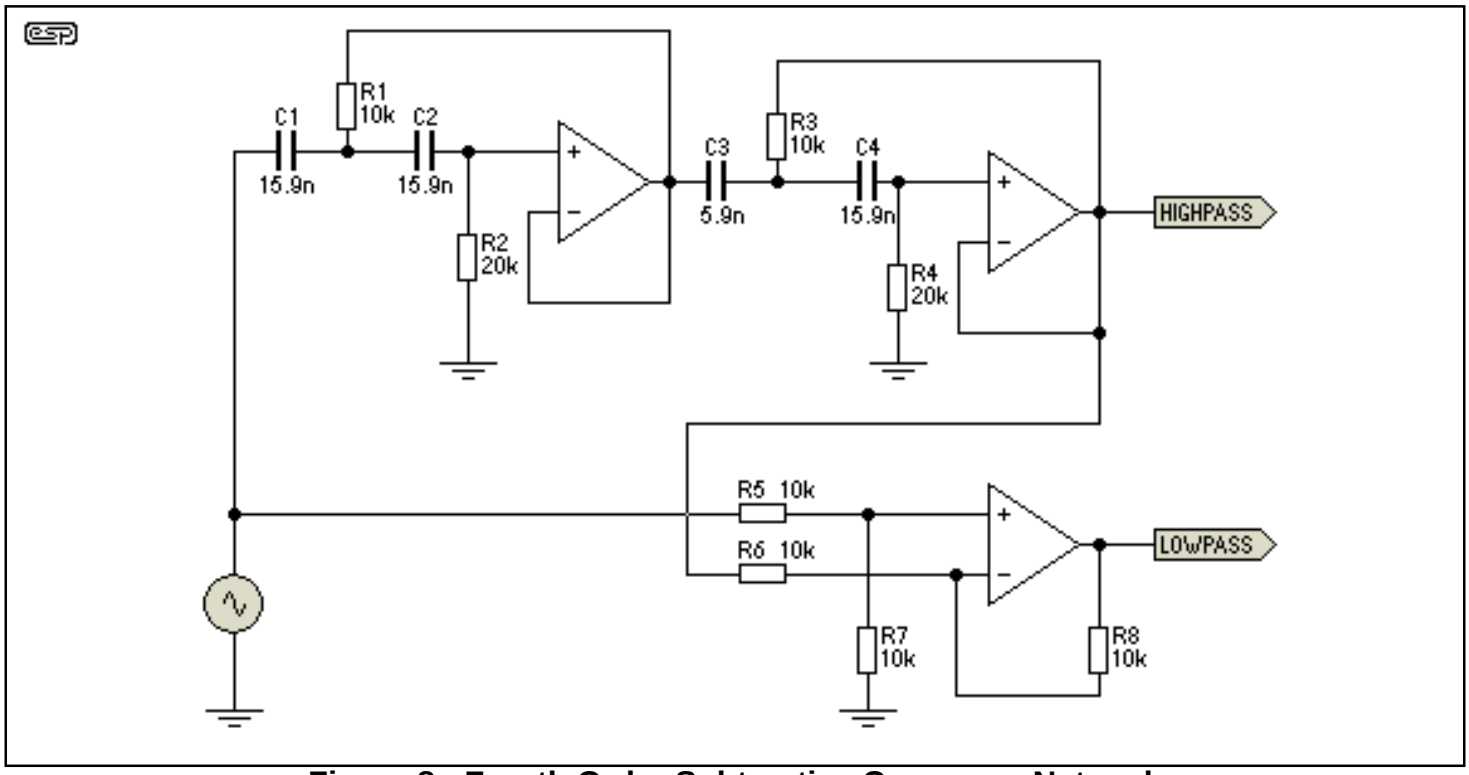

Figure 8 - Fourth Order Subtractive Crossover Network

The amplitude response (below) shows that there is a substantial rise in the response of the low pass section (the derived part of the network). If (and that is a very big ask indeed) the drivers sum as flat as an electrical network, then there isn't much of a problem. It is highly unlikely that the drivers will be able to produce a flat response in reality.

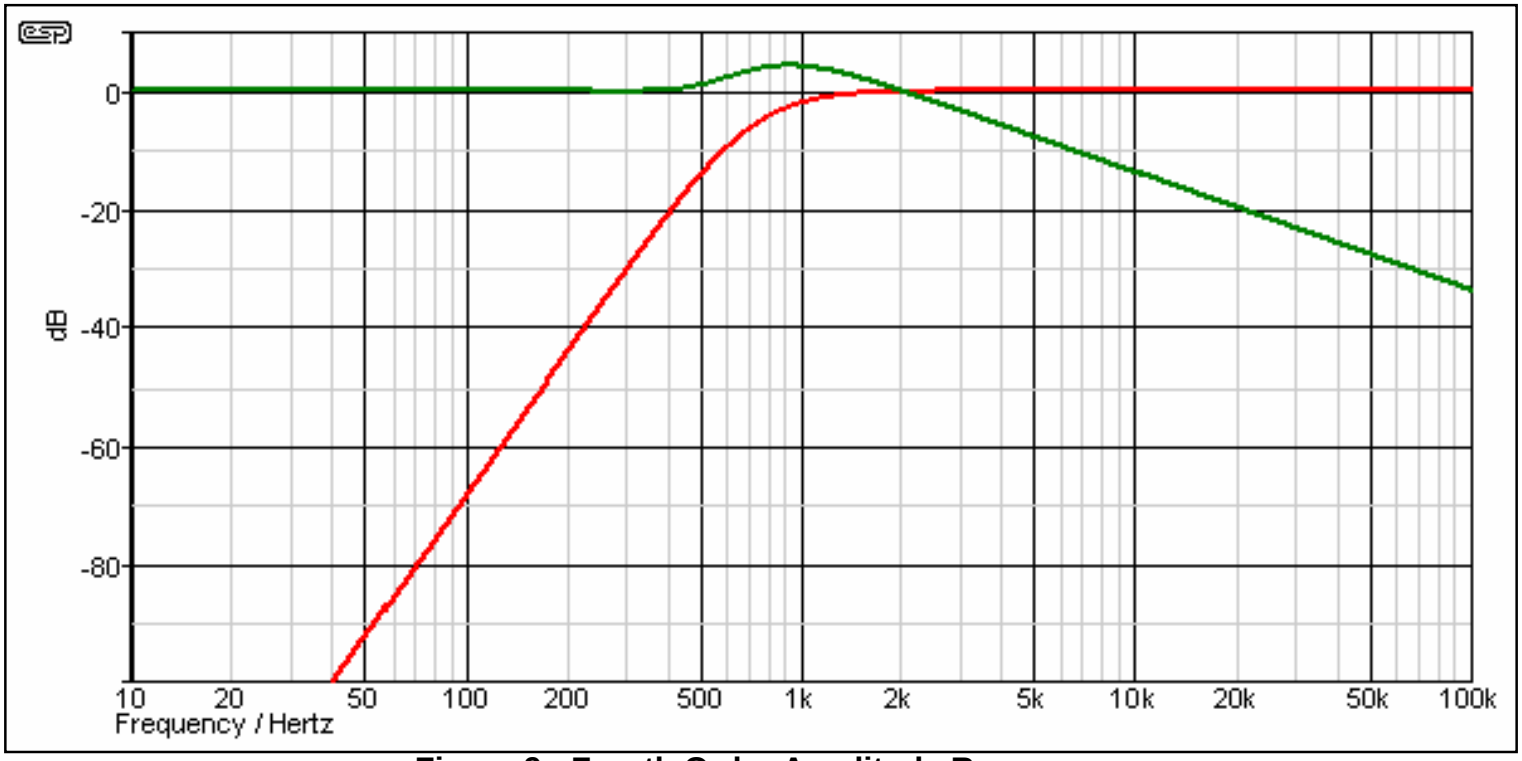

Figure 9 - Fourth Order Amplitude Response

The response peak is about 4dB, and that represents more than double the power applied to the driver over that frequency band. The amount of frequency overlap is (IMO) completely unacceptable, and a system built using this crossover would have to use accurate time alignment. Great care would also be needed to ensure that the polar response of the drivers is very similar over at least 3 octaves across the crossover frequency.

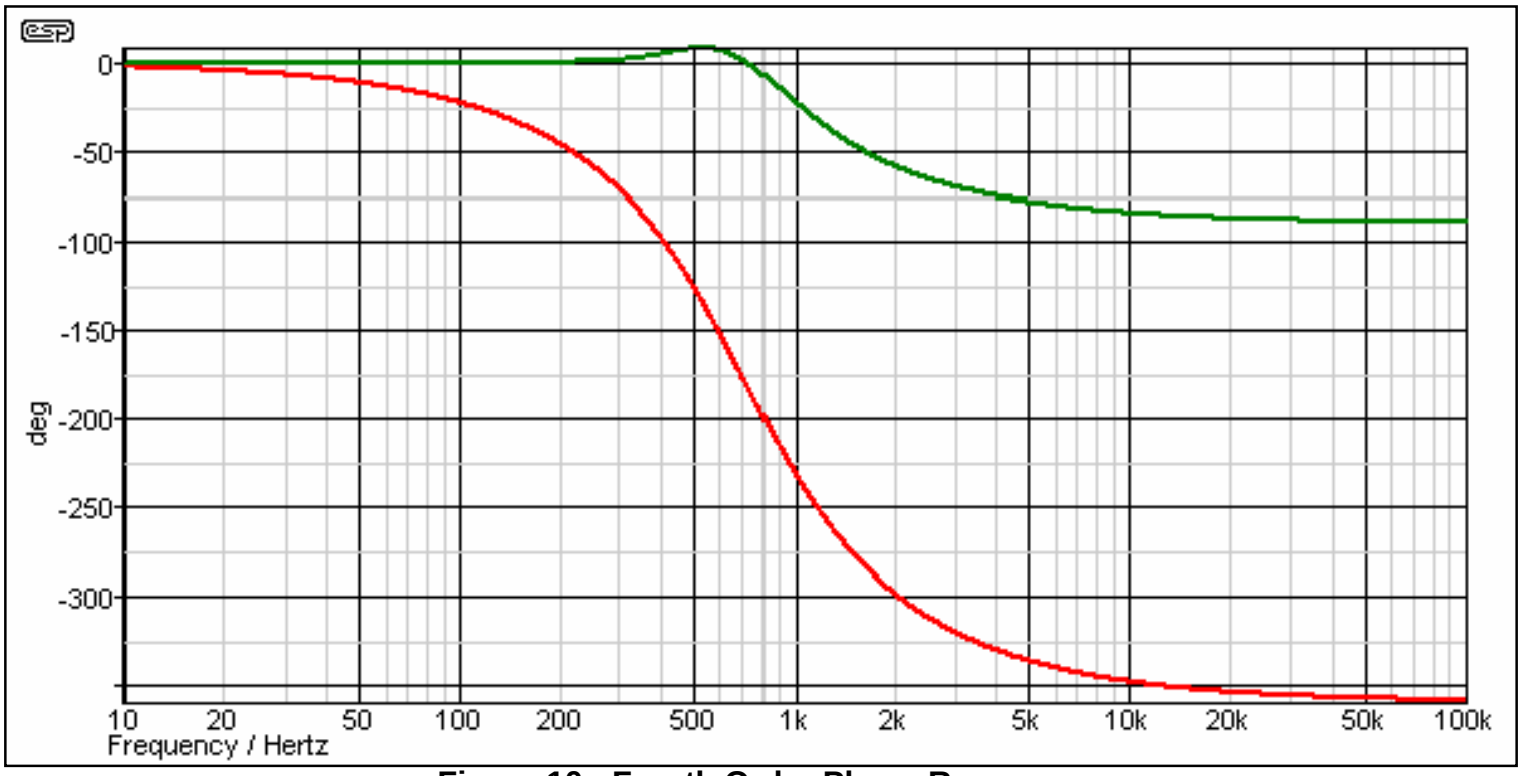

Figure 10 - Fourth Order Phase Response

The phase response also shows a peak, but this is of less consequence than the amplitude peak. In all subtractive filters, they are *not* phase coherent. That is to say that the phase of the signal applied to each driver varies, and the two are not in phase across the crossover region. Unless the phase response of the drivers is very predictable (no phase shift from voicecoil inductance or resonances) the two signals can no longer sum flat - even electrically. Acoustic summing will be worse than electrical summing in all cases.

3.0 - Linkwitz-Riley Filter Comparison

So that everything can be seen in the one article, I have included a schematic of a 24dB/ octave crossover, along with the amplitude and phase response. The first thing you will see is that there is actually little additional complexity. Rather than a complex circuit, it is simply repetitious. This is the simplest of the topologies that will give the desired overall response.

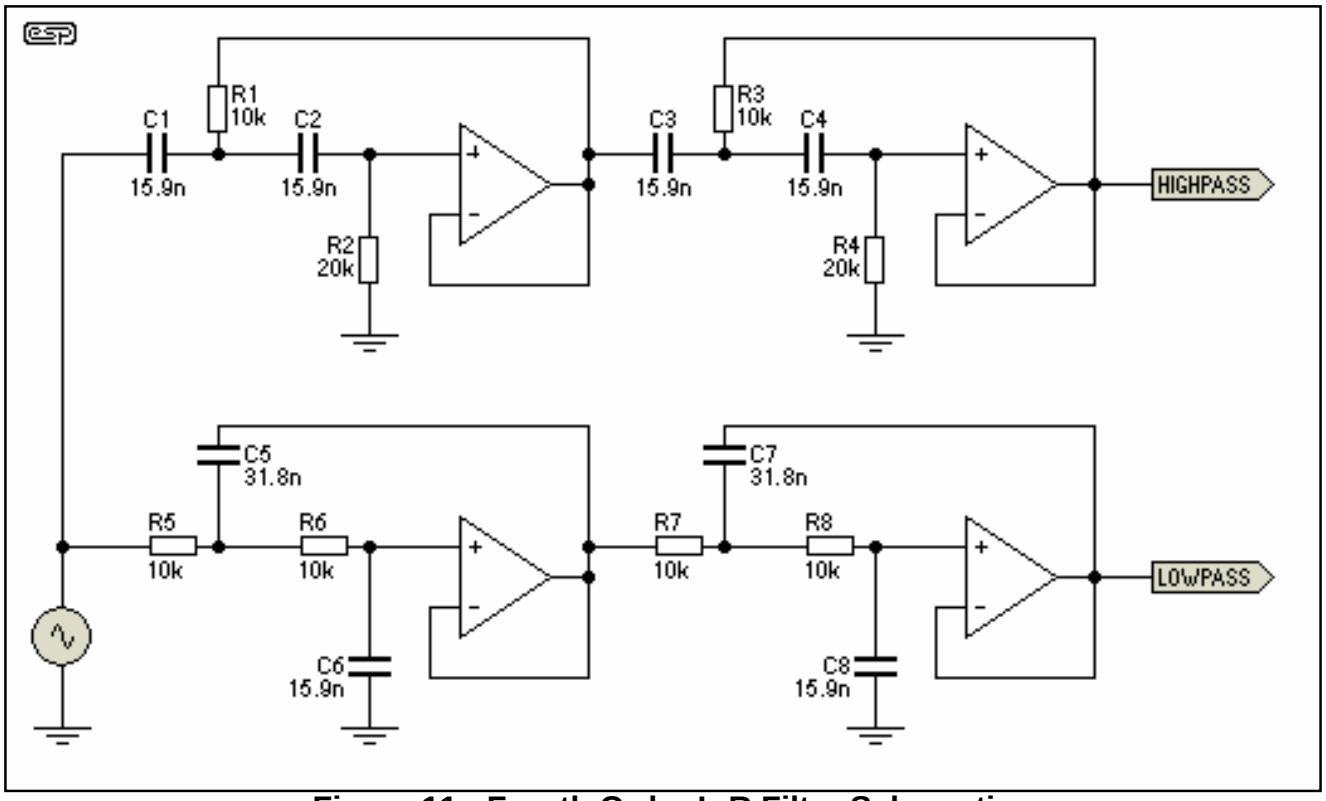

Figure 11 - Fourth Order L-R Filter Schematic

The high pass section is at the top, with the low pass section at the bottom. This is identical to the circuit used in Project 09, which has been a popular project from the time it was first published.

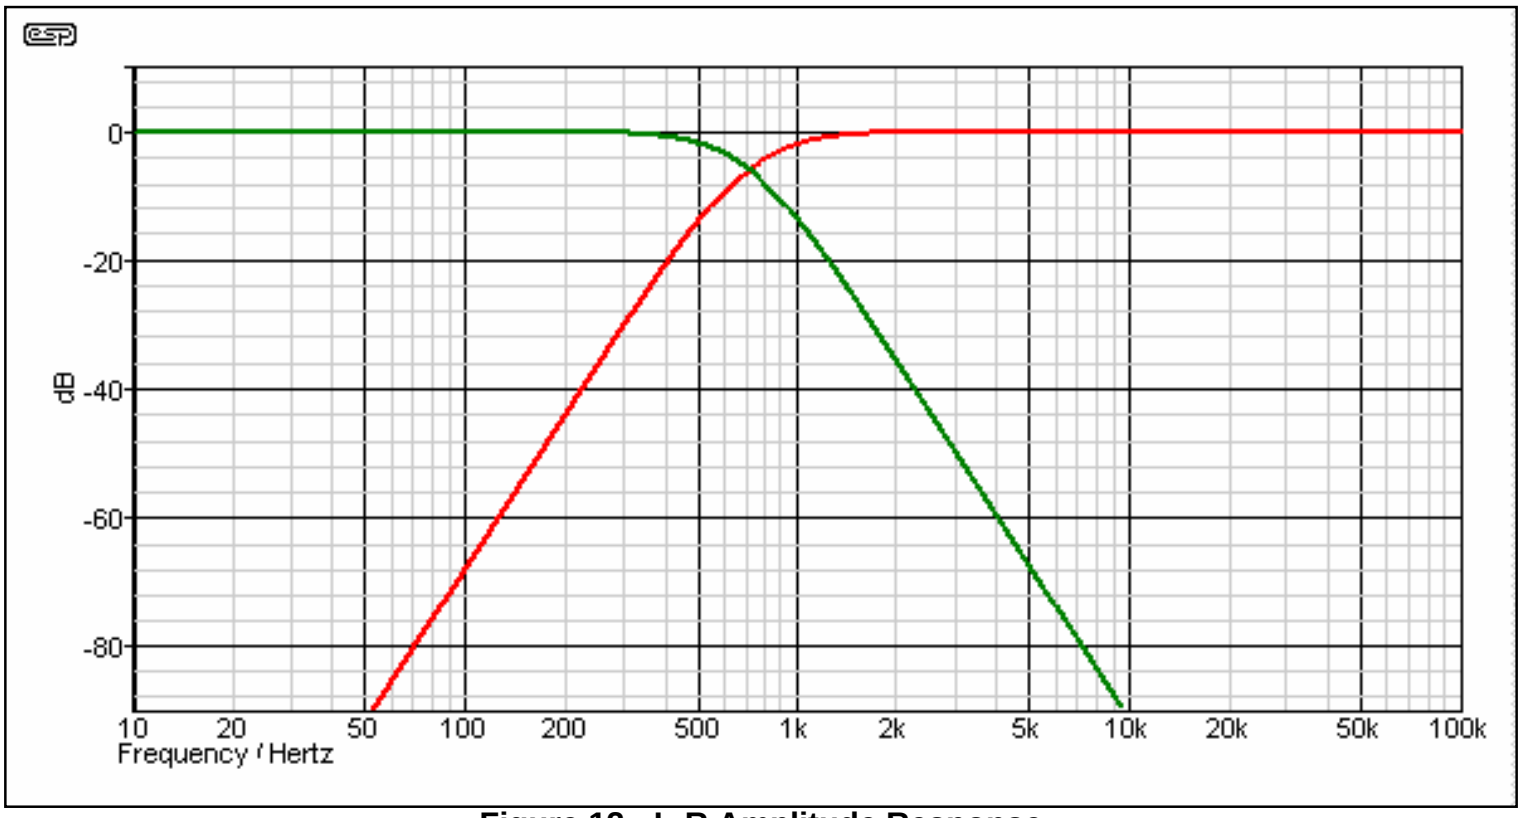

Figure 12 - L-R Amplitude Response

Amplitude response is exactly as we would expect. A nice steep rolloff for both sections, and a clearly defined crossover frequency. Because of the Linkwitz-Riley alignment, the summed output is completely flat (just like the subtractive filters), but without any of the associated problems of excessive overlap. No, it won't pass a squarewave, but the summed output still contains every frequency that made up the original squarewave, and testing by ear reveals that it is not possible to positively identify the squarewave from the modified version. While there is almost always a difference, the nature of the difference has more to do with the loudspeakers than the crossover.

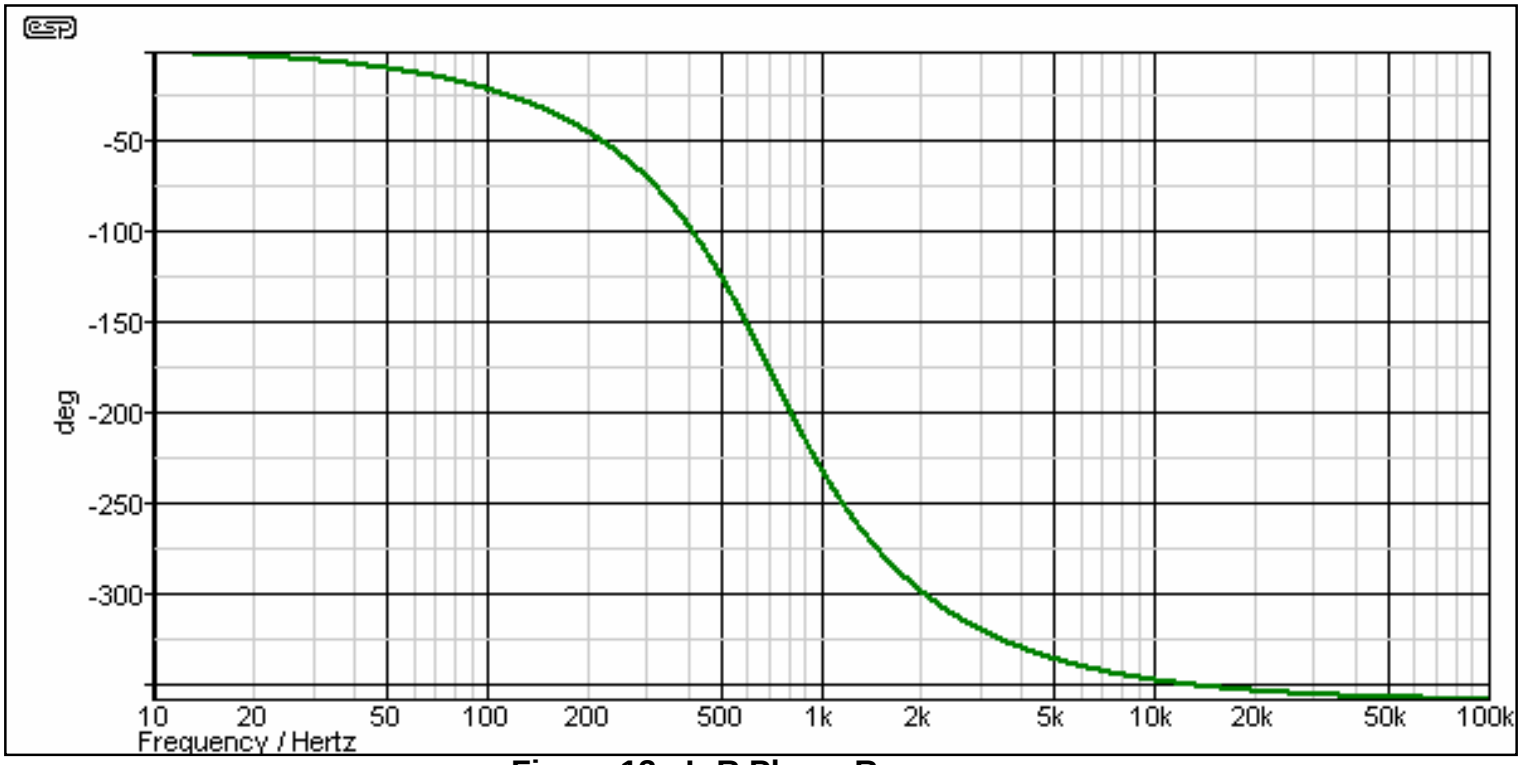

Figure 13 - L-R Phase Response

In case you wondered, no, I didn't leave out the high frequency phase response. It is simply overwritten by the low frequency graph - they are perfectly overlaid. That means that the two drivers remain in phase over the entire frequency range. This filter network relies on proper filtering, rather than hoping that the acoustic outputs of the drivers will complete the job that in reality is only half done by a subtractive filter.

4.0 - Conclusion

The first - and possibly the most important - thing that must be understood is that electrical and acoustical summing are not the same thing. Just because a crossover network sums flat electrically, this does not imply that it must also sum flat acoustically. With subtractive crossovers, the very worst scenario is presented to the drivers, where there is considerable frequency overlap between the adjacent loudspeaker drivers, and unless they have identical polar response over the entire overlap region (and at least an octave either side), the

combined acoustic output will be anything *but* flat. This seems to have been missed by many of the proponents of these filters.

Unlike conventional filters, where the higher the order sections have less overlap than low order, the subtractive networks present the opposite case. The derived section using a 24dB/octave high pass section has the greatest overlap, and we can see from the above that the 6dB network is actually the best in this respect. Let us simply say that this is less than desirable (note careful use of understatement).

The next issue is the derived filter section's rolloff slope - 6dB/octave. All the circuits above derived the low pass section, because that gives the greatest protection for tweeters (and midrange) drivers against excessive excursion. Quite a few published circuits over the years have derived the high pass section, and this places extreme demands on the drivers because of the power delivered below the crossover frequency. In addition, there is the peak at the very frequency where it is least desirable - at the lowest frequency the driver is meant to handle. It gets additional power at that frequency, increasing excursion and hence intermodulation distortion.

Speaking of crossover frequency, it is almost impossible to predict exactly where it is. It is obvious in the first order example, but as the filter order is increased, so too is the overlap region. One might want to use the -3dB frequency of the actual filter as a guide, but that's all it really is - a guide.

So, it should now be obvious that subtractive crossovers are most certainly not the Holy Grail, and in my opinion are virtually useless. Increased overlap at crossover may cause excessive beaming because the drivers are working as a mini-array, poor rolloff slope of the derived filter section can allow cone breakup (or if reversed, will probably cause excessive intermodulation), all because they can reproduce a squarewave. I think not.

The phase shifts caused by conventional crossover networks may seem extreme, but they are generally inaudible. Provided the phase of each driver is controlled and maintained (such as with a Linkwitz-Riley crossover), there are no audible effects. While phase anomalies may be audible if two different speaker systems are operated alongside each other, this is not a problem for home audio systems. The subtractive crossover network still has overall phase shift between drivers, so it doesn't solve that particular problem anyway.

So, if anyone was ever mildly curious, now you know why I have not (and will not) publish a project based on what I consider to be a seriously flawed design.

1.0 - Preamble

In order to save everyone time (including and especially me), I must make a couple of points before anything else is discussed ...

- Had the 'Doppler distortion' effect in loudspeakers been referred to as Phase Modulation Distortion (as I suggest below) from the outset, the vast majority of the arguments denying its existence would never have occurred, since it can be demonstrated by simple reasoning.
- I *know* that the Doppler effect as it is commonly described involves phase shift, and that this is simply a different way of 'looking' at the phenomenon.
- I do not expect you to agree with me - the following is simply my suggestion. It is based on simple logic, describing a well known and real distortion mechanism in loudspeakers, but in a manner that (hopefully) makes a bit more sense than the purely theoretical coverage that most websites present.

Please make sure that you read and understand the above before you decide it is necessary to send me an e-mail pointing out things that I have already acknowledged either above or in the body of the article itself. Should you get the impression that I am sick of e-mails pointing out that the Doppler effect involves a change of phase, or telling me that 'Doppler effect' is the best way to describe the loudspeaker distortion, you are quite correct. I know the phase effect, and need to point out that had the effect been called Phase Modulation Distortion from the

outset, this article (and probably hundreds of others) would never have been written.

To say that this article has stirred up a hornets' nest is putting it mildly. Since the initial article was published, there has been a great deal of correspondence, both for and against what I have written. Many people seem to have missed the point, so to make absolutely sure that it is not missed, I will make it right at the beginning ...

Frequency shift in a loudspeaker is real - it does happen, and the amplitude (frequency deviation) of the shift is *identical* to that predicted by 'conventional' Doppler theory. The peak phase shift occurs at the extremes of the cone movement as one should expect, and indeed, there is zero phase shift at the low frequency zero crossing - the cone's rest position. The rate of change of phase is greatest at the zero crossing point, and this corresponds to the maximum frequency shift.

> In the previous version of this article, I was under the impression that there was no phase variance at the zero crossing point, however, after some correspondence and some further (rather tedious) tests, it can be shown that the peak frequency shift does indeed occur at the point of peak cone velocity - this is not readily apparent on the waveforms shown below, because the resolution required is so great that it could not be achieved using my oscilloscope. As it transpires (and in hindsight - always an exact science), this makes sense, since the peak rate of change of phase (and therefore frequency) *must* occur during the transition from one phase angle to another. My apologies to anyone who may have been mislead.

The Doppler effect is generally applied to moving vehicles (etc.) and the most common explanation is that the wavefront is 'compressed' as the object approaches the listener, and 'stretched' as it heads away. Another way to look at this is that the *phase* of the signal is constantly changing, resulting in the familiar frequency shift. The main point here is that the effect lasts for some relatively considerable period of time, and the observed frequency shift is directly related to the velocity of the approaching (or receding) sound source.

Consider a sound source approaching at 30m/s (108km/h). The sound source is generating a frequency of 1kHz, so as it approaches, the listener will hear not 1kHz, but about 1095Hz - a clearly audible change. As the sound source recedes, the perceived frequency will be 912Hz - again, readily audible (see [Ref 4] for the calculator that I used). As each successive compression or rarefaction of the wavefront reaches the listener, the phase is effectively advanced (or retarded) by approximately 108us or 39°, thus creating 'new' frequencies that are proportional to velocity and the original frequency. I shall leave it to the reader to analyse this further if desired, but suffice to say that this phenomenon has been known for a very long time.

While the principle is well known, the 'phase method' of describing it is not - it is far more common to see the explanation deal with the compressed or expanded wavefront (and wavelength). There is no anomaly here - both descriptions are equally valid, and explain exactly the same phenomenon.

Based on the measurements shown below, it is obvious that the conventionally explained Doppler effect does not occur with a loudspeaker - the periods where the cone is moving towards or away from the listener are too short, and the cone is not moving *through* the medium (air). It could also be stated that it is not the *cone* that is making the sound, but rather the *movement* of the cone. Several correspondents have complained that what amounts to 'movement of the movement' of the cone cannot possibly be seen to be a moving sound source per se. This can create a philosophical conundrum if one delves into it deeply enough, but fortunately this is not necessary. The phase shift model explains this, and it is obviously impossible for the cone to move *without* causing phase shift.

In short, the term 'Doppler distortion' (for a loudspeaker) is completely real, but is also a simple misnomer (IMO) - the frequency shift exists, but it can be shown that the shift in phase is static as well as dynamic. Naturally, the same can be said for any sound source that moves with respect to the listener, regardless of velocity. Minimising cone excursions for any driver that must reproduce higher frequencies is the key to obtaining better sound reproduction - this much is very clear.

1.1 - Introduction

There seems to be a new area of debate on the Net, and it can be found in newsgroups, forum sites and websites in general. For a long time, the existence of so-called Doppler distortion in loudspeakers was taken for granted by most (including the author), but there are now many challenges to this claim - some are well reasoned and have considerable merit, while others are based firmly on the basis that the challenger simply doesn't *believe* that the effect exists at all.

Doppler distortion in loudspeakers is mentioned in so many articles, web sites and references that for years it was considered a simple fact. A great many authors have applied their (not inconsiderable) mathematical skills to the subject, and it is fairly obvious that many (most) of the published results are based on the assumption of cone velocity, rather than absolute position.

The effect of Doppler shift in loudspeakers is believed by many to be audible, and it is (relatively) easy to measure the frequency spectrum and see sidebands that seem to show modulation consistent with frequency modulation. Indeed, the existence of (velocity based) Doppler distortion in loudspeakers was originally established many years ago [Ref 1] and is maintained to this day.

At this point, I would like to thank Siegfried Linkwitz [Ref 2] and Art Ludwig [Ref 10] for their input to this article. My initial published data caused both gentlemen a great deal of work (which I'm sure they could have well done without), but in the spirit of international co-operation they have been very helpful, and contributed a great deal to this (final?) version of the article.

In e-mail correspondence with Siegfried Linkwitz, he said ...

> *The considerable effort you put into this difficult measurement should not go unnoticed and lead to a deeper understanding of the Doppler effect. I certainly had never thought about and made the connection between the now obvious phase shift of the high frequency tone with cone displacement and the Doppler effect. In the same way that the frequency shift is more easy to observe under certain conditions, so is the phase modulation in the case of a loudspeaker. Both are just different descriptions of the identical physical phenomenon to which Doppler's name has become attached.*

Siegfried also said that "*I have not seen the associated PM pointed out in text books, but it follows from FM or PM modulation theory*" - this is really the crux of what this article is about - that no textbooks describe the phase change (and resulting phase/ frequency modulation) as the cone moves closer to or further away from the listener, and this leads to a general misunderstanding as to the real cause of the effect, and obscures other effects that could have been extrapolated had this been more widely known. More to come on this aspect shortly, but rest assured that it will not make a large difference to the way we design (or listen to) loudspeakers, but simply explains other phenomena that were not seen or predicted previously.

This paper has been a long time coming, and has had a considerable amount of input from others - both 'believers' and 'non-believers'. Indeed, it was a non-believer who first took me to task because I referred to 'Doppler distortion' in one of my other articles, and it took some effort on his part for me to see that there was something amiss. Since he prefers to remain anonymous, he will not be named, but suffice to say that his insistence was such that I had to work very hard to prove him wrong. I initially thought that I had failed, but it turns out that the effect was real from the very beginning, but explained in such a way that made no logical sense (to me and presumably to him). Papers such as that by John Kreskovsky [Ref 3] are very convincing, but unfortunately work from the wrong premise (i.e. velocity rather than phase) in the first place. (Note that the page has been updated at some stage, and some of the original claims (as I recall) are no longer there, or have been

modified.)

The original experiments I performed - well over a year ago at the time of writing - were inconclusive, and despite a lot of effort, it was not possible to determine exactly what was happening. Even during tests to try to locate evidence of a frequency shift, while there *was* some evidence that a shift existed, the resolution of the equipment I had at the time was insufficient to be certain. In addition, I did what I suspect many others have done before me, and *removed* the low frequency component from the captured audio signal - this was a mistake, because that information is needed to be able to see exactly where the shift occurs.

This study is as much theoretical as practical - the theory was needed to predict an outcome, and to examine other possibilities. I must thank those who have listened to my rants and hypotheses and supplied additional ideas ... it was one simple point that brought the whole issue into focus, and allowed this page to (finally) become reality ... phase!

2.0 - The Doppler Effect

The Doppler effect is very real, and has been heard by everyone at some stage. The classic example is of the siren or horn on a moving vehicle, which is increased in pitch as the vehicle heads towards you, and reduced in pitch as it heads away. There are countless references and descriptions in books and the Web, and I shall not even try to cite references except one - [Ref 4]. A Web search will tell you everything you ever needed to know (plus a lot more). Doppler shift requires that the sound source is moving with respect to the listener, which means that the listener is either stationary, or moving at a different speed from the originating sound source. An ambulance driver or passenger does not hear any Doppler shift, because s/he is moving at the same speed as the siren, so there is no relative difference in velocity.

There is a requirement for the Doppler effect to exist that there be relative movement through the medium (between the sound source and the listener). It is generally assumed that the medium itself is not moving, or is moving at a lower velocity than the sound source. Should the medium be moving as well, this may increase or decrease the effect from the listener's perspective (information is rather scarce on this point).

That the phenomenon of the Doppler effect is real is not in question - what *is* in question is whether the same effect occurs in a loudspeaker reproducing more than a single tone simultaneously. Furthermore, we should clarify the term 'distortion', since the word is normally applied to a non-linear function. Should the effect be demonstrated to exist in a loudspeaker, then it is obvious that it will appear in an ideal (or theoretically perfect) driver as well, so there *is* no non linearity. Based on this, the effect probably should not be called 'distortion' (although it must be said that anything that adds frequencies that did not exist in the original recording actually *is* distortion, but that is probably a philosophical debate rather than one to be considered by the engineering fraternity).

The first thing to consider is the maximum velocity of a loudspeaker cone, when driven by a signal of any given frequency. This is generally much lower than we might imagine, and the velocity may be calculated by ...

$$V_p = 2 * \pi * f_L * X_p \qquad \text{[Ref 2]}$$

where V_p is the peak cone velocity, f_L is the low frequency and X_p is cone displacement. For example, a cone that is moving ±5mm (10mm total) at a frequency of 50Hz will have a peak velocity of 3.14m/s (11.3km/h) - this is certainly not fast, and in itself would account for a rather small frequency shift. In a system where (conventional velocity based) Doppler effect does change the frequency, the change is given by ...

$$\Delta f_H = 2 * \pi * f_L * f_H * X_p / c$$ [Ref 2]

where f_H is the high frequency (modulated) tone and **c** is the velocity of sound (nominally 345m/s). Using the velocity calculated earlier, we get a shift of 9.1Hz for a high frequency tone of 1kHz (less than 1%). Bear in mind though, that the rate of change needs to be maintained for a reasonable period of time before the frequency shift will become apparent, and 10ms (the time it takes a 50Hz signal to swing from maximum positive to maximum negative) is probably insufficient to cause an audible frequency shift. Our hearing is such that it needs a reasonable number of cycles (which varies with frequency) before we can identify the pitch of a tone.

Remember that for the (conventionally explained) Doppler effect to exist, the 'carrier' (vehicle, train, etc.) or listener must be moving *through* the medium, but a loudspeaker cone does no such thing. The medium (air) will be pushed outwards and sucked inwards by the low frequency movement of the cone, so there is no (or very little) relative movement between them - the medium is moving *with* the cone! What is heard (and most commonly incorrectly attributed to Doppler effect) is a combination of things (in descending order of importance) ...

Intermodulation distortion
Amplitude modulation
Phase shift

Of these, the only one that comes close to frequency modulation (as predicted by much existing theory and practice) is phase shift, and this is caused by the relative position of the cone at any instant in time in relation to the listener. That the shift is small is obvious, and equally obviously it depends on the peak to peak travel of the cone. Assuming a large cone movement for the low frequency signal of (say) 10mm in each direction, this represents a complete cycle (360°) shift at 34,500Hz, or 36° at 3,450Hz (for example). It must be considered that any loudspeaker that is expected to have anywhere near 20mm travel at low frequencies, *and* is expected to reproduce high frequencies as well, will almost certainly generate considerable intermodulation of the higher frequencies.

Interestingly, the phase shift observed will be exactly the same at DC as at any low frequency that causes the same displacement - even moving the whole box relative to the microphone will generate the same amount of (static) phase shift. This is simply a function of the velocity of sound in air, and the wavelength of the high frequency tone. A 10mm change in the position of the box will cause a 36° phase shift (of a 3,450Hz tone) in exactly the same way that 10mm of cone movement will - this is a simple physical relationship.

An interesting effect of amplitude modulation (within the range we can expect from a loudspeaker) is that when you hear it, it sounds like frequency modulation. Again, this is a well known effect, and references abound. The effect is caused by the way our hearing works, and this may be the predominant effect that is heard by listeners who have 'proven' that Doppler distortion exists because they have 'heard' it. In general, the pitch seems to reduce slightly as amplitude is increased for frequencies below around 2kHz, while for frequencies above 2kHz the pitch increases with increased amplitude [Ref 5].

The majority of studies (on websites or elsewhere) that have shown that Doppler distortion *does* exist, have used a spectrum analyser (or FFT - Fast Fourier Transform) to show the sidebands so generated. The spectrum analyser is completely the wrong tool to use for this, as it only shows frequency information - the effects we want to capture are in the time domain, and are best seen with an oscilloscope.

The theory of Doppler shift is velocity based (although as noted above, it can also be explained by phase) - the higher the (relative) velocity between source and listener, the greater the frequency shift. This is extremely difficult to even attempt to measure, since the peak velocity of the cone is so low. With phase shift, velocity is not

relevant - only the variation of distance between source and listener determines the shift, and it can be shown that the peak phase shift coincides with the peak excursion of the cone (positive and negative).

In order to dispense with the idea of loudspeaker Doppler distortion, we must find the flaw in the seemingly intuitive and rather persuasive argument that has been used historically to 'prove' that Doppler distortion does in fact exist. Simply making the point that the sound source must move *through* the medium with respect to the listener is not sufficient, and it has been argued that the cone does in fact do just that. That this action would violate the laws of gaseous matter when subjected to a force is (apparently) insufficient explanation, so further proof is needed.

That there is a shift is not in question - what is at question is the exact nature of the shift, and where it occurs on the low frequency waveform. If the shift observed is indeed in frequency, and caused by the Doppler effect, then it must occur at the point where cone velocity is at its peak - at the zero crossing point of the waveform. However, if the shift is simply one of phase, then the peak (phase) shift will occur at the extremes of excursion, where the cone is effectively stationary. So which is it? Indeed, are the two effectively identical?

One of the biggest difficulties with measuring any of these effects is the fact that the delays (and associated phase shifts) are very small. . If we assume that the effect is indeed Doppler induced and that the deviation is 9Hz as predicted for our demonstration system, then the delay is only (approx.) ±28us. Measuring this in conjunction with ambient noise, distortion, and instrument resolution limitations is not easy, since the waveform period is 1ms - the absolute maximum shift possible is ±2.8%, but is likely to be a lot less. While these things are not a limitation with a simulator or mathematical approach, real life makes it a lot harder for us.

2.1 - Frequency Modulation Characteristics

It is useful to look closely at the effects of frequency modulation, so that we know what we are looking for. A lack of understanding at this level must result in a flawed conclusion, so a thorough understanding of what we *should* find is imperative. If we find exactly the signal characteristics as described below, then the original theory is proven - this is not open to conjecture, since we are dealing with simple facts.

However, should we get results that are quite different, then the observed phenomenon cannot be frequency modulation, and is therefore not related to the Doppler effect.

The signal frequencies used for the physical tests performed later will be different from those used in the theoretical discussion that follows, for reasons that (I hope) will become clear later, but driver total excursion will be as close to ±5mm (10mm total travel) as possible.

For the theoretical examination, the low frequency will be 50Hz, the high frequency 1kHz and the peak to peak cone excursion shall be 10mm (±5mm), therefore frequency shift will be 9Hz (as predicted by the formulae above). The high frequency tone will be modulated at the 50Hz rate, to obtain a maximum of 1009Hz and a minimum of 991Hz. This represents a Modulation Index of 0.18 [Ref 6]. Let's do a quick examination of wavelength, based on the formula above that predicts a frequency change of ±9Hz.

W = c / f

where **W** is wavelength in metres, **c** is the velocity of sound (nominally 345m/s) and **f** is frequency in Hertz.

W = 345 / 1000= 0.345m = 345mm
W = 345 / 991= 0.34813m = 348.13mm
W = 345 / 1009= 0.34192m = 341.92mm

The total change in wavelength is therefore 6.21mm. We could analyse this data forever (or until we became bored), but that is probably enough for now.

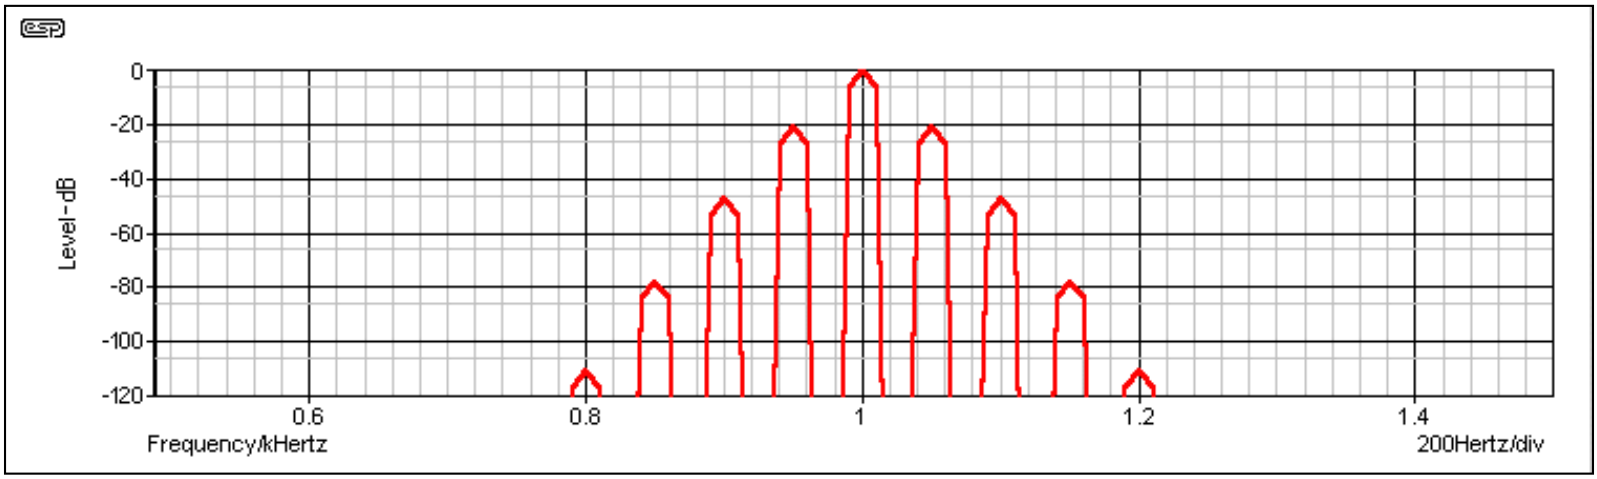

Figure 2.1 - Frequency Spectrum of 1kHz, Modulated by 9Hz at 50Hz Rate

As can be seen from the spectrum display (from a synthesised FM waveform), a frequency modulated (FM) waveform modulated as described has multiple sidebands - although only a limited number is shown for clarity, they are actually infinite and diminish into the noise floor quite rapidly. It is easily determined that the fundamental is at 1kHz (at a level of 0dB), with the first set of sidebands at -20dB (950Hz and 1050Hz). The next set is at -48dB, at frequencies of 900Hz an 1100Hz. The final set is measured at -78dB, at frequencies of 850Hz and 1150Hz. After that, the sidebands are at -111dB or lower - well into the noise floor. A pure sinewave predictably shows a single peak at 1kHz - no surprises there, and it is not shown.

The above assumes that the shift will actually be 9Hz - it has already been explained that this will almost certainly not be the case. In a listening test on a 1kHz tone, modulated by the full 9Hz at a 50Hz rate, it is possible to hear the FM as a slight roughness in the tone ... however using headphones (to eliminate standing waves, room reflections, etc.), the roughness is barely audible. if we assume that the frequency shift is only 4.5Hz - probably still unrealistic, but useful for our purposes - the signal through headphones sounds almost as clean as a pure sinewave.

2.2 - Phase Modulation Characteristics

Phase modulation [Ref 7] is actually very similar to frequency modulation - so much so that some narrow-band FM communications systems actually use PM (Phase Modulation) because it is easier to implement. Unfortunately, while it may well be easier for radio frequency signals, it is harder to synthesise than FM in audio, and no sound editor that I have access to is capable of creating a PM signal. The end result is sufficiently similar though (audibly speaking) that it is almost immaterial.

What is certainly *not* immaterial is the spectrum of a PM signal, so I was forced to build a phase modulator (using my Simulator and a standard analogue phase shifting circuit) that would operate satisfactorily at the modulation frequency of 50Hz. This proved irksome, but the results were gratifying, as it is now possible to display a spectrum analysis of a PM waveform, with (almost) the same characteristics as the FM signal referred to in section 2.1. This is an important step - without this, we do not have a useful reference and may be left with conjecture. Imagine the embarrassment if it had transpired that PM has a spectrum similar to intermodulation.

For the sake of this exercise, the spectrum of the PM signal is not shown - it is essentially *identical* to that shown above for FM. For all intents and purposes there is no difference whatsoever. Although there actually is a (very)

subtle difference, it is not visible until it is below the -120dB level, so is irrelevant in practical terms.

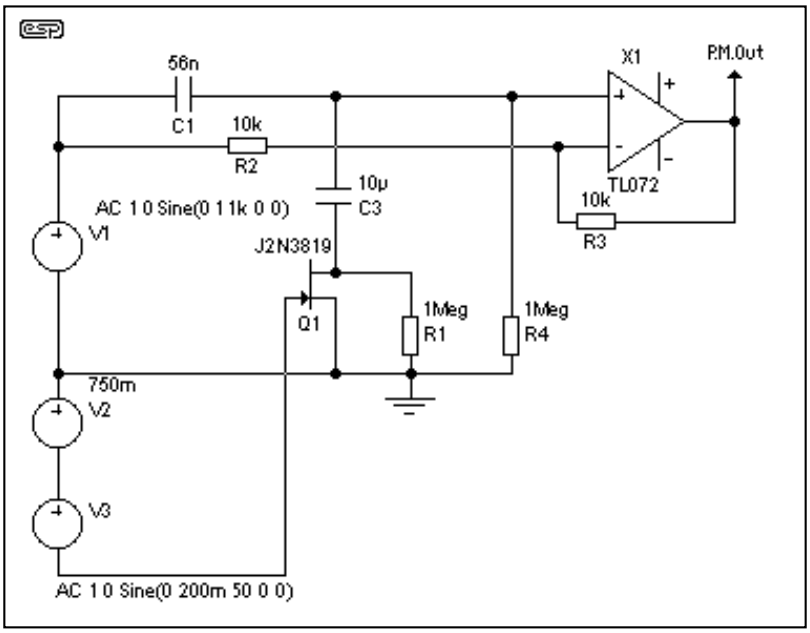

Figure 2.2.1 - Phase Modulator as used to Generate Phase Modulation

For reference, Figure 2.2.1 shows the schematic for the phase modulator that I used to make the comparisons. This was created in Simetrix [Ref 8] and is not too different from a real-life working circuit.

2.3 - Test Methodology

The next stage is to determine a test method that will show the effect - this is not a simple task, because we know that any shift will be small, and is invariably accompanied by amplitude modulation and intermodulation. Because of this, a spectrum analyser is useless, as it will show intermodulation sidebands that will completely mask any frequency variation. The instrument of choice is an oscilloscope, because that is capable of displaying information in the time domain, where the problem occurs.

If the (velocity based) Doppler theory is correct, we should expect to see a set of waveforms similar to that shown in Figure 2.3, where a low frequency tone is mixed with a high frequency tone, and fed to a loudspeaker. This signal is also fed to one channel of the oscilloscope, and the other is used to display the audio waveform reproduced by the loudspeaker, and picked up by a microphone. The gains of the two are carefully matched so that the waveforms are perfectly overlayed - any discrepancy should be visible. This can only be done using a digital storage oscilloscope, because the waveform must be captured and expanded so that any shift is visible.

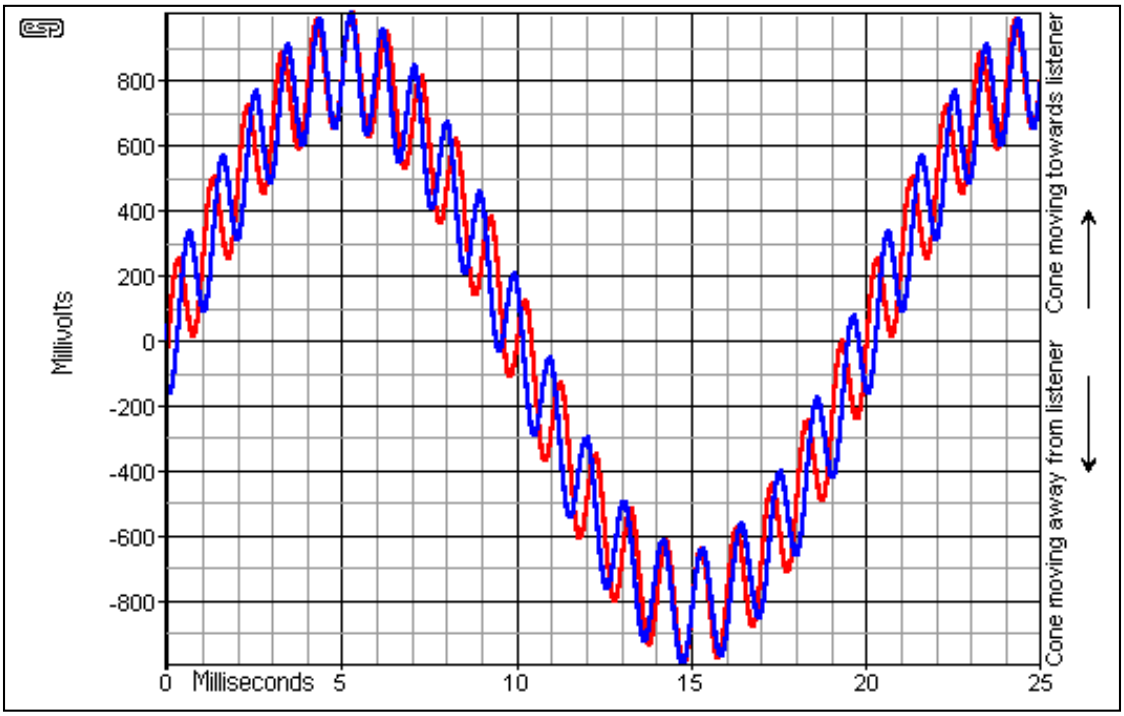

Figure 2.3 - Expected Oscilloscope Display for Doppler Modulation of the High Frequency

The red trace shows the unmodulated carrier riding on the LF waveform (i.e. the electrical signal sent to the loudspeaker), and the blue trace shows what we should expect to see on the oscilloscope from the audio signal picked up by the microphone. Note that the frequency deviation has been exaggerated for clarity - if it were that easy to see there would be no argument. It is quite apparent that with FM, the modulation is at its maximum at the LF zero crossing (maximum acceleration), and is at minimum (signals in phase) at the LF signal peaks.

If the shift is a genuine Doppler shift, then we will see the signal compressed or stretched at the zero crossing points of the LF waveform, and at the peaks of the LF waveform the HF signal should be in phase, since LF cone movement is effectively zero (for a moment in time, at least).

On the other hand, if the shift is one of phase, then the maximum variation between electrical and acoustical signals will occur at the *peak* of the LF waveform (positive or negative), as shown in Figure 2.4 below. This stage of theoretical analysis is very important - it is far easier to figure out what one should look for in advance than it is to try to figure out what one is looking at with no background.

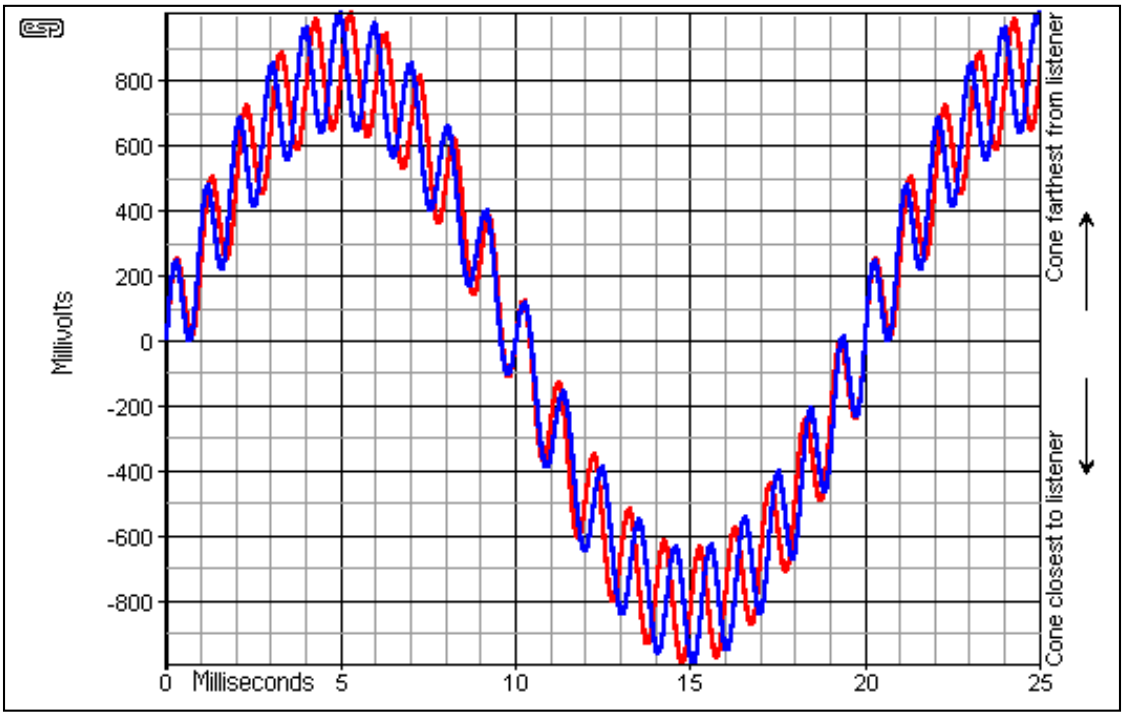

Figure 2.4 - Expected Oscilloscope Display for Phase Modulation of the High Frequency

The red trace again shows the unmodulated carrier riding on the LF waveform (the electrical signal), and as before the blue trace shows what we should expect to see on the oscilloscope from the audio signal. Note that the phase modulation too has been exaggerated for clarity. You can see easily that for phase modulation, the maximum variation is at the LF waveform peaks, where the distance from the cone's rest position is at its greatest. There is no modulation at the zero position, despite this being the point of maximum velocity for the LF signal.

This alone should start to give the astute reader a hint - the cone is *definitely* moving closer to and farther away from the microphone, so there must be a variation in the relative phase. After all, the microphone position had to be adjusted to ensure that the acoustic and electrical high frequency signals were in phase during the setup phase. If you are anything like me, at this point you'll be saying '*Of course! This **must** be so*.' (or words to that effect).

Figure 2.5 shows a schematic of the test setup. Several things are critical to get a usable result, and these include the following ...

- Woofer mounting - the woofer was not in an enclosure, to maximise the excursion. At the same time, it must be firmly held to prevent any movement that could give false readings.
- Microphone placement - the positioning of the mic is very important, since it is essential to have the electrical and acoustic signals in phase when the cone is at its rest position.
- Signal frequencies - the woofer frequency was chosen to give high excursion (close to resonance), and was adjusted slightly to alter the phase of the electrical vs. acoustic signal. The upper frequency was selected to be as high as the woofer could reproduce, so that any shift would affect as many cycles of the HF waveform as possible, making it easier to see any variance.
- Signal levels - just as important as phase, the electrical and acoustic signal levels have to be as close as possible. This allows a direct comparison with minimum error. It also allows measurement (or least a visual impression) of amplitude modulation, as this is useful for the final analysis.
- Setup position - the experiment must be set up so that it is far enough from the signal generating and measuring equipment that physical movement of the person (or persons) conducting the test don't affect the phase relationships. An experiment of this nature relies on accurate phase relationships, and these are

easily disturbed by movement near the experiment itself.

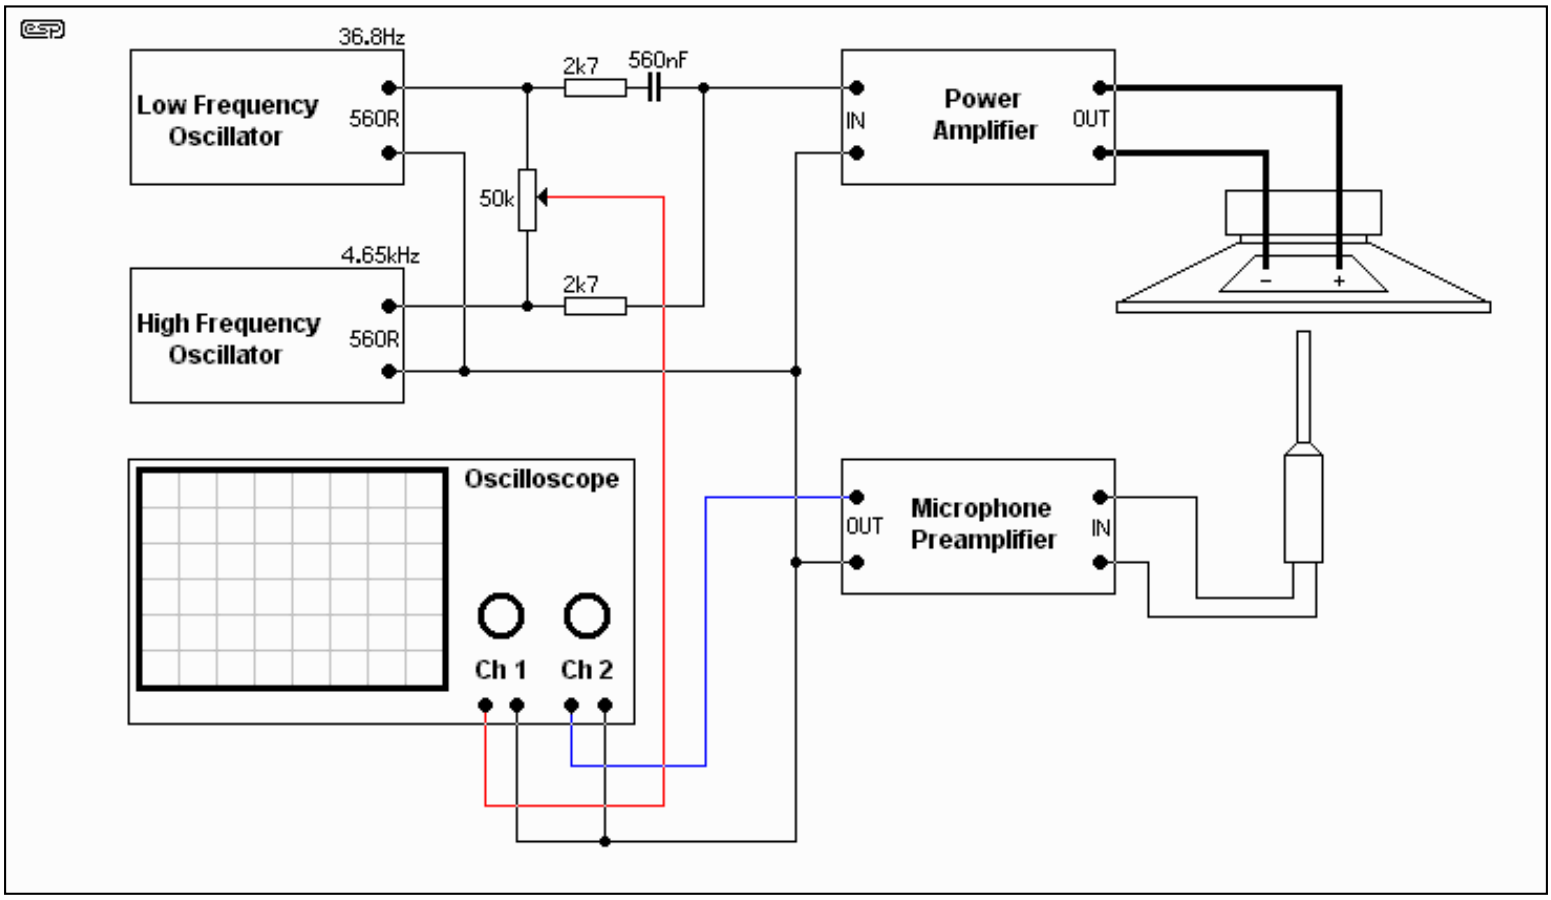

Figure 2.5 - Test Setup Circuit Diagram

The 50k pot allows the exact 'blend' of low and high frequency signals for the reference trace (Channel 1 on the oscilloscope). By varying the levels from the two oscillators, the loudspeaker drive signal is changed to suit requirements, and the mic preamp also has a gain control so the acoustic signal level can be exactly matched to the reference - in both phase and amplitude. The 560nF cap was needed to rotate the LF phase enough to be able to use a sensible frequency.

It is important to understand the exact test setup used to perform the test. First, the speaker is excited by the HF tone only, and the microphone gain and physical position adjusted so that the electrical and acoustic signals are exactly in phase. This is the reference signal, and it is imperative that this is done very accurately, or the end result will be nonsense. The HF signal is then removed, and the LF signal is applied - because of the use of a close microphone, there will be little LF phase shift ... but the speaker must be operated at (or near) resonance, or the reactive load will cause the electrical and acoustic waveforms to be out of phase.

This can be used to our advantage - by changing the low frequency slightly, we can advance or retard the phase just enough to make sure the signals are again perfectly aligned. By operating the woofer near resonance, the best relationship between cone excursion and power is possible - setup and adjustment take some time, and a smoking woofer voicecoil is not helpful. Likewise, for the high frequency signal, it is advantageous to use the highest frequency possible, so that any shift that occurs is maximised, and becomes easier to see on the oscilloscope. Because of the relatively short wavelength, mic positioning will correct all phasing errors (the voicecoil is inductive, and causes phase shift at high frequencies). Also note that the woofer will not be a linear piston at such a high frequency, so measured phase variations may not agree 100% with those calculated.

One might imagine that the test would be easier if the low frequency were filtered out, since that allows a better resolution of the HF, but then we would lose the essential information that shows us where the LF zero crossing

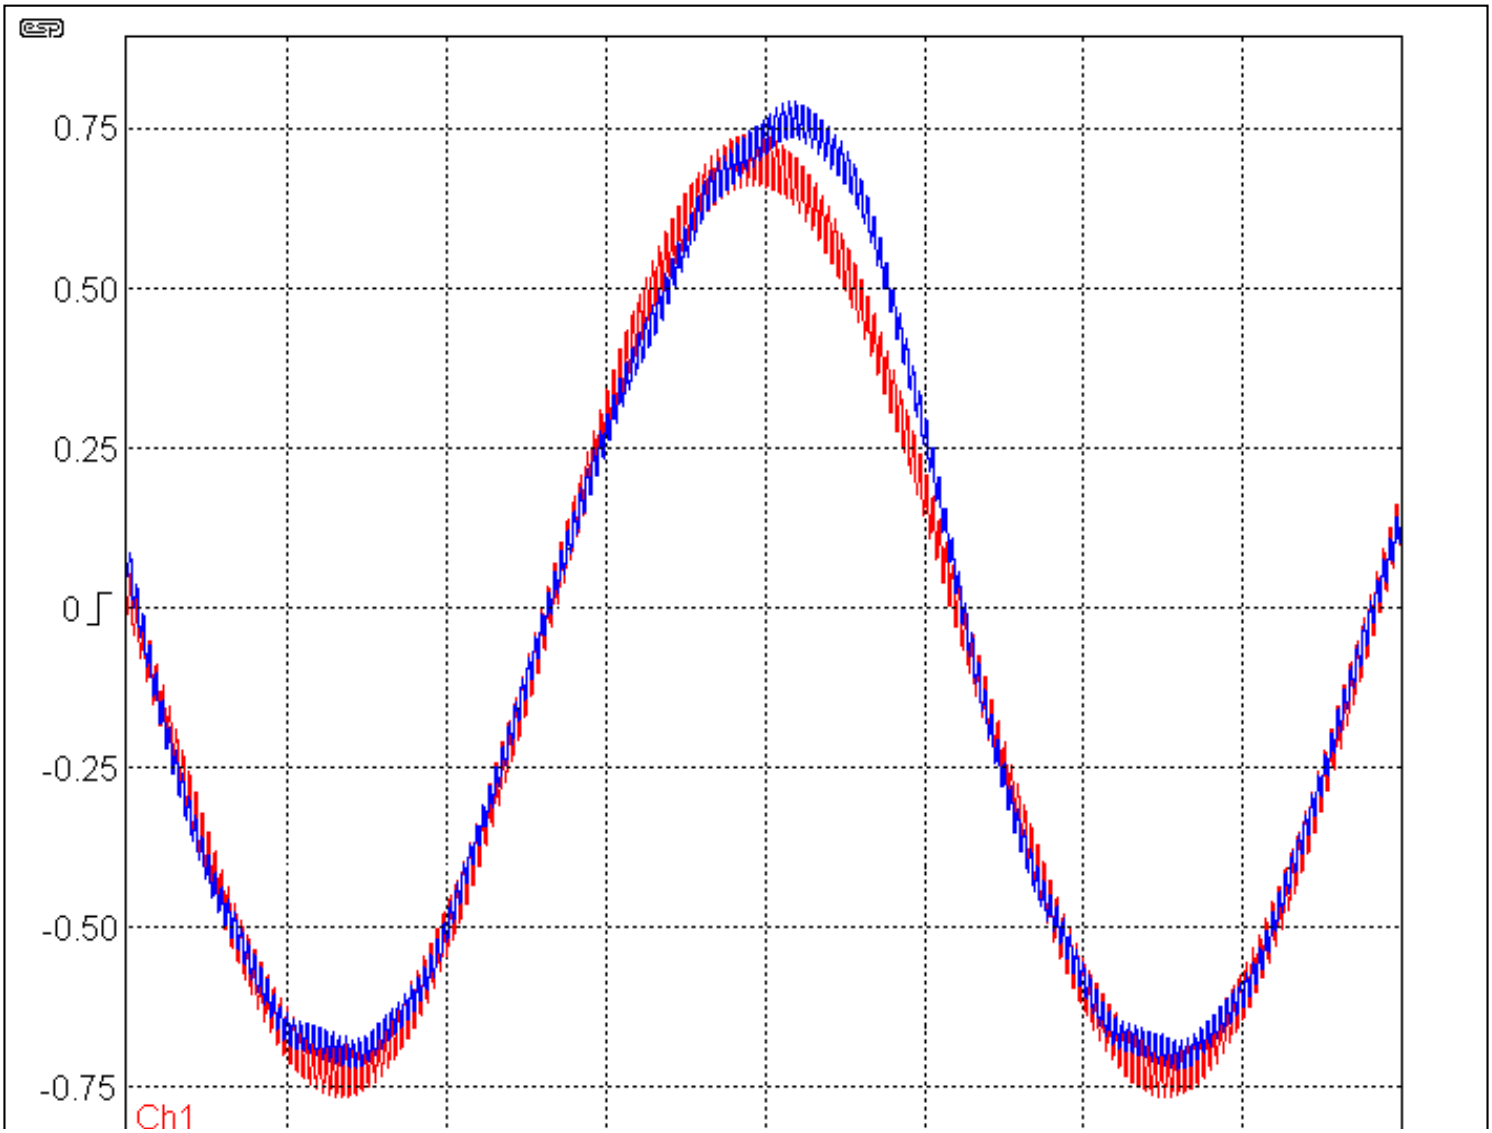
points and waveform peaks are - these are the parts of the waveform where we need to see what is happening, and we *need* the LF data.

As a point of interest, it must be stated that the microphone's diaphragm does not in any way influence the test results, since it is an electret capacitor mic. These microphones respond to pressure, and diaphragm movement is virtually nil - it is probably around the same as the movement of the human ear-drum, so any thoughts that this may introduce an 'anti-Doppler' effect are simply untrue. In comparison to cone movement, the travel is infinitesimal, and can safely be ignored.

Not so the woofer however - it proved necessary to wedge the woofer (sitting in a plastic crate filled with fibreglass) with a piece of wood from the ceiling to stop it from walking around the workshop floor! With an applied frequency of 36.8Hz (required to obtain the correct phase relationship and sufficient travel), there was no way it wanted to stay put. Even the high power 'digital' amp I used proved to be a problem as it kept cutting out, and I finished up using one of my P101 MOSFET amps - this was more than up to the task, and didn't get above warm, despite the load.

3.0 - Test Results

This is almost an anti-climax, since it should be fairly obvious by now what we will see. The results do not show a great deal of phase shift, but it *is* visible. It was necessary to adjust the signal levels slightly to get the best alignment, since as you can see in Figure 3.1 there is significant LF waveform distortion.



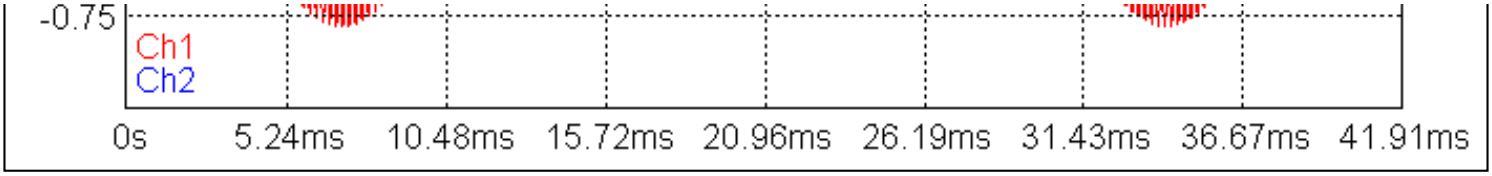


Figure 3.1 - The Composite Waveforms - Signal and Acoustic

As with all the following plots, the electrical signal is in red, and the acoustic signal in blue. It is obvious that any phase shift in the acoustic signal is not visible in the above, so the following three graphs show the expanded waveform at different points. The oscilloscope used is a Tiepie PC based instrument, and for this work was operated at a sample rate of 2.5Ms/s (2.5 million samples/ second) at 12 bits resolution, and with a record size of 130,972 samples. It exceeds the resolution available from my normal bench oscilloscope by a wide margin.

Amplitude modulation is easily seen, and was also quite audible during the test - even with earmuffs. Look at the peaks of the waveform, and you can see that there is a big difference between the electrical and acoustic signal HF amplitudes - in a perfect woofer, these would be identical. Likewise, the low frequency signal would not be distorted (and this was from a high excursion subwoofer). Although the waveform looks a little like the power amp was clipping, this is not the case - the distortion seen is from the loudspeaker itself.

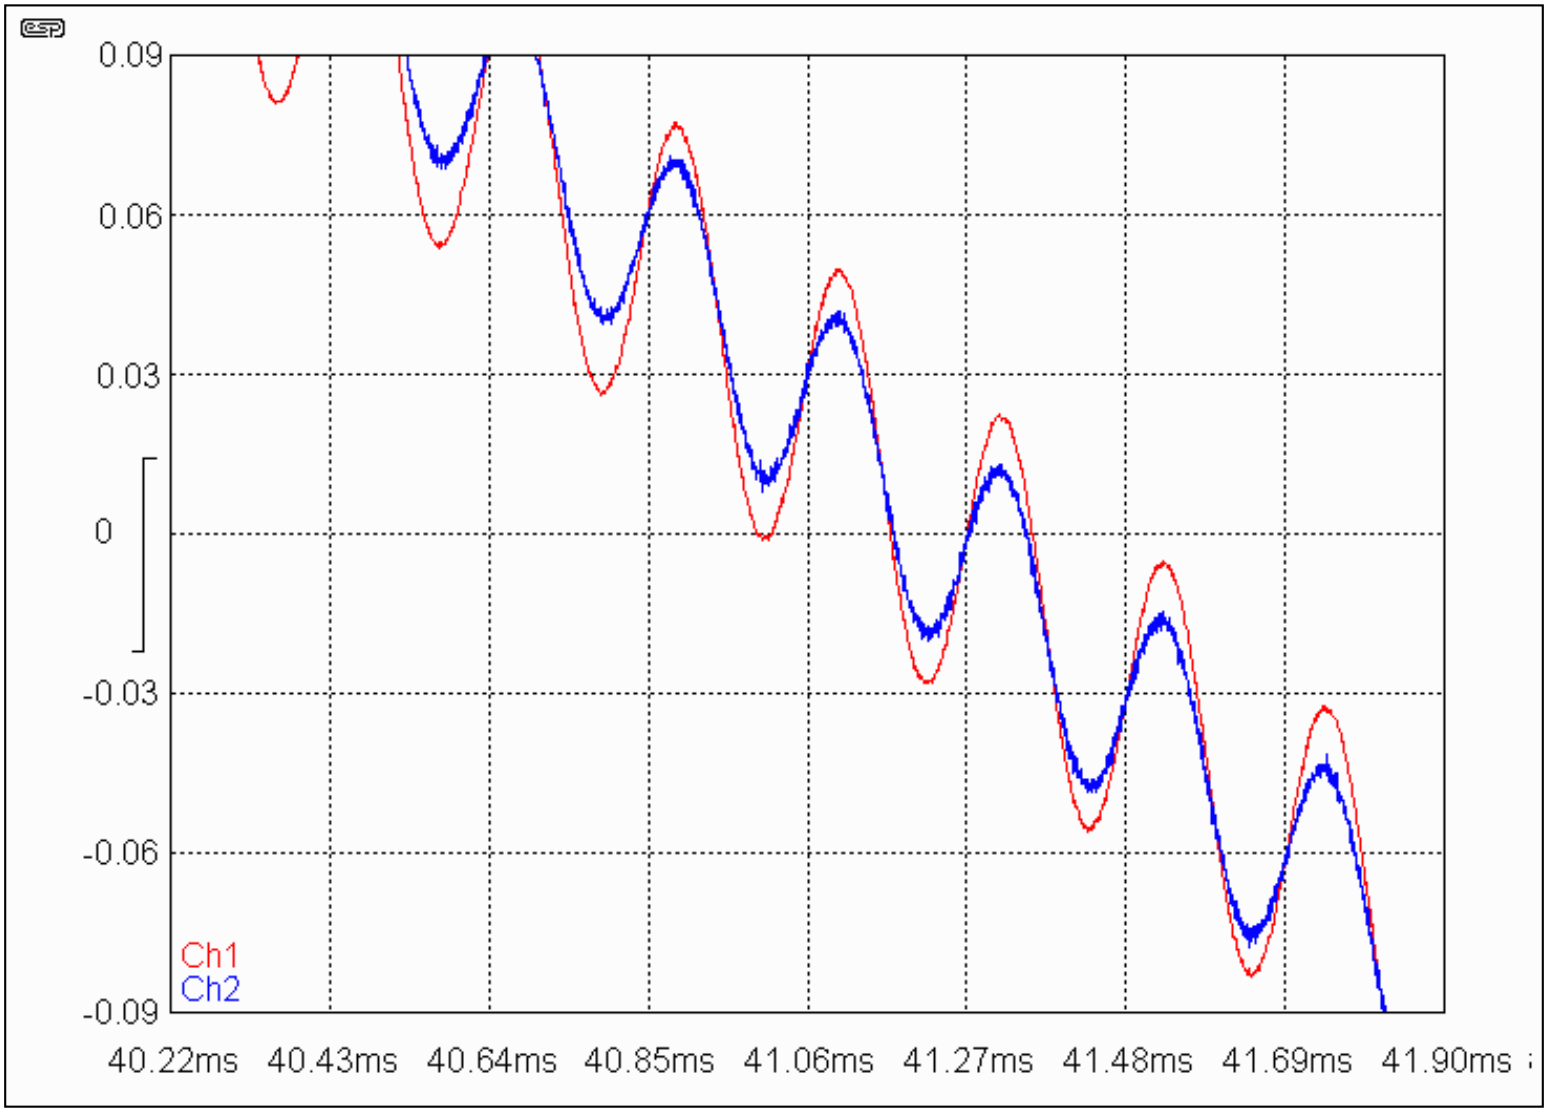

Figure 3.2 - Signals at LF Zero Crossing

It is quite apparent that there is no phase shift at the LF zero-crossing point, even though this is the area where cone velocity is highest. While not really visible here (much higher resolution is needed to be able to measure it),

there *is* a change to the period of the reproduced waveform - unfortunately, it only amounts to a pixel at best in the chart, and is easily missed. If the periodic time of a waveform changes, so does its frequency. For a 1kHz signal (having a period of 1000us), we can expect to see a change of only a few microseconds in the period (typically less than 10us, or 1%). This is a challenge to measure, as should be obvious.

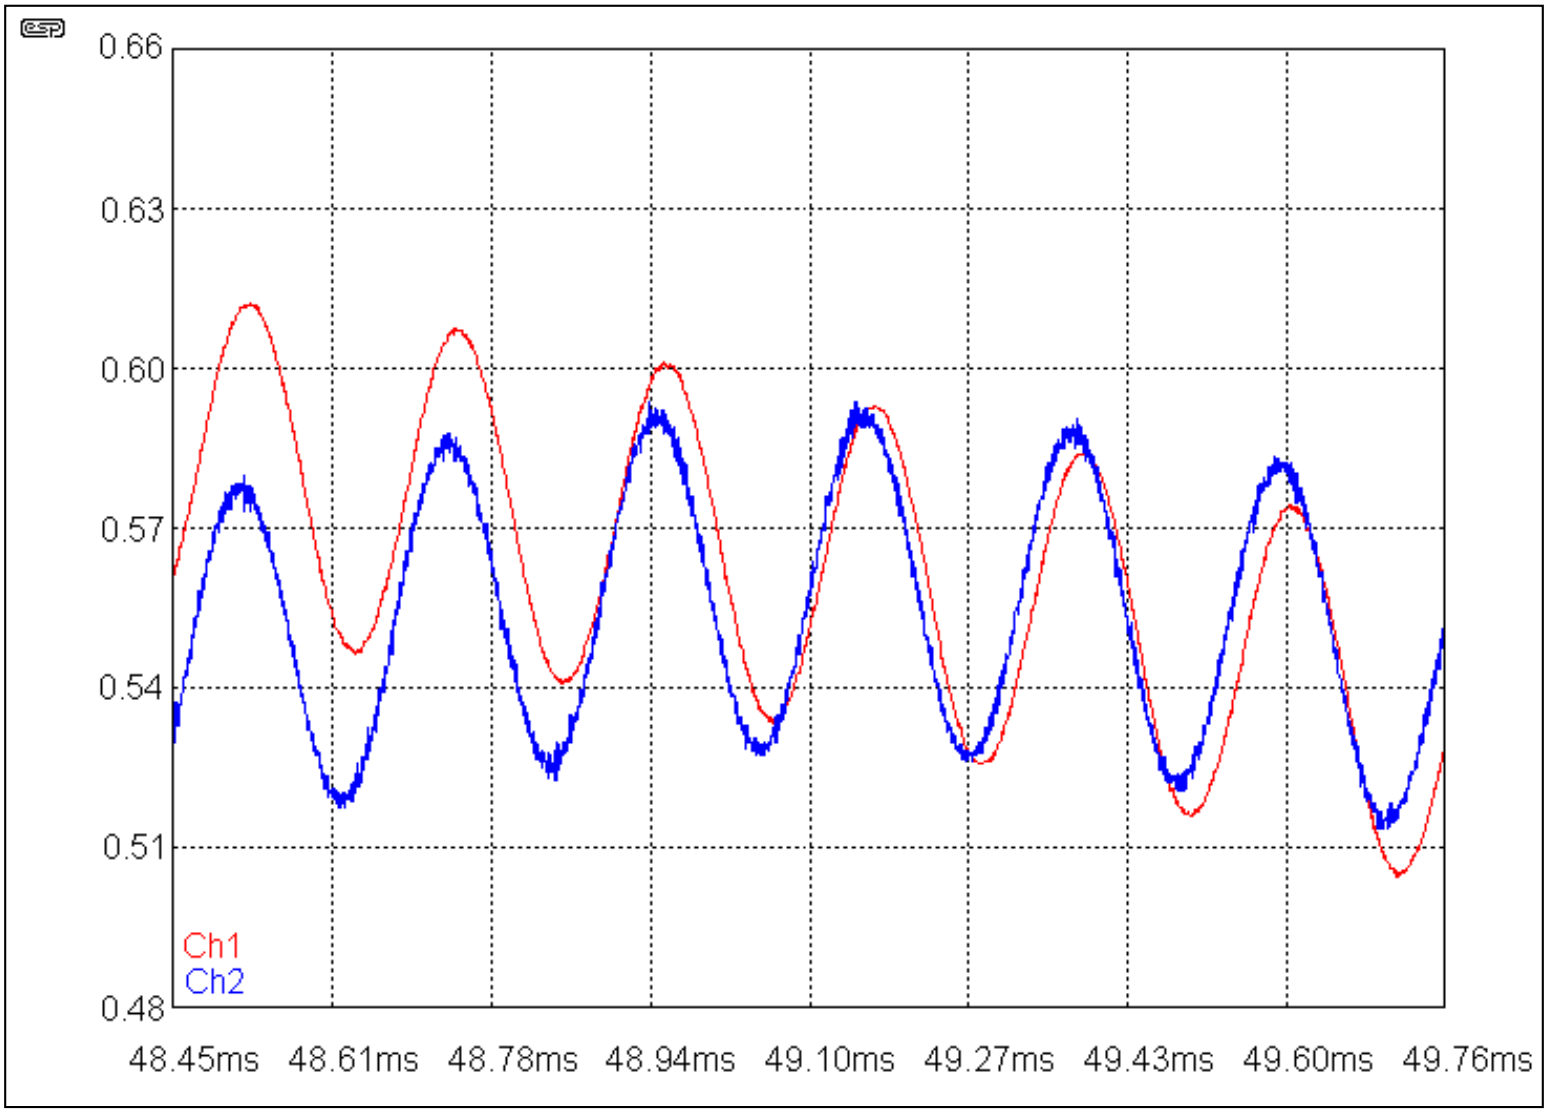

Figure 3.3 - Signals at LF Positive Peak

Here, we can see that the HF acoustic signal is arriving just before the electrical signal - the cone is closer to the microphone, so the signal arrives earlier. Look at the waveform peaks - not the zero-crossing points. The difference is discernible, but is still quite small. This is quite possibly the first time you have *ever* seen this effect, and it's all captured from a real test.

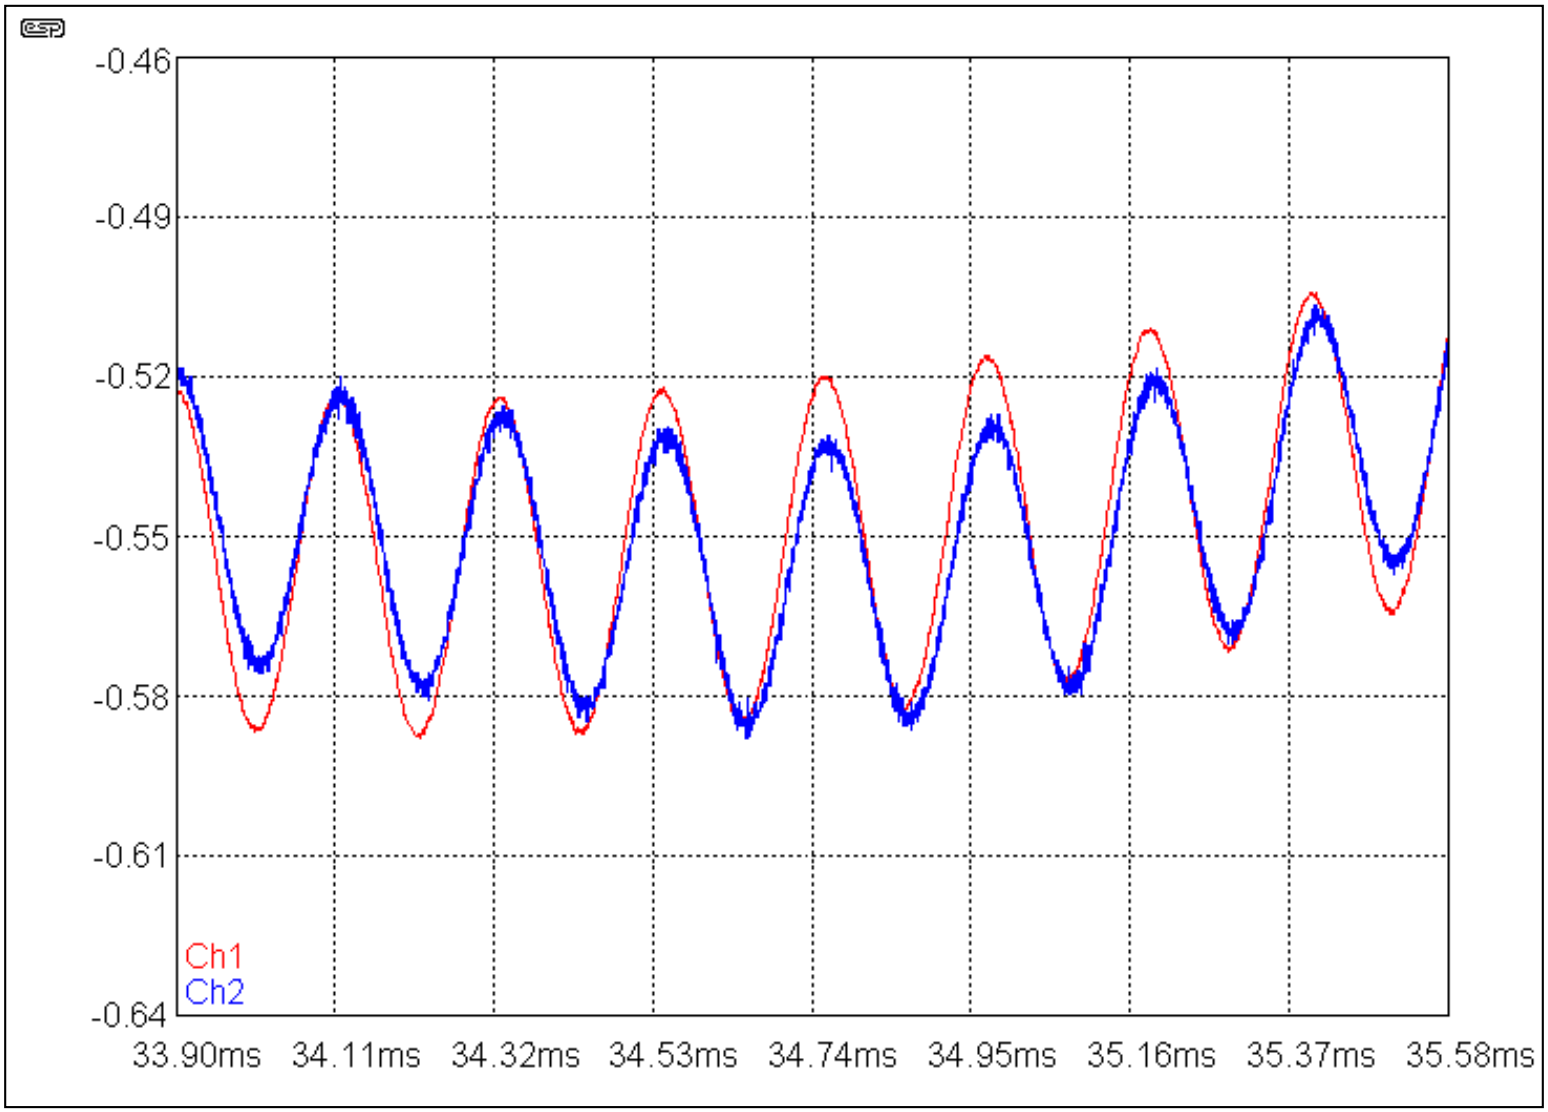

Figure 3.4 - Signals at LF Negative Peak

While not quite as pronounced as with the previous example, a small amount of shift is visible, since the cone is now further from the microphone than before. Even using a 4.65kHz signal, the wavelength is still just over 74mm, so the cone travel I was able to achieve without excessive distortion makes the variations smaller than desirable. The variation is there though, as predicted.

It is important to point out that the only manipulation of these graphs was to reverse them, because the microphone I used inverted the signal (so the positive and negative excursions were back to front). Otherwise, the graphs are as they were saved from the PC oscilloscope, but the text (inserted when the graph is saved) was removed to minimise file size.

4.0 - Conclusion

Upon testing, it is easily seen that the maximum phase shift of the HF signal occurs at the peak of the LF waveform. There is little or no discernible (phase) shift at the LF zero crossing, so the effect is phase shift, caused by the cone being closer (or further away) from the observer/listener at any point in time. Yes, there is an effective frequency shift, but (and although this is an apparently minor point, it very important), the shift is **not** caused by the Doppler effect per se (i.e. the 'conventional' velocity based interpretation), so cannot (or should not) be correctly called 'Doppler distortion'. Exactly the same phase shift can be seen simply by disconnecting the LF signal, and manually moving the cone or microphone (slowly) by the same amount, or by using DC or an

extremely low frequency to achieve the same result. This cannot cause the Doppler effect, as should be obvious. What it does is shift the phase, and if the phase shift is fast enough, then the phase modulation will 'create' frequency modulation - exactly as predicted.

It is fair to state that 'Doppler distortion' in loudspeakers exists, but the term is misleading.

It is equally fair to state that Phase Modulation in loudspeakers also exists, and is the correct definition of the effect.

Using the predictions that may now be obtained based on phase modulation, it can be demonstrated that the phase shift is independent of the LF modulation frequency, and depends only on the peak-to-peak amplitude. Nonetheless, the FM component of the phase modulation that *is* produced is a direct function of the LF modulation frequency. The two theories are not at odds with each other, but describe the same effect from a different perspective. The phase modulation model is more intuitive, and eliminates any of the arguments about the sound source moving through the medium etc. While it is unlikely that any of this will make the arguments go away, the procedures described here can be reproduced by anyone with the right equipment. Indeed, a complete test is not even needed to be able to see clearly that changing the mic position with respect to the sound source will change the phase - everything else can be calculated from there.

Further analysis reveals that the traditional predictive formulae that have been used work - they predict exactly the same frequency shift as is obtained by analysis of the phase modulation. What was not taken into consideration was the fact that the observed FM was really PM all along (a subtle difference). Since the peak cone travel was always used as part of the equation - as it must be to determine instantaneous velocity - the analysis turns out to be identical regardless of the method used. When the rate of change of phase is considered (where maximum rate of change implies maximum frequency shift), the peak frequency variation coincides with the maximum rate of change of phase, so the maximum frequency shift is also seen at this point.

> **Note:** By examining the phase model described herein, and upon realising that it is identical to the conventionally explained Doppler effect, it is now obvious that there is no requirement for the sound source to move *through* the medium at all. While this is a common argument by the non-believers, it fails to stand up to scrutiny. All that is required is that the sound source moves with respect to the listener - whether (or not) it moves through the medium is immaterial. While this may not be apparent from the traditional descriptions and explanations of the effect, the phase model makes the situation quite clear.

Very much unlike many (most?) of the other examinations of the subject, this test procedure was performed on a real speaker, and the results of these real-life tests are shown above. There is sufficient information in this paper to allow anyone else to duplicate the results, provided the necessary equipment is available. This is encouraged - the more people who understand the physics that cause the effect the better, and I would be delighted to hear from others who have applied this (or any other) test method to demonstrate the mechanism involved.

This is *not* merely a theoretical discussion of the effect, but contains the unadulterated results of the test procedure described. At the risk of offending those who believe that there are things in audio that no instrument other than well trained ears can detect, this is proof that a properly designed test method can be devised, and a theory thus proven or disproven.

The effect is very small (to the point of being virtually inaudible by itself), and is usually swamped (or masked if you prefer) by amplitude modulation and intermodulation distortion, so could be considered immaterial in any typical loudspeaker system. If people really want to describe the effect as a distortion - not an unreasonable assumption, since it does exist - then it should be re-named. The correct term is (in my opinion) Phase Modulation Distortion (PMD), and I suggest that the term 'Doppler distortion' be dropped from usage, since it is too easy for people to misinterpret.

Even PMD is possibly technically incorrect, since the effect is perfectly linear, and will occur in a perfect

loudspeaker. Regardless, it is probable that people will want to call it distortion. Linear or not, it still adds something to the signal that was not there in the first place, and it is not unreasonable to call that distortion.

Many readers will be glad to see that there is no mathematical proof of PMD, nor have I attempted to devise a formula to allow you to calculate the shift of any given frequency with a known LF cone displacement. So many others have already done this that there is no reason for me to add more on the topic.

Siegfried Linkwitz is one who has done exactly that - the mathematical proof (and equivalency) may be seen on his site, and his page now covers the topic from both the traditional and 'new' perspectives.

The methods that may be used to minimise PMD are exactly the same as those used to minimise intermodulation distortion, primarily, reduce the excursion of the mid-bass driver. This may be done by using a crossover and a subwoofer, or by choosing an alignment that reduces the low frequency excursion to the absolute minimum. Naturally, a 3-way system will outperform a 2-way in this respect, since the midrange driver's excursion will be minimal with no bass content.

Finally, it should be understood that this is a purely physical phenomenon, and short of extensive DSP (Digital Signal Processing) nothing can be done to prevent it if a driver is expected to handle bass and high frequencies simultaneously. While DSP is quite capable of applying a delay correction to remove the effect, the frequency shift is so small that the benefits are of dubious value.

If you *really* want to hear Doppler shift in a loudspeaker, get hold of a Leslie rotating speaker cabinet [Ref 9]. The high frequency rotating horn (in particular) satisfies all the criteria for Doppler effect - the sound source moves through the medium, and has sufficient diameter (and speed) to create a spectacular sound effect. There is also considerable amplitude modulation, and interesting phase effects as well. That you cannot expect to get this from a conventional loudspeaker is readily apparent, since Don Leslie would have not had to go to all that trouble if it were otherwise.

Introduction

This is not the final word on this topic, and I am sure that others with more (and better) equipment than I have could do much more. An hour or so of testing is hardly a fully scientific study, but the results agree with expectations for voltage and current drive - what came as a surprise was just how nasty negative impedance really is.

This article was prompted by a reader who did some simulations of a loudspeaker having no voice coil resistance. Of course, this is not possible, but driving with negative impedance can theoretically accomplish the same thing.

Negative impedance has been around for quite some time (probably about 50 years, maybe more), but I suspect that I have one of the few amplifiers around that can be preset to any impedance between -16 Ohms and +32 ohms. To this end, it was reasonably easy to test, and I used 42Hz as the test frequency - being representative of a typical bass signal (open "E" on a bass guitar). Just to make matters as bad as they could be, this is also very close to the resonant frequency of the test loudspeaker and enclosure.

I used a sound level meter at close range (100mm) connected to my oscilloscope to see the actual loudspeaker waveform. The speaker is a 4 Ohm 300mm Cerwin Vega subwoofer, in a 28 litre sealed box. This box has been used many times as a test system for the Electronically Assisted Subwoofer (see EAS project), described on these pages.

During these tests I made no real attempt to use zero crossing switching, since this was difficult for a quick test (my tone burst generator is on the blink and needs repair - one day). The lower trace is the output from the signal generator, and switching could - and did - take place whenever I switched the output.

The upper trace of each oscilloscope screen photo is the signal taken directly from my sound level meter, and the lower trace is the input signal. I made no real attempt to maintain any specific level, since it was immediately apparent that this made little difference.

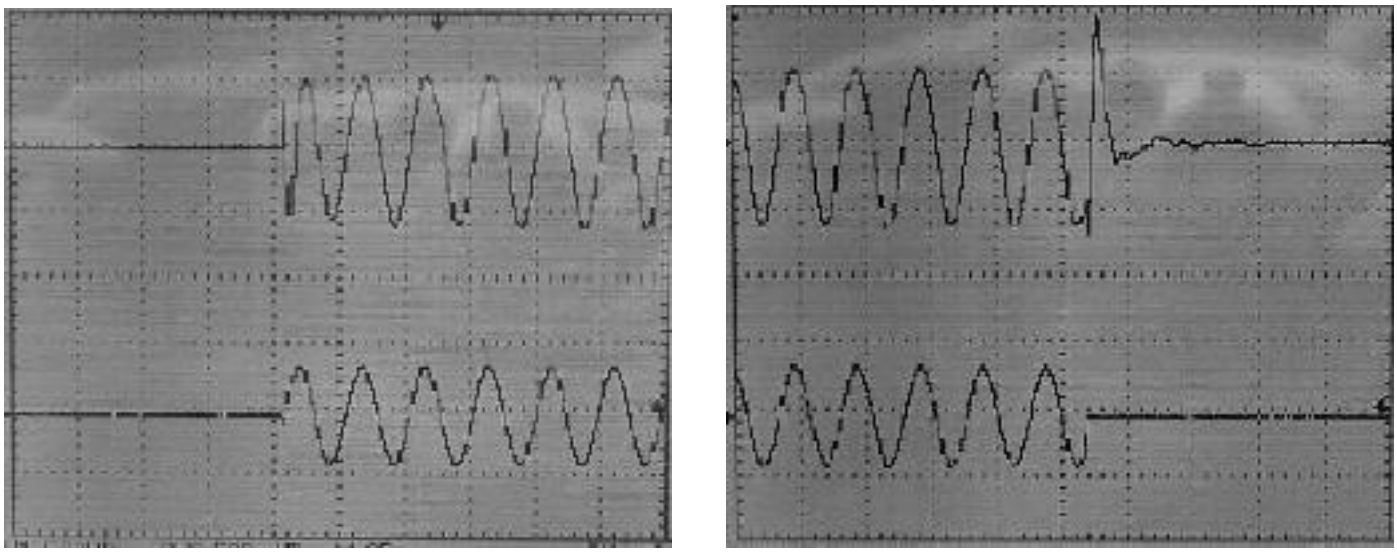
The waveforms displayed are exactly as measured, and the phase and timings were not tampered with in any way. The input signal was not bandwidth limited, nor was the amplifier output - the test results are therefore "worst case".

Transients are generated at the moment of switching - it is predominantly these that are of interest - a photo of an oscilloscope trace of a 42Hz waveform is fundamentally boring, whatever the source. The oscilloscope traces shown were captured with my digital camera - less than ideal, but it works (other than the ghostly image of the camera reflected in the front of the display).

Conventional Voltage Drive

Voltage drive is the most common way to drive loudspeakers. In theory, a "perfect" voltage amplifier has zero ohms output impedance, but this is never achieved in practice. Output impedances of 0.1 ohm or less are not uncommon at low frequencies,

representing a "damping factor" of 80 or more.

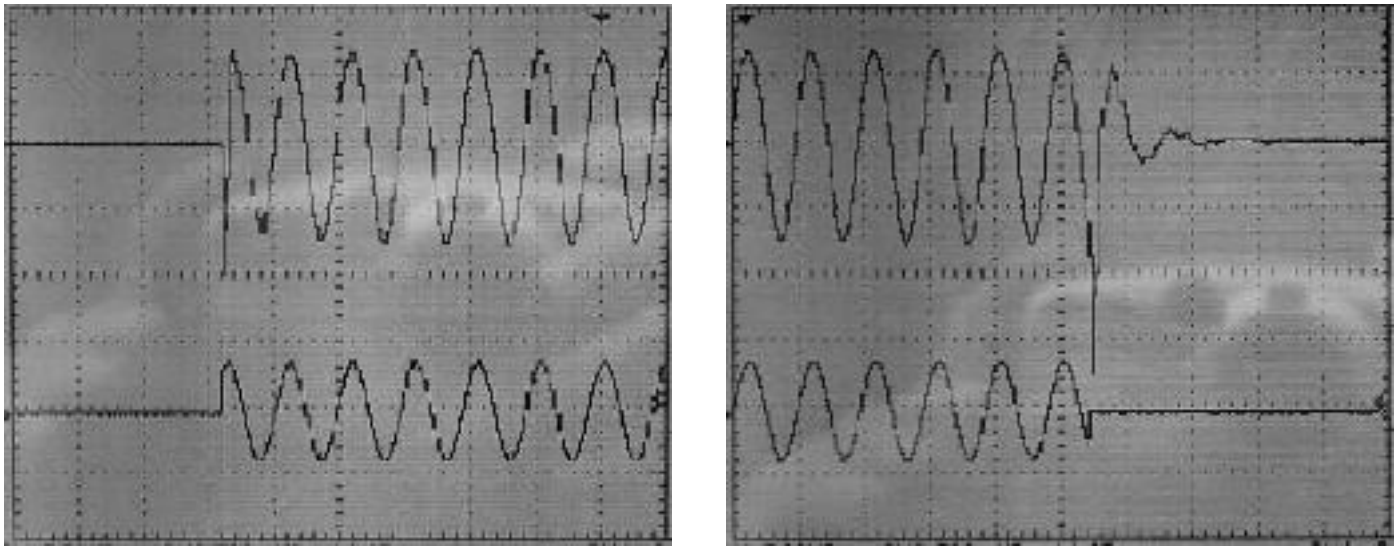


Voltage Drive - Z = <0.5 Ohms

One might say that this is text book performance. There is evidence of the switching transient, but overall this combination is well behaved. This is the most common connection for loudspeakers, and seems to be about as good as it gets. Overhang (ringing after the signal has gone) is almost non-existent.

Current Drive at +3 Ohms

With a pure current drive signal, the input determines the current that flows through a loudspeaker (or other) load. This is rarely used in practice, as it is unsuitable for driving speakers. Using a defined impedance means that the amplifier's output is dependent on the load impedance at any given frequency, but in a way that is predictable. This can be used to advantage, but is most commonly (and IMHO incorrectly) frowned upon. Generally, I would suggest that the amplifier's output impedance should be no greater than the speaker impedance (and preferably less).

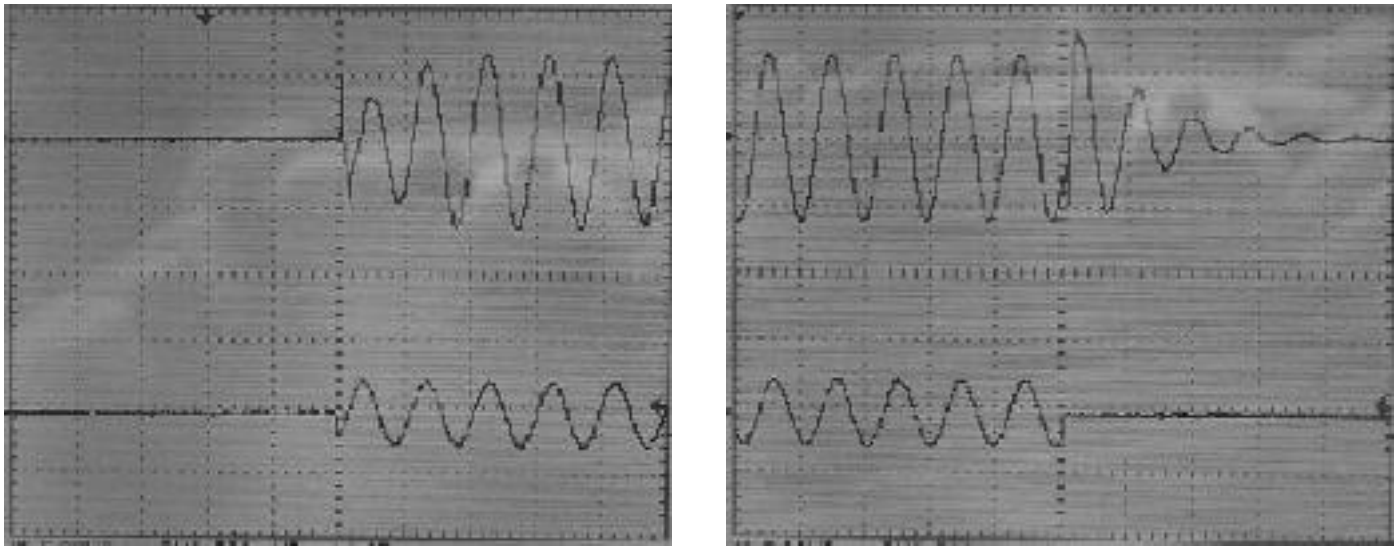


Current Drive - Z = +3 Ohms

The switching transient is still in evidence, as is to be expected - the big spike is a result of the switching point, and is not unique to current drive. The attack is almost perfect, but a slight ringing is apparent when signal is removed. Although this is quite visible, it is inaudible (at least in my workshop), and since bass signals don't normally stop partway through a cycle, it is unlikely to be audible in a typical room, whose response will be far worse than the speaker.

Current Drive at +32 Ohms

This is the same as the previous definition, but in this example, the output impedance was increased to 32 ohms - this is 8 times the quoted impedance of the speaker I used.



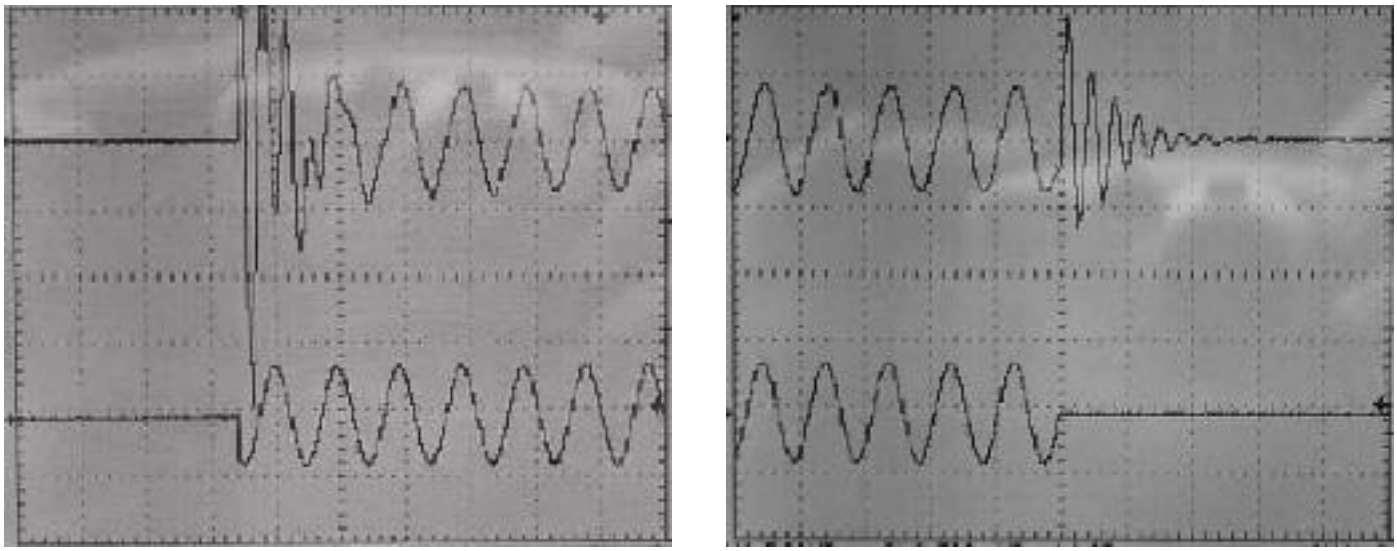
Current Drive - Z = +32 Ohms

This is an extreme impedance, and would never be used in practice. There is a slow attack, with the signal building up to the steady state level. Considerable ringing is apparent when the signal is removed. This is both visible and (in my workshop, only just) audible. This is not a good combination for hi-fi, but may be quite acceptable for a guitar or bass amp (for example), as the colouration simply adds timbre to the sound of the instrument. The switching transient is almost non-existent, as the energy is converted into underdamped cone movement instead.

This is "slow" bass, with a woolliness that may be attributed to some valve amplifiers - especially those with no (or very little) feedback. There are many people who like the sound like this, and this is perfectly OK. Each to his own, and all that. In general, the impedance is too high in my opinion.

Negative Impedance Drive at -3 Ohms

Negative impedance does exactly what it implies - when the load is increased (with a lower impedance), the signal applied to the load increases (i.e. the exact opposite of what normally happens). This results in an intrinsically unstable system, and great care must be taken to prevent the creation of an oscillator.



Negative Impedance Drive - Z = -3 Ohms

The performance of this combination is completely unacceptable in every sense of the term. This combination could never be used in practice, for any reason. There is a vicious attack, with the signal doing something at a frequency completely unrelated to the input signal - unrelated in any way that I can determine, at least. Considerable ringing is apparent (again at an unrelated frequency) when the signal is removed. This is highly visible and audible, and the sound of the attack and decay is grossly inferior to

any other combination. The others (using positive impedance) have some character, but it is related to the signal, and makes some sort of musical sense.

To add insult to injury, the amp decided to become an oscillator (at about 15Hz) on a few occasions, this being one of the risks of negative impedance. It subsided, but was a little disconcerting. I doubt that this is high on the "desirable" list for most audiophiles.

Reducing the negative impedance to -1.5 Ohms stopped the oscillation entirely, but the effect on the attack and decay performance was merely a minor reduction of the many artefacts created, and was still quite unacceptable.

Conclusion

As I mentioned in one or more articles on these pages, I have never found a cone speaker that "likes" negative impedance. Horn compression drivers seem quite happy and this is a test that I may now be forced to perform to find out what it does, and how it affects the sound (other than an apparent improvement in bandwidth).

The net result of these tests indicate what has long been known - that voltage drive remains the best choice for most loudspeakers, regardless of some desirable characteristics of defined current drive. With additional internal damping, moderate current drive can modify the Qts of the loudspeaker driver, and allow an enclosure design that is (typically) larger than optimal for flattest amplitude (Butterworth) response.

There was recently an article in Electronics World, where it was claimed that current drive helps to compensate for the resonant peak and voice coil inductance in a driver. While this is undoubtedly true (I've been doing it for many, many years), the designer must be very careful to ensure that the enclosure is particularly well damped, to avoid "overhang" when the signal is removed. This will typically manifest itself as poorly defined bass, particularly on transients, since the speaker must rely primarily on its own devices for damping.

Overall, this exercise has simply proven that which has already been proven by so many before me ...

- Voltage drive is the best choice in the vast majority of cases
- Moderate values of positive impedance can be useful - if the enclosure is particularly well damped
- Negative impedance is loathsome, and should be avoided

For further reading on the subject of modifying amplifier impedance, see the Impedance article, and Project 56 (Variable Impedance) shows you how to accomplish this.

Introduction

From the editor ...

Project 71 has been a very popular project, and with good reason. Unfortunately, most people who have built it, don't actually know how it works. Jeremy Wolf wrote this article with some considerable consultation from Siegfried Linkwitz and a small amount from

me. Since the Linkwitz transform circuit seems so mysterious (which it is), it is assumed by many readers of The Audio Pages (and others) that it must be complex. The mathematics certainly are, but the principle is not, as Jeremy explains.

There are caveats (of course) and compromises (which are a base requirement in every speaker ever made), but this article explains the overall benefit. I know the benefits well - a sealed equalised subwoofer will simply wipe the floor with anything else, provided that you have done your homework. Now, you don't even have to do that, since Jeremy has done it for you.

How The Linkwitz Transform Circuit Works

Q What is a Linkwitz Transform?

A The Linkwitz transform was developed by Siegfried Linkwitz. It allows you to take a driver in a sealed enclosure that has an Fc and Qtc for that box and lets you "transform" or simulate a new Fc and Qtc for that driver in that box.

Q How does it work?

A Magic

Q No seriously, how does it work?

A It works by creating a precise equalisation curve to compensate for any peaking or rolling off that the driver is encountering. By doing this, a new Fc and Qtc can be assigned to that system.

Actually it is a simulation because you cannot physically change the Fc and Qtc of a closed system without actually making the box bigger or smaller or putting stuffing in the box and making it appear bigger. The following is an example of the above explanation with graphs to help clarify what is being said.

An Example System

Ok, let's assume that you have a driver with the following specifications.

Fs = 33.5 Hz
Qts = 0.75
Vas = 46.1 litres (1.647 ft³)

Now we are going to put this driver in a 38 litre (1.378 ft³) box. This will net us a Qtc of 1.0 This speaker in this box will yield the following results (these data can all be obtained from the Linkwitz Transform spreadsheet on the downloads page, courtesy of True Audio) ..

Fc = 49.6 Hz
F3 = 39.0 Hz
Qtc = 1.000
Vb = 38 litres

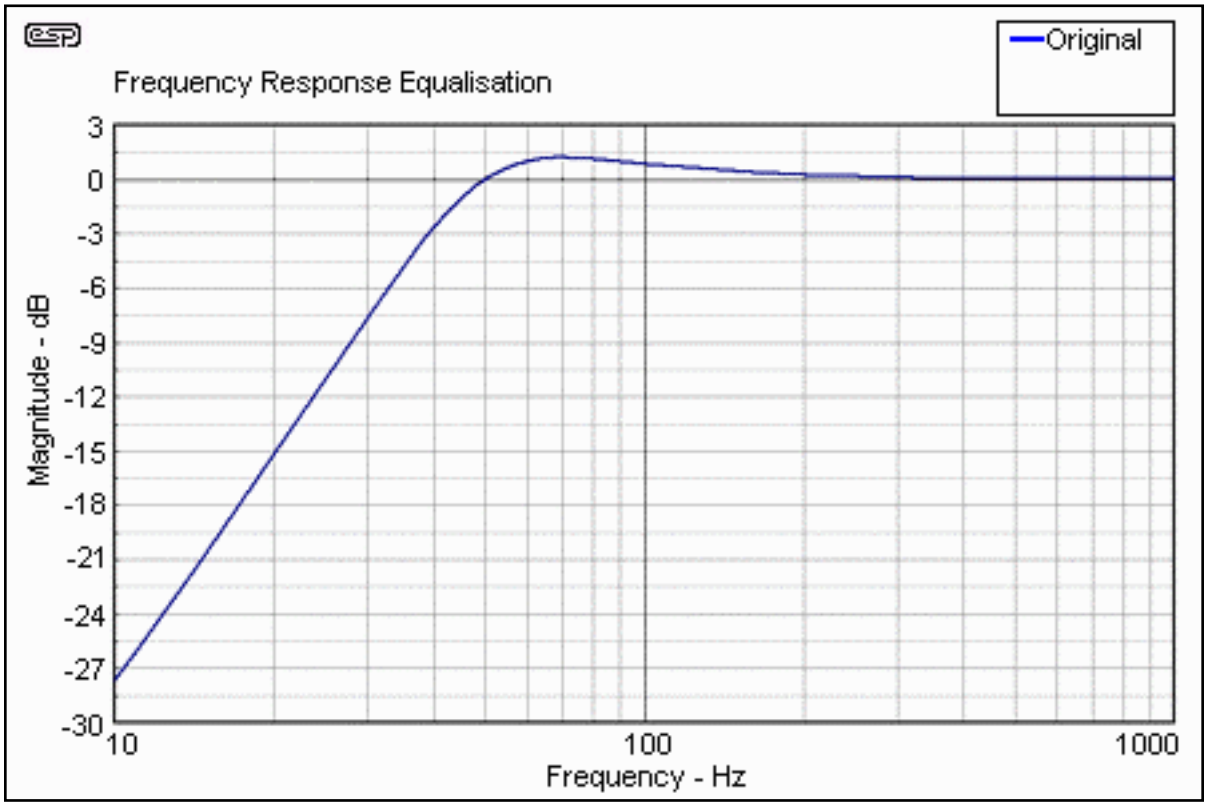

Figure 1 - Unequalised Speaker in 38 Litre Box

If you notice in this graph, there is a 1.2 dB hump before the roll off occurs. While this response is ok for your average listener, we are not satisfied with it and want to change the response. Wouldn't it be nice if we could simply move the Fc down to say 20 Hz and have the Qtc = 0.707 to get a response that looked more like this ...

Fc = 20.0 Hz
F3 = 20.0 Hz
Qtc = 0.707

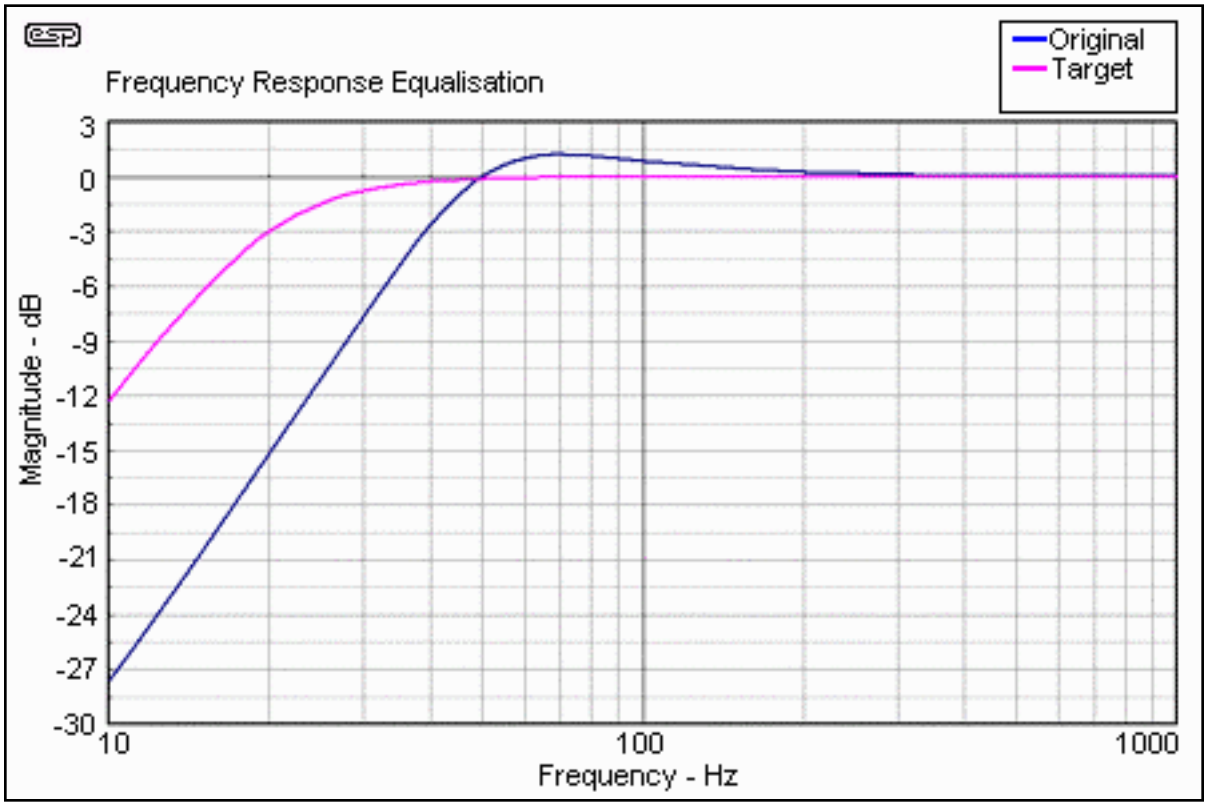

Figure 2 - Equalisation (Transformation) to Qtc = 0.707

As you can see, the magenta line is the newly transformed response. It is much more suited for low frequency reproduction after being transformed. There will now be a much greater output in the lower octaves.

And to show that the Fc is actually down at 20 Hz, here is a response of the same driver in that same box with after being transformed to a Qtc of 1.00 and Fc of 20 Hz. The slight peak causes the response to be 0 dB at 20 Hz, and this response is easily created by the Linkwitz transform spreadsheet if desired.

Fc = 20.0 Hz
F3 = 20.0 Hz
Qtc = 1.000

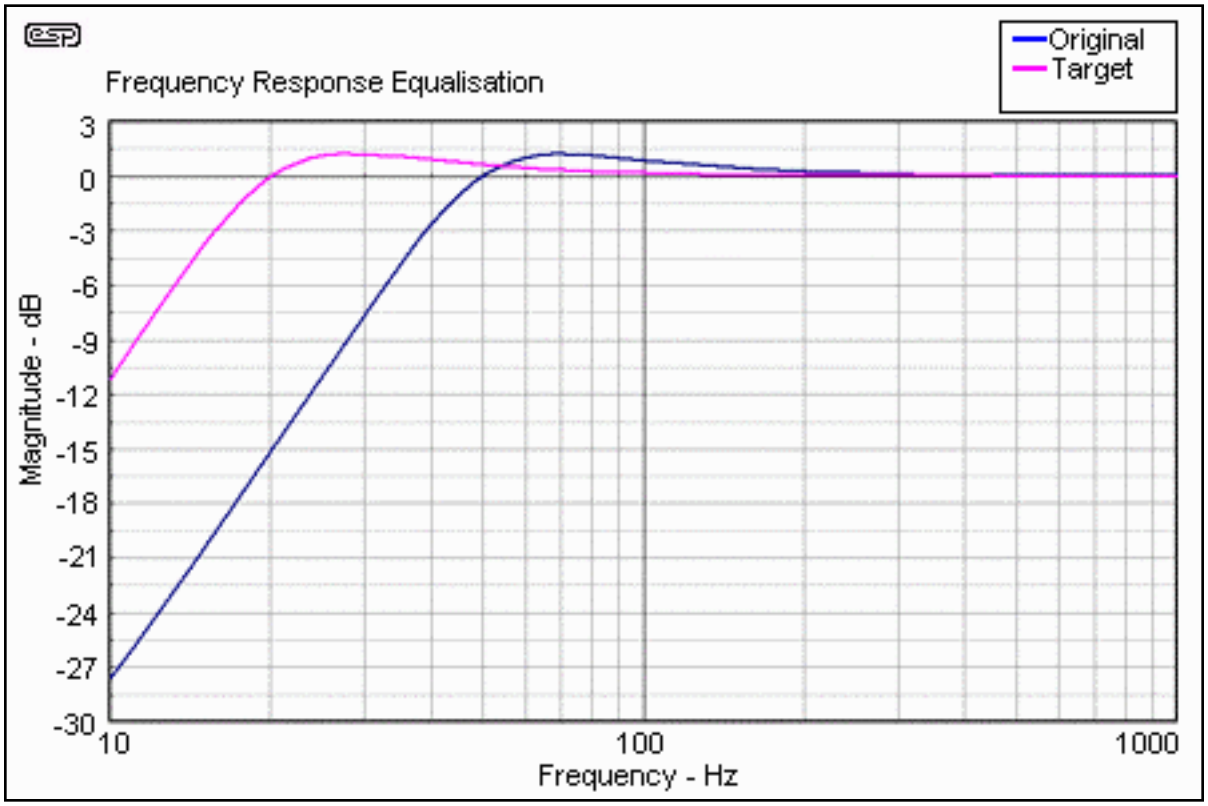

Figure 3 - Equalisation (Transformation) to Qtc = 1.0

Getting back to our desired response of Qtc .707 and Fc of 20 Hz. The graph in Figure 4 shows the compensation that the Linkwitz transform is using in order to flatten out the response curve of our driver.

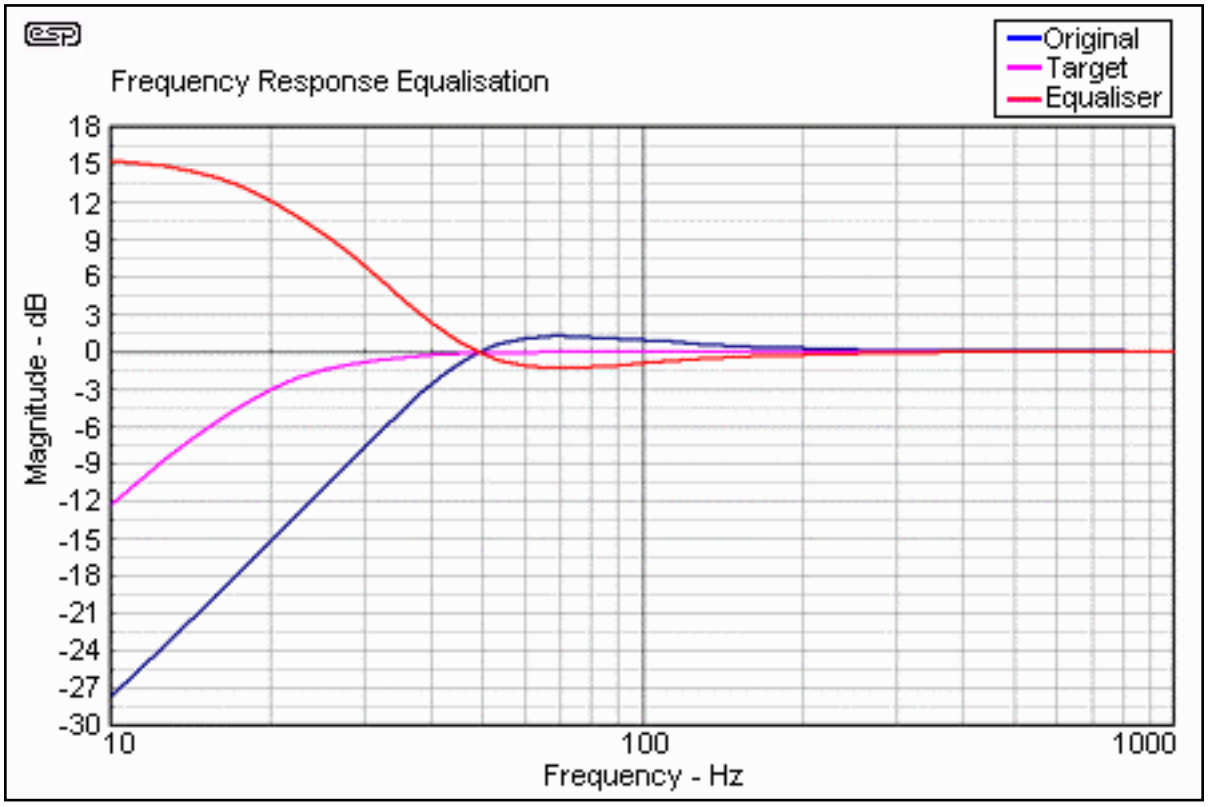

Figure 4 - Equalisation Applied by Linkwitz Transform Circuit

The blue line represents the original driver with a Qtc of 1.0 and an Fc 49.6 Hz, F3 of 39 Hz. The red line represents the equalisation curve that the Linkwitz transform is supplying to the amplifier in order to compensate for the new Qtc and Fc. The transform is cutting out 1.2 dB in order to compensate for the Qtc of 1.0, which is causing a 1.2 dB, boost around 70 Hz. It is then providing boost at the lower frequencies at a rate that is equal to the natural roll off of a sealed enclosure. Instead of rolling off at 12 dB an octave, the speaker is being forced to maintain a flatter response due to the amplifier giving it a lot more power at the lower frequencies. For example at 20 Hz, the amplifier is giving the speaker an additional 12 dB of gain, or 16 times more power than at frequencies above 50 Hz.

Getting this kind of response out of a sealed enclosure setup requires some tradeoffs. You will be giving up some of the overall SPL producing capability of the driver because of the excursion overhead needed at the lower frequencies.

Compromises

If your speaker is flat down to 50 Hz and you want to extend one octave below that to 25 Hz then you will lose 12 dB of overall output capability when producing sound at 25 Hz because you are using up all of the driver's excursion and most likely power handling capability too.

We'll say that we have an imaginary speaker that has these basic parameters ...

Efficiency	88 dB/m/W
Xmax	4 mm
Max Power	250W

The driver is in a sealed box with a Qtc of 0.707 (optimally flat). We'll also say that it is flat down to 50 Hz, and at 50 Hz it is capable of producing (just under) 112dB SPL at full rated power. Let's say that the speaker is in a sealed enclosure, and an equaliser will be used to obtain the last octave (down to 25 Hz).

Below the Fc of 50 Hz the speaker will roll off at 12 dB / octave. That means at 25 Hz, the output of the speaker will only be 100 dB. To obtain the same 112dB output as before, you will need 4 times the excursion and 16 times the power (i.e.4,000 Watts!) as

at 50Hz. This is because for every octave lower that you want the speaker to produce you need 4 times the excursion, and in order to obtain the excursion in an equalised system, you must have 16 times the power. To put this another way, excursion is equal to the inverse square of frequency. Half the frequency, four times the excursion, one quarter the frequency, eight times the excursion (etc.). The power requirement is the square of the excursion.

So, now that our speaker does not roll of at 12 dB / octave (because of the equaliser) and maintains a flat response to 25 Hz, it will need to use 4 times more excursion and 16 times the power to produce 25 Hz at 112 dB.

Now comes that tradeoff part that I was talking about before. The driver is using all of its power rating and 1 mm of its 4 mm of Xmax to produce 112dB at 50Hz. Now we want to achieve a flat response down to 25Hz by using the Linkwitz transform. That means we will be trading off some of our 112 dB SPL to gain some low frequency flat response. The speaker will be using 4 times the 1 mm Xmax or 4 mm of excursion to produce this 25 Hz frequency. The power needed is well in excess of the speaker ratings, so must be limited to 250W.

If we want to use this speaker in the transform, we now need to trade off 12 dB total maximum output for a total maximum output of 100 dB that is flat from 25 Hz up. That's not too bad of a trade in my opinion. But remember, this is only an imaginary driver that I made up, not a real world example, although in reality, most "real" speaker drivers will not be all that far off. Every 3 dB increase in SPL requires double the previous amount of power. And in our case we needed 12 dB of gain which is 16x more power.

The two things to remember from this example are ...

- every 6 dB increase in loudness requires 2x the excursion and 4 times the power
- every octave lower you go requires 4x the excursion and 16 times the power

---

Power Compression

Power compression is another aspect that should be considered. This occurs whan any loudspeaker is driven with a significant amount of power. The voice coil heats up, and the available power is reduced accordingly. Depending on the program material, you may easily lose 6 dB of SPL because of power compression (assuming that the system is being pushed to its limits). Power compression cannot be compensated for by using more power, as it is dynamic in nature. The effects are (perhaps surprisingly) not as

noticable as one might expect, since sustained high power at extremely low frequencies is rare in virtually all normal program material.

Fortunately, this is not as big a problem as may be imagined, since typical low frequency energy levels are actually surprisingly low most of the time (see Power Distribution below). Home theatre systems will be called upon to reproduce large amounts of relatively deep bass, but only for short periods at a time.

With most music, there is very little energy below 40 Hz, so power and excursion are not normally a problem. Pipe organ music is an exception - the 64' pipe on a full pipe organ is 16 Hz, but it is not used a great deal - in some cases because of the structural damage it does to the building housing the organ! If you are an aficionado of such music, I suggest that you use the largest box you can, with a very large driver. It may be wise to reinforce your home while you are at it (and no, I'm not joking).

Guidelines

With the explanation and examples out of the way, you might be wondering what kind of specs to look for when choosing a driver. Here are some guidelines that should help you.

- Look for a driver with a BIG linear Xmax. The driver should have a one-way Xmax of over 12 mm (0.5").
- Look for a driver that is 300 mm (12 inches) or bigger. Remember, that producing low frequencies is all about displacing large quantities of air.
- The driver should have a high power handling capability, in my opinion at least 300 watts RMS. The driver will need a lot of power to hit those low frequencies.
- The driver should also have a low Fs. It should be the lowest you can find. The reason for this is because you want the transform to use as little gain as possible to reach the lower frequencies. The lower the Fs of your driver, the lower the Fc of the closed box system will be and the lower overall gain the circuit needs to apply.
- And finally the driver should have a high sensitivity rating, unless you have a really big amp to power it. The higher the efficiency rating of the driver is, the less power it will take to reach those insanely low frequencies. If you have a driver that is 89 dB sensitivity and a driver that is 92 dB sensitivity, the 92 dB driver will require half as much power as the 89 dB unit, for the same sound pressure level.

These guidelines are just that, only guidelines. One thing that you need to be careful of is the excursion and the power the driver can handle. I say this because these are the two that ***will*** damage your precious driver if you exceed them by too much. When I first

did my setup, I thought that a single 300 mm (12") driver would be more than adequate based on my equations for excursion and amount of surface area they had. I was wrong because of my seating location and the room that I was placing them in. Don't get me wrong, a single 300 mm sounds awesome, but 3 x 300s is absolutely unreal because I can hit 105 dB at 25 Hz from my listening position. My listening position also happens to be the place with the best bass response in my room.

Power Distribution (by Gareth Abrey)

I was in the process of building a Linkwitz Transform cct for my 305mm (12") sub. ESP said in the articles about ELF and EAS that low frequency content in music has much lower power levels than the power calculations would suggest. I decided to investigate this, and digitised some tracks off various CDs with various styles of music.

My sound editor gives the WAVE graph amplitude in 16bits (-32000 to 32000). I then performed a low pass filter of 40hz on the track and found the highest peaks, then compared them to the highest peaks of the full range signal, and did a dB calculation ...

20 log (V) (where V is the 16bit amplitude)

Typically, I got peaks of +/-30 000 for the full range signal, and only +/-4000 for the < 40hz signal. This is a 17.5dB difference. The results are tabulated below.

Music Type	**Relative Level at <40Hz**
Rock music	- 13dB
Maria Carey Song	- 15dB
Rap Music	- 14dB
R&B song	- 12dB
Rave track	- 12dB
Second Rave Track	- 21dB
Vinyl Bass Track	- 11dB
Rave track with bass sweep	- 9 dB
Average	**- 11.875 dB (12dB)**

These figures would suggest that boosts of around 10-12dB are possible with the Linkwitz circuit, before any extra amplifier power is needed above that which is required for the frequencies above 40hz.

Editor's Notes

1. There is a strong case for applying a highpass filter at between 5 and 15 Hz. This prevents excessive excursions at sub-audible frequencies, and offers a measure of driver protection. Ideally, this filter would have a steep slope (12 dB / octave minimum), but a simple 6 dB (first order) filter can still be used. The filter may be before or after the Linkwitz transform circuit, having the same effect regardless of physical position.

Use of any filter will have an effect on the actual response of the completed system, however this is generally small, causing perhaps a 2 dB error at 20 Hz. It is probable that virtually ***any*** room will create errors many times this figure, so it can generally be discounted.

2. There is a recommendation in the spreadsheet (see downloads page) that great care is needed with a maximum boost over 20 dB. I think that this is understatement, and care is needed with any boost above about 10 dB. The increase in power and cone excursion becomes extreme, although with most music, the actual energy level of signals below 40 Hz is relatively low.

There are some exceptions to this, and it should never be assumed that you won't need the power or excursion - someone ***will*** eventually prove you wrong.

3. You must remember that the box is sealed. The pressure exerted by a 380 mm (15") cone with an Xmax of 10 mm will literally split the seams of a box that is not sturdy enough (it apparently happens quite regularly with a certain well known subwoofer using a similar principle). The box must be as strong as you can make it - screwed, glued, and substantial internal cleats at all joins are essential. There is no such thing as a box that is too strong, but make sure that you account for the volume occupied by the strength members when you do the calculations). Bracing is usually not needed, since the frequencies are so low that panel resonance is unlikely if the unit is a self contained subwoofer. All panels should be of 18 mm (minimum) sturdy ply or medium density fibreboard (MDF) - do not use chipboard, the box will not hold together!

4. The use of a small (say 5 mm) vent stoppered with felt to present a significant resistance to airflow is also a good idea - especially if the woofer does not use a vented polepiece (via the dustcap). This allows air pressure to equalise slowly, since you will have to expend considerable effort to make sure that the box has no air leaks. If present, they will whistle or make some other equally undesirable noise when the subwoofer is in

use. It is unlikely that you will be able to blame the dog for these noises (in case you thought you might get away with that excuse :-)

5. The Linkwitz transform circuit is available as a PCB with full construction details. The board incorporates a 15 Hz filter (this can be changed) and uses one dual opamp. To have a look, see Project 71.

6. My thanks to Jeremy for putting this article together. His efforts have saved me an enormous amount of time, and the article is written directly for the beginner or relatively non-technical reader. As many of you may have noticed, this is something I often have trouble with :-)

7. I would also like to thank Gareth for his contribution, which is a useful addition. The power calculations he did are somewhat more scientific that the "gut feel" method I had applied - even though the net result is much the same.

Update Information

Jeremy sent me an e-mail from a reader, who pointed out a couple of errors in the calculations for excursion and power. I have amended the "offending" section, which is now (hopefully) correct.

14 Sept 2002 - Added Gareth's power calculation information.

1.0 - Introduction

The Neville Thiele Method™ * (or simply NTM™ *) crossover network has been described in AES papers and elsewhere, but there is scant information available to most of us about exactly what it is and how it works. There have been claims that it is anything from 48dB/octave to 100dB/octave, and that it may replace the Linkwitz-Riley crossover for general use.

What is not generally available is a description of the filter type, or any information about how it works. This article hopes to rectify that, and de-mystify the hype that inevitably builds up when something new and exciting is first introduced, but with little supporting data to allow an informed choice.

I must confess that I was mightily perplexed when I saw my first NTM crossover - it was claimed to be 100dB/octave, the published frequency response I saw first showed 24dB/octave, and the circuit had far too few opamps and caps to approach any conventional filter greater than 24dB/octave. There was no opportunity to try to analyse the circuit or run any tests, since it didn't belong to me, wasn't in my workshop, and I only had the opportunity to have a brief look inside the case.

It was only when I saw the real frequency response graph of an NTM crossover that the penny dropped, and I recognised that it was probably an elliptical filter.

2.0 - Description

The descriptions that one usually finds describe a filter network and a notch filter. These are combined to produce a filter with a greatly accelerated rolloff slope. Part of the description from a brochure by BSS audio [1] states the following ...

> A Neville Thiele Method™ Crossover Filter (NTM™) is a new type of electrical/acoustical filter offering significant performance advantages over all previous crossover filter types in audio applications.

The article continues with a description of 'how it works' - while not actually giving any figures whatsoever - just the diagram referred to ...

> The NTM crossover uses a unique notched response to achieve a very steep roll-off rate outside the pass-band. The 4th order Thiele crossover amplitude response looks like the diagram overleaf. You will see that notches in the responses speed-up the rate of roll-off. Beyond the notch, the response rises again, but remains respectably attenuated.

I object (a bit) to the term 'unique' in the above. The filter type is described in 'The Active Filter Cookbook [2], and is commonly known as an elliptical or Cauer filter. There is no denying that this filter type is rather obscure (not too many will have heard of it), but it is neither new nor unique. It is however, an *extremely* clever application of an old technique, with some lateral thinking and necessary adaptation to maintain a *flat* summed response. Its use in a crossover network is certainly new, and the application is unique (if not the filter type itself).

The frequency response is shown below, and this is an almost perfect match to that shown in the BSS brochure. The frequency and amplitude scales are different (from the BSS graph), but the response is virtually identical. For comparison, the response of a Linkwitz-Riley filter is also shown. Not shown is the summed response, which is completely flat for both filters.

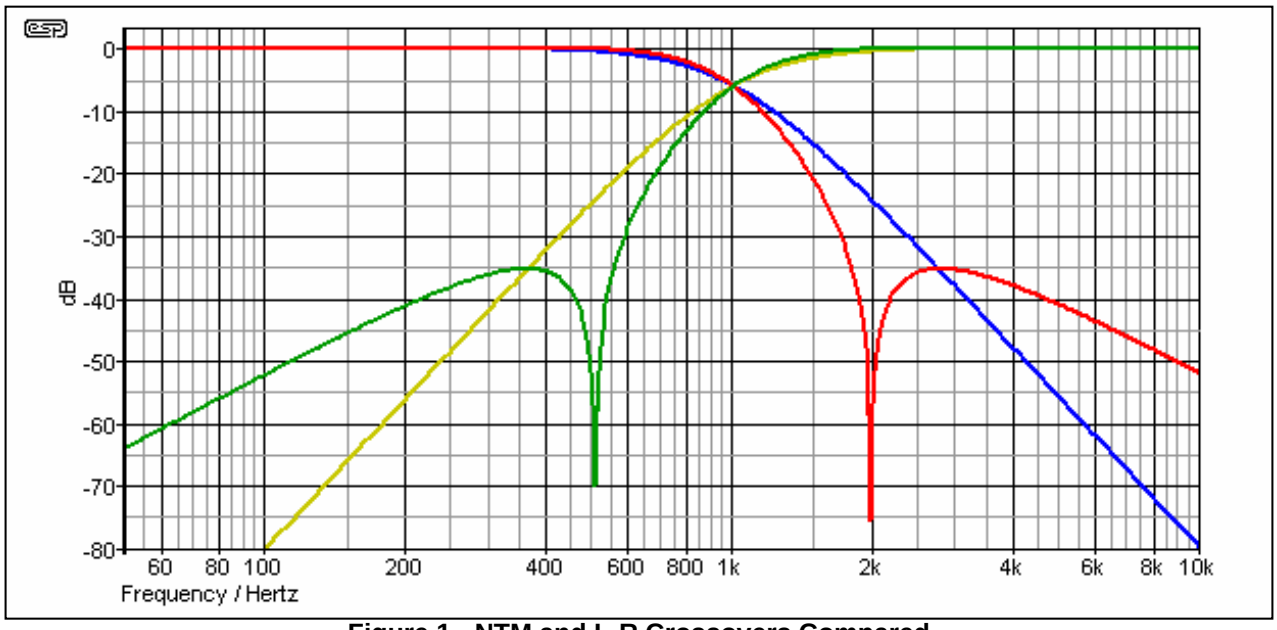

Figure 1 - NTM and L-R Crossovers Compared

The NTM crossover response is shown in green (high pass) and red (low pass), while the L-R equivalent is in a yellowish colour (high pass) and blue (low pass). It is undeniable that at one octave either side of the 1kHz crossover frequency shown, the response is better than 60dB down from the nominal output level. Looking at the L-R filter by comparison, at the same frequency it is only 30dB down. Unfortunately, the response of an elliptical filter rises again after the notch - again readily visible.

About ½ an octave above and below each notch, response is back up to about -36dB (equal to the L-R), and beyond

that performance is inferior to the Linkwitz-Riley implementation. Ultimate rolloff for a fourth order elliptical filter is 12dB/octave. None of this is shabby by any means, but it does show that some of the descriptions used in advertising literature are rather misleading once the full details are known.

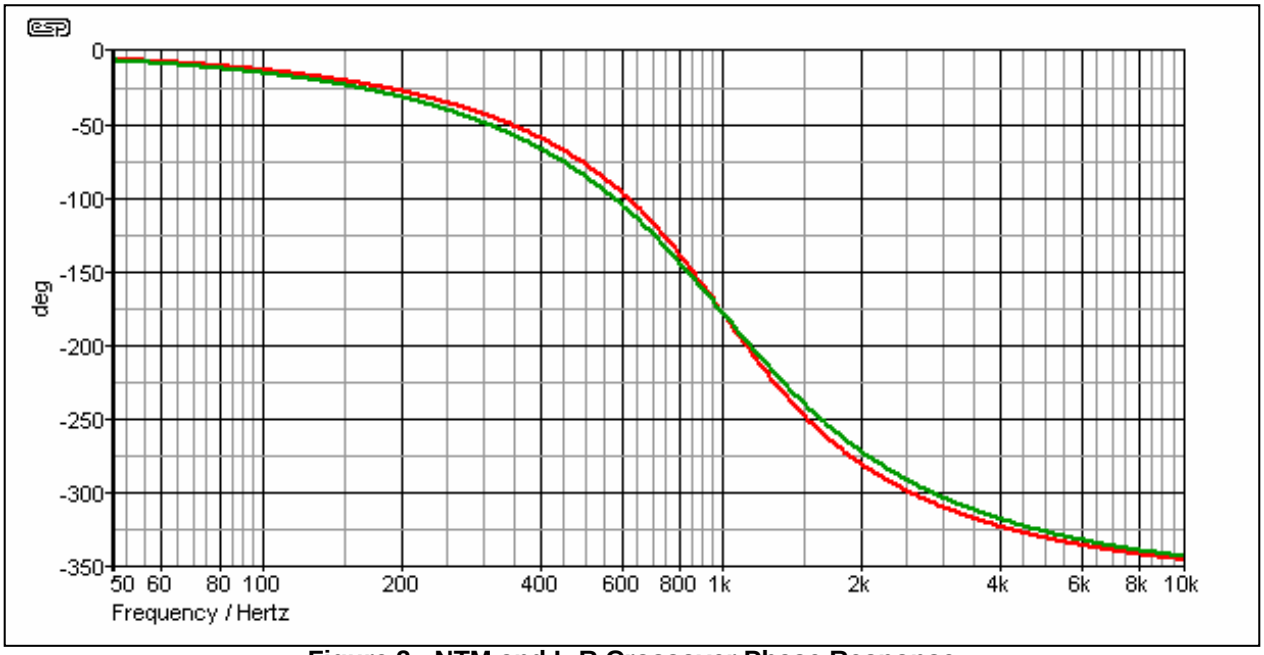

Figure 2 - NTM and L-R Crossover Phase Response

There is not much phase difference between the two - they are (for all intents and purposes) the same in this respect. The red graph is the NTM filter, and the L-R is shown in green. Both filters have a 360 degree shift across the band, with the NTM filter being *very* slightly worse in this respect than the L-R filter.

In real terms, the difference is marginal only, and should not be audible. Despite the apparently radical phase shift, both drivers remain in phase with both filter types, and the phase shift in itself is normally inaudible (despite some claims to the contrary). While there are circumstances that can make phase shift audible, such a discussion is outside the scope of this article.

2.1 - The Circuit Diagram

Please note that the diagram shown below is taken directly from my simulation. It is not (and does not purport to be) the actual circuit of an NTM filter, but I strongly suspect that it will be rather similar. I have not seen the actual circuit, nor has it been traced from an actual working NTM crossover, so the 'real thing' could possibly be completely different.

The general principle of an elliptical filter is/should be pretty well known in engineering circles where filters are used extensively, and it consists of a conventional second order filter, followed by a second order state-variable filter.

The high pass and low pass outputs of each state-variable filter are summed to give the response shown above. The values shown are those used in the simulation. The hardest part of implementing a filter such as this is component 'sensitivity' - the requirement for close tolerance is increased compared to (say) a more conventional Linkwitz-Riley crossover network.

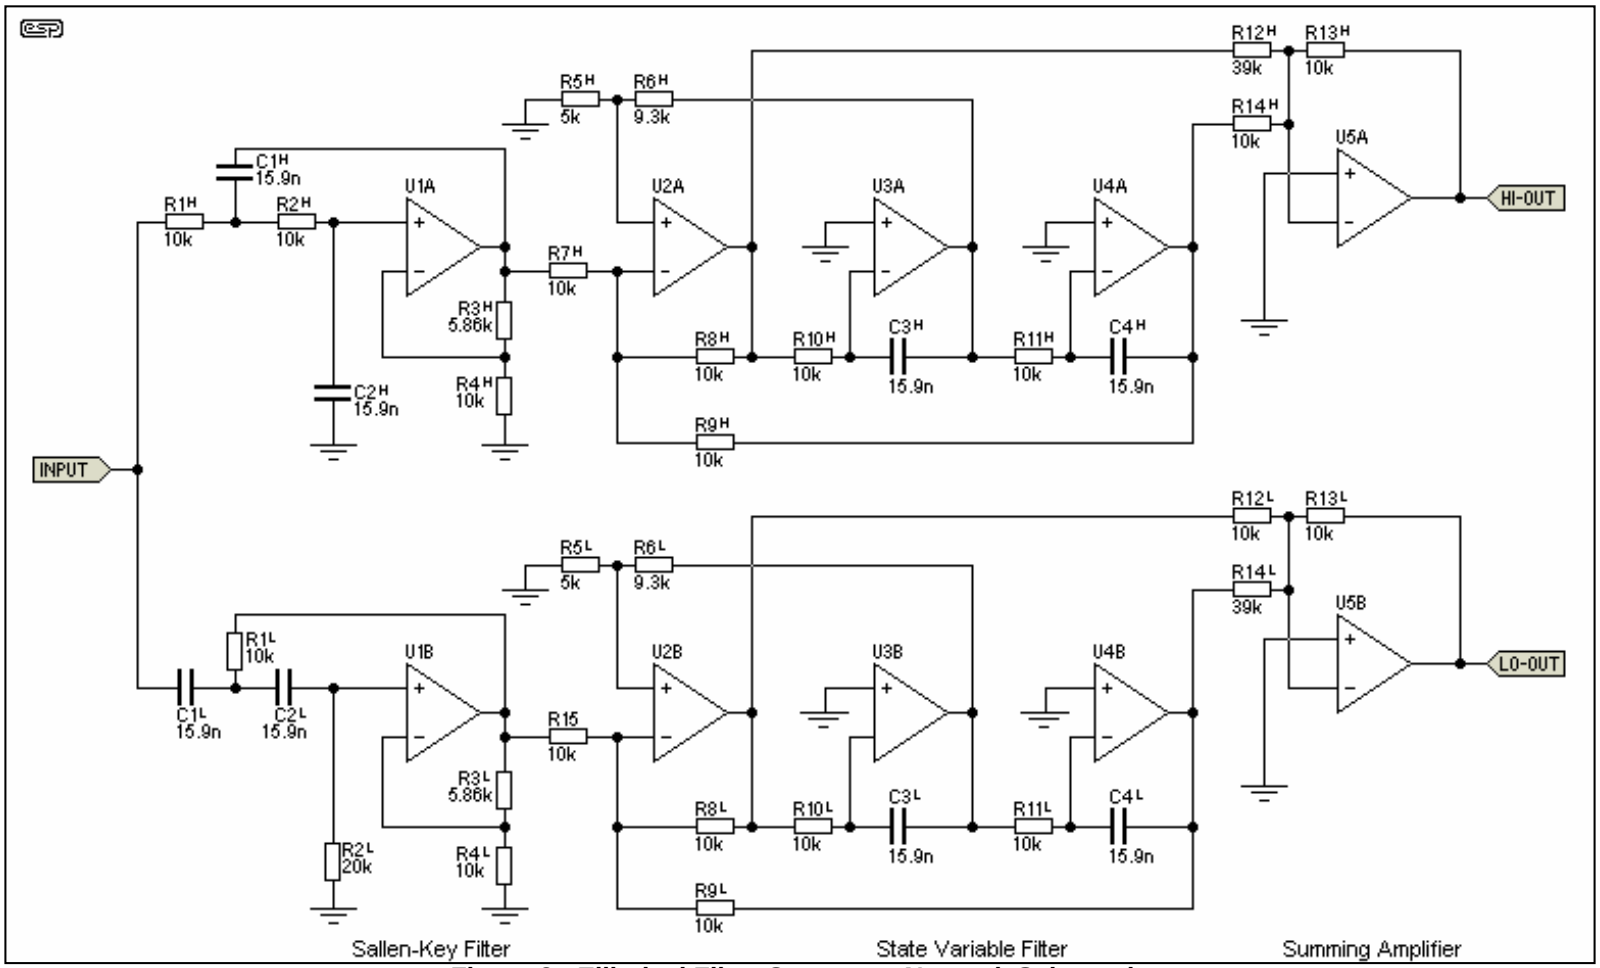

Figure 3 - Elliptical Filter Crossover Network Schematic

As you can see, the capacitor values are non-standard, but that was done to obtain a nominal 1kHz crossover frequency. This was selected because it is a defacto standard when showing general filter responses. It is not a useful crossover frequency for real use. Phase response is shown above, and is almost identical for both filters (NTM and L-R), and the ripple in the summed outputs is less than 0.2dB.

2.2 - Circuit Explanation

The circuit itself is relatively conventional for this filter type, but there are some important variations and points that need some explanation. The first stage (around U1) is what is known as an 'equal component value' Sallen-Key filter. Unlike the standard circuit such as that shown in P09, the Q of the circuit is determined by the gain of the opamp, rather than the filter component values. This allows the circuit to use the same capacitor values as the next stage.

The second filter is a state variable type, using U2, 3 and 4. The filter frequency is set by R10, R11, C3 and C4, and the Q is adjusted by R6. The Q needs to be somewhat higher than for a standard filter, because the summing amplifier (U5) adds a selected amount of (out of phase) high pass to the low pass filter (and vice versa). This creates the notch, and R12 determines the notch frequency.

For such a complex filter, it is remarkably tolerant to component variations, but predictably less so than a fourth order L-R filter of the type used for Project 09.

In case you were wondering, the circuit shown will work, but the frequency determining components will have to be changed to get the frequencies needed rather than the 1kHz shown. In answer to the question (which *will* get asked at some stage) "How do I change the frequency?", the answer is that you will have to figure that out for yourself. This is not (and is definitely not intended to be) a construction project ... it is an explanation of how the circuit works. No

more, no less.

3.0 - Conclusion

This article has hopefully removed some of the mystery behind the NTM crossover network, and shows what can be achieved using some lateral thinking. The rise in amplitude beyond the notch is rather unfortunate, but at -35dB represents an effective power that is over 3,000 times (3,162 to be exact) less than the maximum applied.

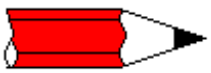
This means that for an applied 100W input power to a loudspeaker driver (via the crossover of course), the worst case out-of-band power level (> 1 octave) is only 31mW. This is further attenuated at a rate of 12dB/octave. At 3 octaves from the crossover frequency, (125Hz and 3kHz), the out-of-band power level is down by 48dB - 1.58mW for 100W input. This is insignificant.

By comparison, the L-R crossover is at -24dB one octave from crossover frequency (400mW), at two octaves it is at -48dB (as above - 1.58mW), and at three octaves it has an output of -72dB (6.3uW) - again, assuming 100W input power to the loudspeaker drivers. For all practical purposes, this is also insignificant.

The end result is that loudspeaker drivers can be pushed closer to their limits, because the out-of-band power is reduced. There is usually no good reason to push any driver that hard in a domestic system, but it can result in a useful improvement for high powered professional applications.

The greatest benefit is obtained at between ½ octave to 1 octave either side of the crossover frequency, with an improvement of around 10dB at the ½ octave frequency, increasing dramatically to the 1 octave point. This represents a significant improvement, but only where drivers are being pushed to their limits. In a domestic system, all drivers will (or *should*) generally have sufficient 'spare' bandwidth to be able to cope with the out-of-band power levels with no stress whatsoever.

Overall, the circuit is very impressive though - not so much because of the cunning application of elliptical filters, but more because of a complete re-think about the way such filters are normally designed and tuned. The Neville Thiele Method™ certainly delivers a very worthwhile improvement in overall crossover network performance.



Please note that the NTM crossover network is patented, so commercial use of the information presented here will infringe patent rights and may result in a law suit or other potentially expensive unpleasantness.

Also, as pointed out above, the circuit shown is **not** taken from any literature, service manual, physical crossover or anywhere else. It is my interpretation of a circuit that will achieve the same result as an NTM crossover produced by a licensed manufacturer.

Based on extensive searches, it would appear that this is the first published circuit (for general viewing) that achieves the results claimed for the NTM crossover network. It remains to be seen if I am asked to remove the circuit (since I haven't used any proprietary information, no laws have been broken - the details published here are all my own work).

Introduction

The speaker system shown here is part of my own system, and is intended for tri-amping, so there will be no pasive crossover details. I am using the Linkwitz-Riley crossover (Project 09), my existing amps for the bass and midrange, and (probably) Project 19 LM3876 amp for the tweeters (this is still to be decided at the time of writing).

The enclosures are designed as mirror image pairs for the best imaging. Midrange and tweeter drivers have been carefully located so that diffraction effects are minimised, by ensuring that the distances are different from the centre to each edge of the baffle.

The drivers are as described below, with each having been selected for response, linearity and power handling. Each is excellent in it own right - not necessarily the most expensive, but all have very good performance.

Table 1 - Driver Details

The Focal 5K4411 is described as a 5¼" Polykevlar Midrange with phase plug, and although I am normally not a great fan of Kevlar, the cone is well treated to prevent the normally nasty breakup effects at high frequencies.

Initial Assembly

The cabinets are made from 18mm Medium Density Fibreboard (MDF), with a laminated construction for the baffle. Figure 1 shows the laminating in progress - I used every clamp I could find to keep them together.

Figures 1 and 2 - Laminating the Baffles ... Enclosure, Half Assembled

The boxes are very solidly braced, and the various stages of the construction are shown below. The midrange is in its own sealed enclosure of approximately 14 litres, and the total volume for the woofer is 35 litres. The tweeter is in its own tiny enclosure, fully isolated from any back pressure from the midrange.

Midrange and tweeter are to be surrounded by a felt-filled cutout, and the front edges of the enclosure will be rounded to reduce refraction. All drivers are mounted as close to each other as possible. To this end, the bottom of the tweeter has been cut off so it sits closer to the midrange than would otherwise be possible. This necessitated the separate tweeter enclosure, since the mounting flange no longer seals the tweeter properly. No grille cloth will be used, as the frame would cause refractions I would much rather be without.

All drivers are secured with metal thread screws and tee nuts. The latter are very firmly attached and glued in position to ensure that they don't come off while I am assembling

the system. Those for the woofer are visible in the photo. The brace above the woofer and the base and side of the midrange enclosure are also seen. The small section beside the midrange enclosure forms part of the main cabinet, and will be stuffed full of fibreglass before final assembly.

The enclosures are quite intricate, and represent a significant amount of work (not to mention sawdust!). As always, the initial preparation takes the longest in terms of assembly. Once all the panels are cut, holes drilled and rebates rebated, the actual assembly is fairly fast, and the boxes were brought from basic bits of MDF to their current status in less than one day. The preparation took the best part of a full weekend.

Figures 3 and 4 - Rear View of Cabinets ... Front / Rear Views

In Figure 3, you can see the rear view of the two boxes (upside down). The block of plywood below the midrange cutout forms the tweeter enclosure, and again, you can see the tee nuts glued in position. At this stage, no corner reinforcements or "minor" internal braces have been added - these are being prepared from various offcuts, and will be added next.

The front view of the left speaker shows the cutout for the felt around the midrange and tweeter. The right box is a mirror image. As you may be able to tell from the photos, these shots were taken shortly after assembly - the glue is not dry yet. All panels are glued and screwed or nailed - the selection of screws or nails was based on the stage of assembly. A nail gun is very fast, and does a great job, but is fairly useless in the first stages of the assembly where initial alignment is critical.

Final Assembly

Now that the boxes are basically assembled, the corner braces, panel braces and rear panel support trim can be added. Figure 5 shows one box from the front, with the drivers mounted to check that everything lines up. Once the backs go on, there is nothing that can be done about a misaligned brace or inadequate clearance, so everything has to be right before this happens.

The colour of the Focal driver's cone is a little unfortunate, but the system is being put together for the sound, with appearance taking second place. Despite the foregoing, the screw heads securing the drivers *will* be painted black before the boxes are finished. The recess for the felt can be seen in Figure 5, as can the rounded edges (only at the front - the others are "conventional", and just lightly sanded to take off the sharp edge that would be too easily damaged).

Figure 5, 6 and 7 - Front and Rear View of Box Showing Drivers and Braces

The internal braces were installed using wood glue, but this was reinforced after the photos were taken, using automotive body filler. This is very strong, and sticks to wood extremely well, providing a very well braced and extremely sturdy box. Don't underestimate the usefulness of "bog" for cabinet making - it is a better adhesive and better gap filler than almost anything I have ever used. Highly recommended :-) Unfortunately, it is no good with solid timber that is to be stained and varnished, but it can be veneered over perfectly well.

Note that the braces are all at an angle to help break up any internal standing waves. Considering the amount of fibreglass that will be used, this is probably unnecessary, but

it is worth the very minor effort. Note also the carpet that is glued and stapled to the bottom of the midrange enclosure. There is also some carpet wrapped around the tweeter enclosure "block" to prevent diffraction within the box itself, although this cannot be seen in the photos.

At the bottom of the box, the tee nuts for mounting the stand can be seen. As with all tee nuts in this project, they are glued into position so they cannot come loose.

Drawings

Not a great deal here - the boxes were designed pretty much "on the fly", but knowing exactly what I wanted. The drawing came last - basically after the boxes were completed to the degree shown above. This is not a complete drawing - braces and the side of the midrange are not shown, but these are not overly critical (perhaps surprisingly, or perhaps not). All dimensions shown are in millimetres, and the drawing is not to scale.

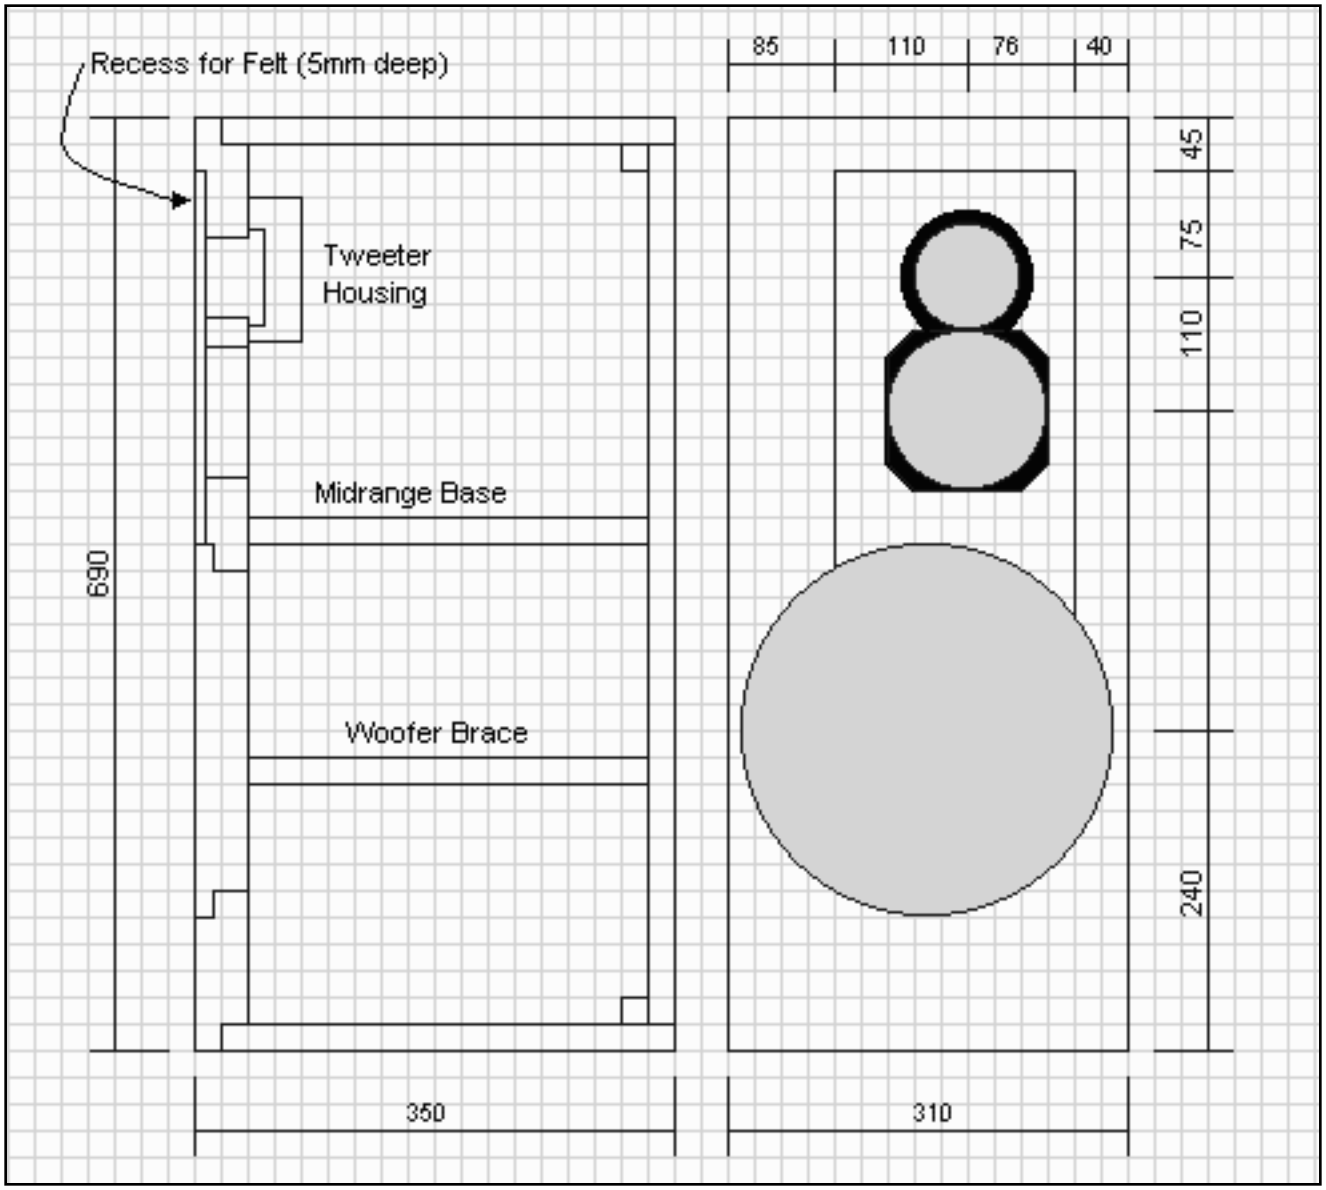

Figure 8 - Side and Front Elevations

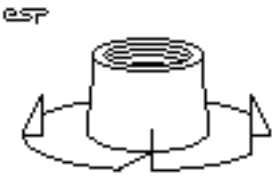
As noted above, the midrange housing is about 14 litres, so it is quite easy to work out where the side panel goes - simply determine the distance based on the volume of the enclosure.

The actual volume becomes slightly less than the calculated value, because of the braces and the volume of the speakers themselves. The response will be plotted (then measured) in the next episode. In the meantime, the photos below show the boxes with all the fibreglass in place, both with and without the back installed. The enclosures are now ready for final sanding and finishing (after a listening test, of course :-)

Figures 9 and 10 - All Fibreglass Installed ... One Back In Place

As can be seen, the packing is extensive. The panels are all very acoustically dead, and a full test for airtight sections will be performed before the drivers are installed. I am not entirely sure how to do this properly yet, but I'm sure I will think of something before next weekend :-)



The cutout for the connector panel can be seen in Figure 10, and again, this is held in place by tee nuts that are glued in place. It is a source of considerable annoyance to many reviewers that so many speaker manufacturers use particle board screws to attach the drivers to the baffle - and this includes many "high end" models. While my speakers will not get "reviewed" (other than by friends in the industry), I do not think that anything less than a metal thread screw is adequate for fastening drivers - or anything else for that matter. The combination of the metal thread screws and tee nuts is almost indestructible - the box will rip apart before the screws fall out! The drawing of a tee nut may help those who don't know about these wonderous little fasteners. Drill a hole and hammer it in (and use a little glue to ensure it *never* falls out).

Driver Maths

As some readers may be aware, the amp I am using at present has an output impedance of about 2 ohms. This has the effect of increasing the Qts (total Q) of the drivers, which was useful in my current speakers, but is equally valuable with the new drivers. I have not determined the exact impedance I will need yet, but the basic results that I will need are shown below.

Visaton GS-250 Woofer

Qts - 0.28 Standard, 0.34 Desired

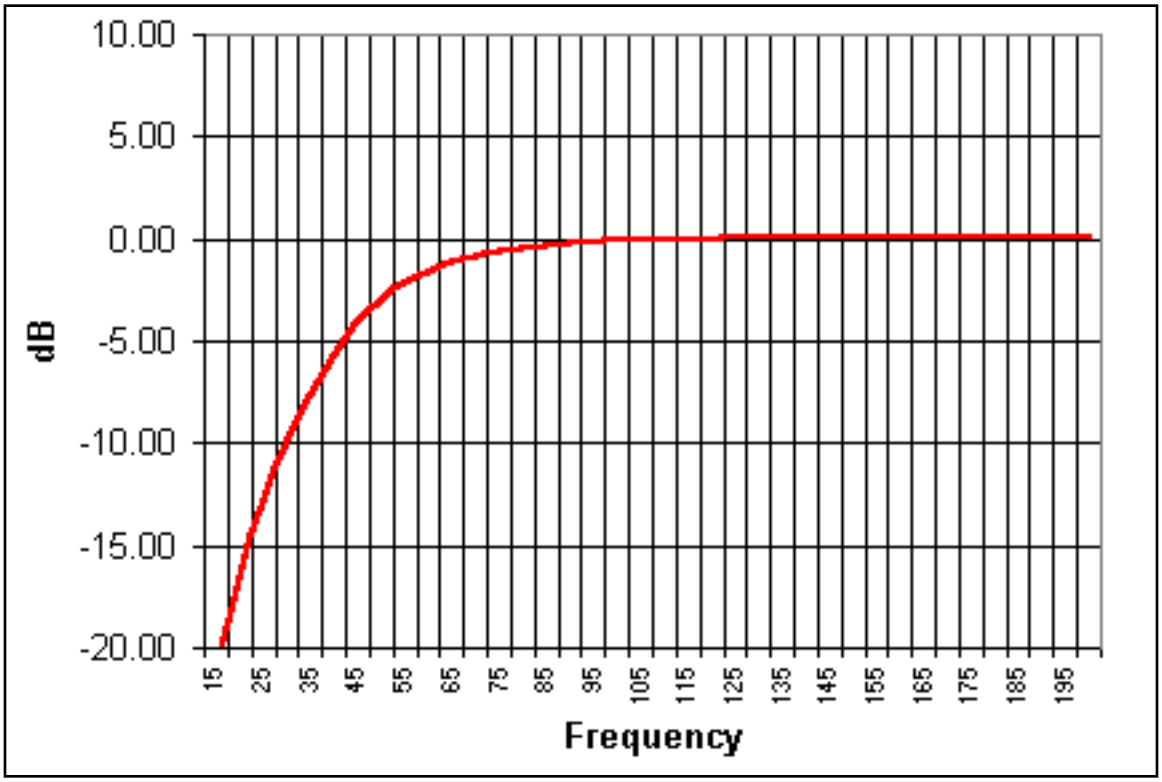


Figure 11 - Desired Woofer Response (Qts = 0.34)

This is about as good as it gets, the response is much more desirable than it would be if driven from a "conventional" amplifier with close to zero ohms output impedance. Resonance is at 53Hz, and F3 is 50Hz.

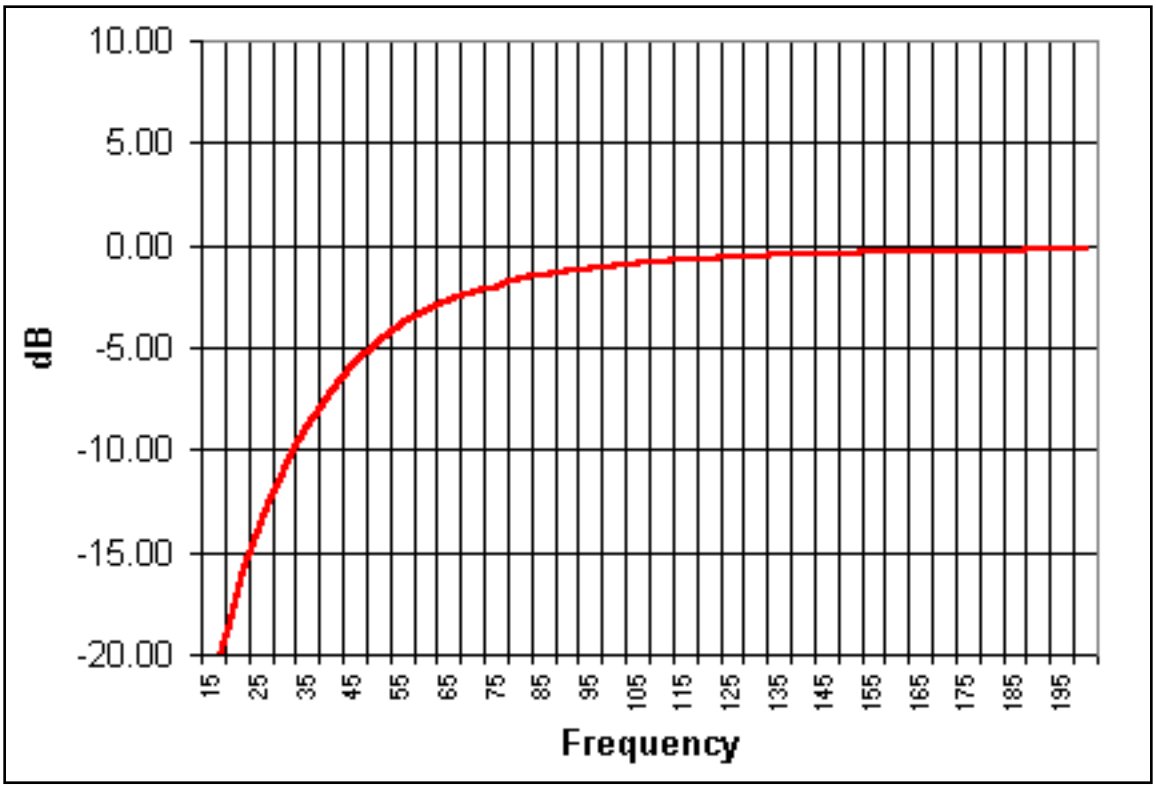

Figure 12 - Existing Woofer Response (Qts = 0.28)

Resonance remains at 53Hz and F3 is 61Hz - combined with the slow droop, this is not as good as it should (or could) be. The suggested size for the box is 22 litres, giving F3 of 63Hz - somewhat higher than I want.

The slow droop in response is quite typical of any speaker in a box that's too big, but the downside of making the box smaller is that the low frequency -3dB frequency increases (as it must). A Linkwitz transform circuit could be used to achieve the same result, but with added electronics and a lot more work than simply increasing the amp's output impedance.

Focal 5K4411 Midrange
Qts - 0.32 Standard, 0.60 Desired

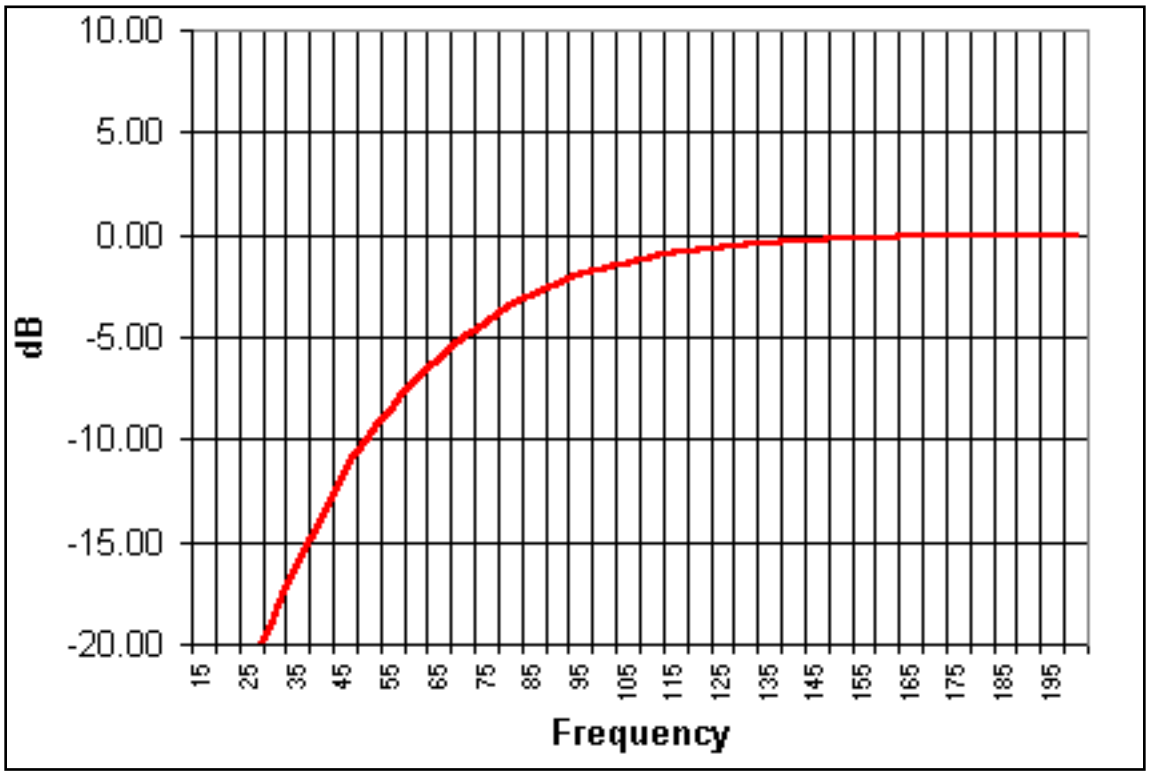

Figure 13 - Desired Midrange Response (Qts = 0.60)

Resonance is 88Hz, and F3 is 83Hz, which is just fine, since it will be crossed over at 300Hz. This is an excellent result - all I have to do now is determine the exact output impedance I need to obtain this result.

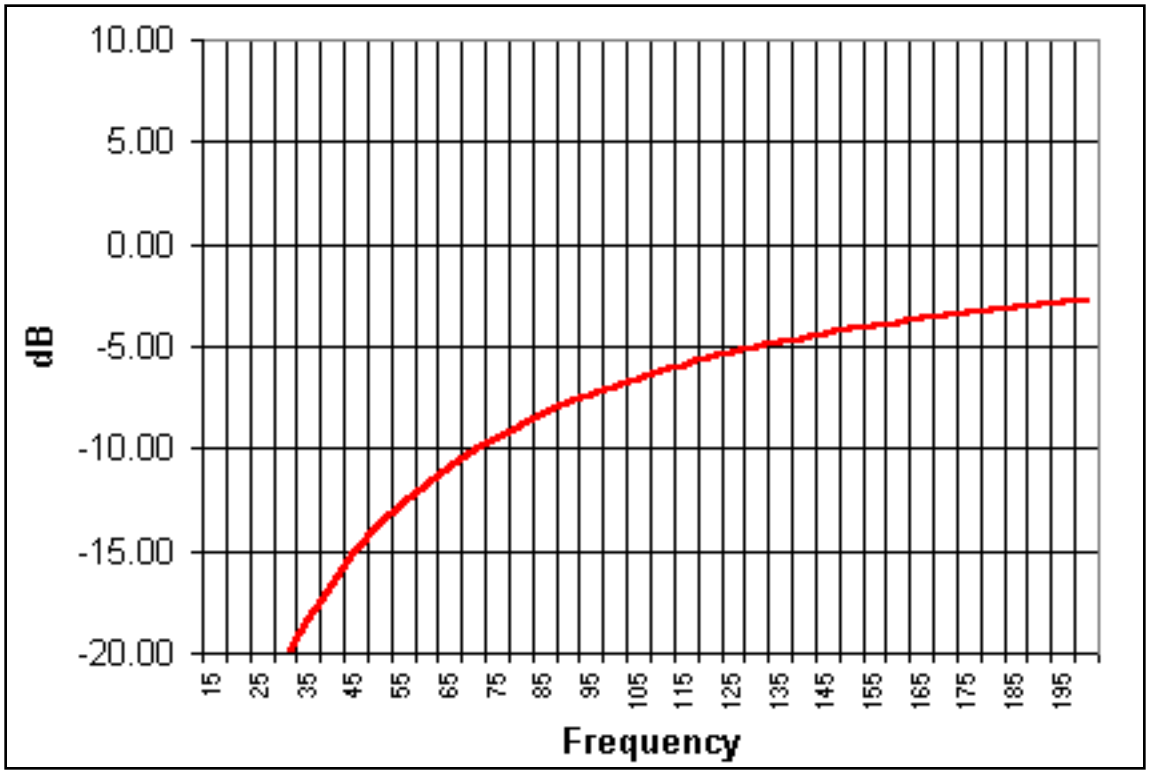

Figure 14 - Existing Midrange Response (Qts = 0.32)

Using a conventional drive amplifier gives resonance is still 88Hz (as it should be), but F3 is 187 Hz - way too high. Again, equalisation could be used, but adds additional electronics to the equation. The slow droop extends all the way to the crossover frequency, a less than desirable outcome. Again, using a higher than "normal" amplifier impedance can correct for parameters that are not exactly what you want.

First Listen, + Measurements

The first listen has shown that these loudspeakers are exceptional. Hooked up to my triamped test bench amp, all I had available for the inaugural listen was an FM tuner, but the results sounded very impressive. Bass, mid and treble are well balanced, there is virtually no panel resonance, and the sound quality remains extremely good above, below and each side of the axes. Listening from a separate section of my workshop showed that the overall balance is very good indeed.

It never sounded like a speaker around the corner, but with speech I was almost tempted to rush back to see who was there - very lifelike indeed. Bass is actually much better than expected, and with an amp output impedance of 4 ohms, there was very good extension to 40Hz, and even 20Hz was reproduced (but somewhat subdued, as is to be expected).

The resonance of the Visaton driver in the cabinet is 52Hz - quite close to the calculated value. The Focal was a different matter, with resonance at 69Hz - considerably lower than the specifications indicate. This is of little consequence for a triamped system, but shows the importance of verifying the important driver parameters which will have a profound (and undesirable) effect on any passive crossover.

A near field scan of frequency response of each driver (bass and midrange) indicates that the response is almost dead flat across the designed frequency ranges. There are the usual minor peaks and dips, but absolutely no major "suck-outs" or resonant peaks were to be seen - or heard. The response across the crossover frequency is harder to measure near field (actually it is almost impossible), but there was no audible variation - so much so, that I had to check the frequency and feel the drivers to find out which one was reproducing at the time.

The system is very well behaved with any crossover frequency between 100 Hz and 400 Hz (bass to midrange), and is also extremely tolerant of anything between 2 kHz to 4 kHz between midrange and tweeter. I will be using 250 Hz and 3 kHz crossover frequencies, and a power analysis is yet to be performed to verify the relative power needs of each driver. Bass and midrange are expected to be about equal because of a slightly lower than my "normal" crossover frequency, and different driver sensitivities. I don't expect that more than about 10W will be needed for the tweeter to balance the 70W available for bass and mid.

The drivers have now been removed from the enclosure, and final finishing is in progress. This is destined to be time consuming, but I used four coats of black spray enamel, followed by four coats of clear. The final finish will be to rub the cabinets down with Scandanavian finishing oil and fine steel wool. This imparts a lovely smooth satin finish, and is similar to the final treatment of the subwoofer project described in the Projects Pages.

Finishing and Assembling

The final finish is rather nice, but cannot really be shown to any great advantage on a web page. You will get some idea from the photos that follow. Figures 15 and 16 show front and rear views respectively. The felt surrounding the midrange and tweeter can be seen, and the connection panel is visible in Figure 16.

Figures 15 / 16 - Front and Rear of Completed Boxes

Figure 17 shows a close up of the midrange and tweeter - not exactly exciting in hindsight, but it does give you a better idea of how the drivers are close-coupled, the felt surround itself, etc.

Figure 17 - Mid and Tweeter

The full length photo in Figure 18 lets you see the finish (to some degree at least), and what the final enclosure looks like. The stand is mounted using metal thread screws and a felt spacer to prevent vibration. This is shown in a little more detail later.

Figure 18 - Finished Enclosure

The photo in Figure 19 shows what had to be done to get the height right. The only stands I could get were 300mm high, and this was too much. I cut off the top section, then re-attached it to the shortened stand with screws and nuts. Welding was out of the question, since it would have damaged the finish badly.

Figures 19 / 20 - Speaker Stand and Connection Panel

The connection panel shows how the binding posts were glued in position to prevent them from coming loose. The colour coding of the connectors should have had a violet or blue binding post for treble, but my supplier didn't have any :-(

Figure 21 - A 1.5V Cell ??

Figure 21 seems somewhat incongruous at first sight, but I used it to ensure that all speakers were properly phased. When a positive potential is applied to the plus (+) terminal of a speaker, it is meant to produce a positive pressure wave, so the cone should move outwards. This is readily seen even with 1.5V on any speaker, and the current is low enough that it will not damage the most sensitive tweeter.

Listening

The speakers are in operation, and my old faithfuls have been relegated to a spare room. Since I am by nature somewhat impatient (OK, *very* impatient), I wanted the speakers operational before I'd built the electronic crossover and tweeter amplifier. Since all speakers simply terminate on the rear panel, it was a simple matter to use an

external passive crossover network between midrange and tweeter as a temporary measure.

As regular readers well know, I am not a fan of passive crossovers, however, listening to my new speakers was more important than waiting until I could triamp them properly. I used a commercial 12dB/octave crossover, which would normally mean that it would be Butterworth alignment (See Passive Crossover Design for more info). This I did not want, so with a bit of an educated guess I decided that 12 Ohm resistors in parallel with each driver would do quite nicely, converting the filter alignment to a sub-Bessel (Linkwitz-Riley) having a Q of 0.5. A quick bench test confirmed that this was almost perfect, but in reality, there is a small discrepancy because I didn't equalise the midrange driver's inductance. This was acceptable, since it is temporary only.

The sound is wonderful ! Even before careful equalisation and the full electronic crossover (including baffle step compensation), I am extremely satisfied with the performance. There is a hint of over-brightness, but otherwise colouration is extremely low, and imaging is superb. The definition is extremely good, and voices sound so natural that you'd almost swear that the person was in the room.

Introduction

The speakers are complete, as described in Part 1 of this article. The next phase (actually completed some time ago now) was to finalise the Linkwitz Riley crossover, tweeter amp and re-establish my phono preamp. The idea was to make the final design a complement to the VP103 valve preamp, both in looks and function.

To this end, one power switch now brings my preamp and all seven power amplifiers on-line (six for the stereo tri-amped speakers, and the sub-woofer amp). There are four amplifiers in my original power amp unit, a further two in the tweeter amp, and the separate sub amplifier.

All mains switching is performed in the tweeter amp unit, which has a 20A relay. This is powered from the 12.6V heater supply from the preamp - I added an extra output for the supply, and there is a corresponding input on the tweeter amp unit. There is zero power usage when the system is off.

Initial Assembly

Construction was not without difficulty. For example, neither the toroidal power transformer nor the heatsink would fit in a 1RU (1 "rack unit" is 44.45 mm, or 1 3/4 inches) rack case, so some modifications were performed so that they would. I was able to utilise many of my workshop "toys" to bring this project to fruition - always a good thing, since it justifies their purchase to SWMBO (She Who Must Be Obeyed :-)

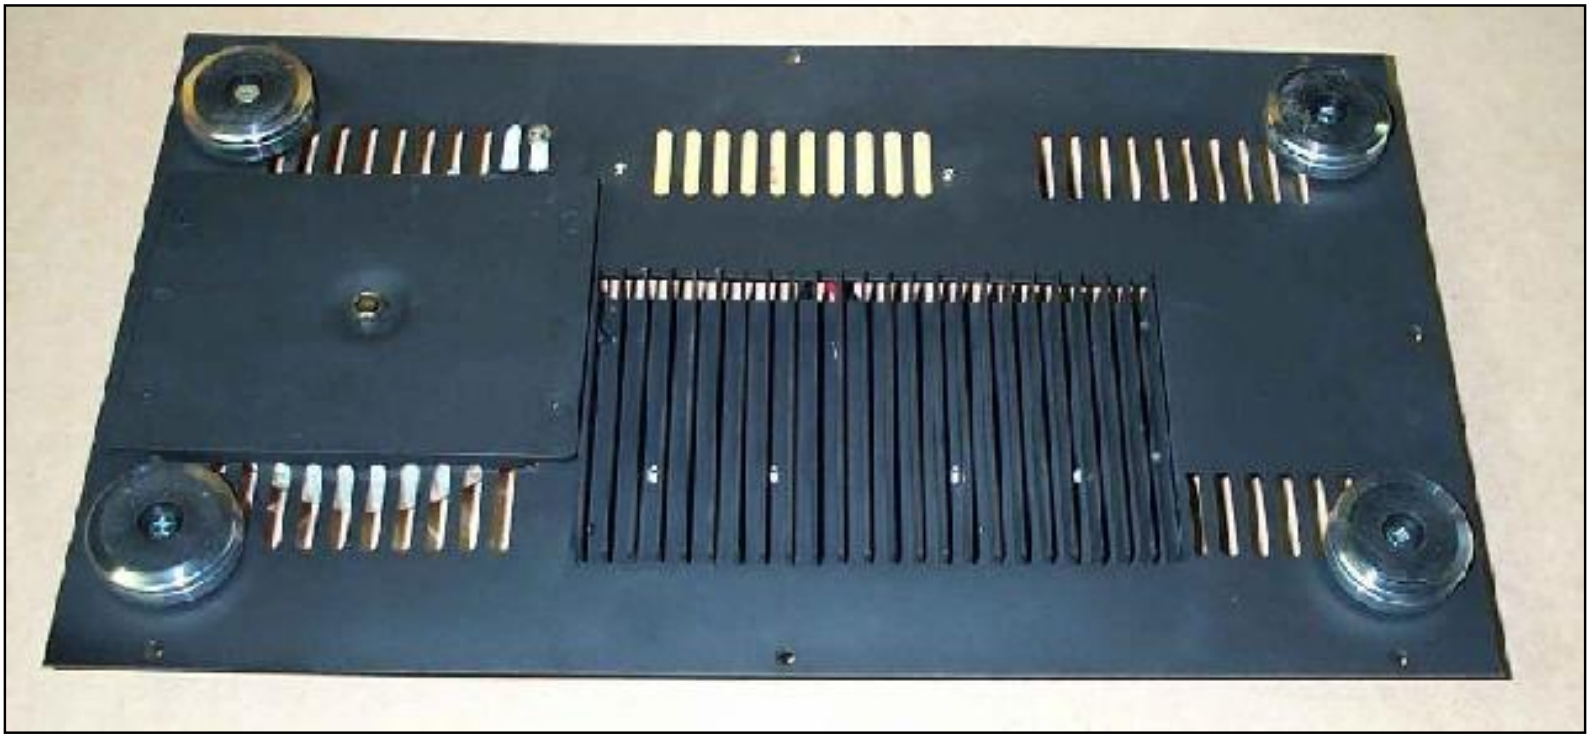

Figure 1 - Base of the Rack Case

Figure 1 shows that there is a cutout for both heatsink and transformer, and both project about 10mm below the bottom of the case. The bottom plate was cut and bent to provide mounting flanges for the heatsink, and a separate panel was attached for the transformer.

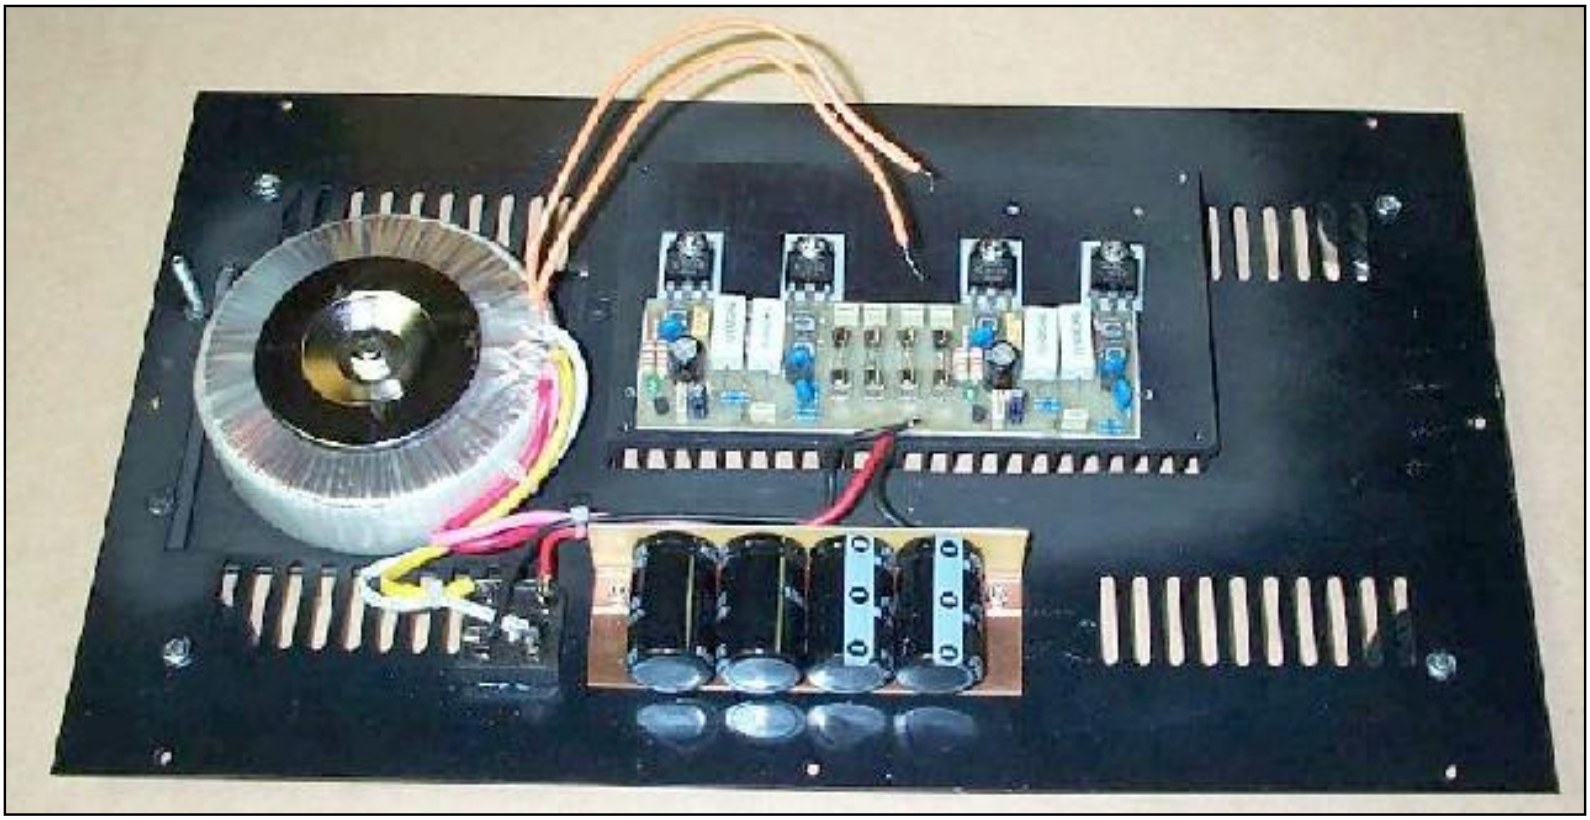

Figure 2 - Top View of Baseplate

In the view in Figure 2, the transformer can be seen, now recessed into its little cavity. The large screw to the left is for earthing. The power supply has been wired at this stage, and the filter caps were mounted on a piece of blank PCB material that I mechanically etched using a hand-held engraver unit. The power amplifier is actually the prototype of the Project 3A amplifier board - before I decided to extend the PCB for the output transistors.

The supply voltage is +/-25V from a 120VA toroid, and the amp is used only above 3,500Hz, so loading is light, even at very high volume. As you shall see, the main supply is also used for the preamp power supply (Project 05), which powers all the smaller boards.

Final Assembly

The next photos shows the unit in a very advanced stage - it is almost complete. All the circuit boards are wired and installed, as well as the switching module (bottom right) and muting relays (bottom centre). Standard IEC mains connectors are used for mains input and switched output, with all mains connections properly shrouded to prevent contact.

Figure 3 - Rear View

The inscrutable box on the left side houses the phono preamp. Being high sensitivity, the last thing I wanted was hum or other noise, so complete shielding was the answer. It is also made with adjustable gain, since I use a (relatively) high output moving coil pickup most of the time.

The earth connection for the turntable is on the extreme left of the rear panel. That is followed by phono inputs and outputs, and the gain switch. The next set of connectors is the input from the preamp, followed by midrange and low frequency outputs. The "ordinary" phono socket is for the DC switching voltage. The set of binding posts / banana sockets is for the tweeters - not surprisingly.

Figure 4 - Front View

From the front, you can see the Linkwitz-Riley crossover - two boards stacked on top of each other on the extreme right. Just to the left is the power supply unit (Project 05), and you get a clearer look at the muting relay board (just right of centre at the top of the picture).

Although it all looks neat and tidy, there were a few stages where it looked like a rat's nest, while I moved wiring about to get the lowest noise levels. Because there is so much packed into a small case, this was not a simple task, and even moving a cable by a few millimetres made a substantial difference - especially the wiring to the tweeter amp inputs.

In this view, the power supply regulator is again visible, and no - the heatsinks do not touch each other, it just looks that way in the photo. They are actually held apart with a small dab of hot-melt glue, to make sure that they cannot short out.

As you can see, there is no power switch, just one green LED on the front panel (plus the obligatory ESP logo, of course).

Listening Tests

The final listening tests with this system have been a true revelation. It is quite possibly the most revealing system I have heard, with nothing - ever - disappearing into the mix. Even at quite astonishing sound levels (about 110dB peak!), a violin does not tear out your ear drums and leave them bleeding on the floor. It just sounds like an incredibly loud violin. Other instruments fare equally well, as do vocals, both male and female. Normally though, I have

found that my preferred (serious) listening level is most usually about 90dB (average unweighted), and often less.

> After some measurements, I can give the following (completely useless :-) information. For an average listening level of 85dB SPL, I measure just under 3V at the midrange and woofer terminals - i.e. about 1W for each. The tweeter voltage is around 1V, or 125mW. From this, I deduce that the total power per speaker is about 2W on average - the tweeter power can be ignored as insignificant. With speaker efficiency of 90dB/W/m, this means that I have a room loss of about 10dB at the listening position, based on applied power versus measured SPL. (Listening distance is about 2.5 metres.)

One thing that this system has highlighted is just how bad some recordings really are, and the artefacts of compressors and limiters (for example) are immediately audible. Although I prefer to listen to the music, rather than the recording technique or the system, sometimes it is just not possible when every flaw is revealed so clearly. As a result, I am re-assessing my CD and vinyl collection to some degree - in many cases to hear details that I have never noticed before. As always, there is a good and a bad side to having such a transparent system.

In fact, the sound is so realistic, that from another room voices sound as if there are people in my lounge room. On more than one occasion, I have had to get up and see who was there when I am working in my study, only to find that it is just the TV, which (naturally!) is connected through the hi-fi as well.

Overall, I am enormously satisfied with the speakers, crossover and indeed the complete system. It has not been a cheap exercise, but compared to the cost of purchasing a system that could come anywhere near it, I feel that I have a real bargain.

1.0 Introduction

While there are many articles elsewhere that discuss passive crossover design, not all follow a scientific approach. There are several 'off-the-wall' designs scattered throughout the Internet that are a case in point, and unless there is *real* science described in any article you see, it is best avoided.

Highly recommended reading is Project 82 - Loudspeaker Test Box. This will make quite a bit of the testing described below redundant, and you will be able to see at a glance what network is best suited to your drivers. It does not do notch filters though, so this is something that you may still need to determine mathematically (or just cheat and use the spreadsheet)

Most people who have read my pages will know by now that I am not a fan of passive crossovers. However, sometimes it is the only sensible approach, or is necessary because of financial considerations or just for simplicity. Before deciding on the use of a passive rather than active crossover, the following article will surprise you - perhaps even enough to make you decide to go active after all.

Where passives are to be used, I prefer a simple 6dB/octave unit, but in many cases this is not possible - most commonly because of the low rate of roll-off, which can cause excessive power to be delivered within the stop band. This can excite the resonant frequency of tweeters, and causes a honkiness in the upper midrange - usually subtle, but audible nonetheless.

A conventional Butterworth 12dB/octave filter is still by far the most common crossover, but is now under threat from the Linkwitz-Riley alignment. The latter has a crossover frequency where the output of each filter is 6dB down, and this has the advantage of a zero rise in output at the crossover frequency. The 'conventional' crossover filter is 3dB down at crossover, and the summed output shows a slight peak of 3dB at the crossover frequency. This phenomenon occurs with both electronic and passive crossovers using the Butterworth alignment. While it is possible to modify the frequency or slope of either the high or low pass section to compensate (usually by manipulation of both amplitude and phase response), this is uncommon in budget designs, and non-existent for off-the-shelf crossover networks.

All crossover networks have problems. Some have more than others. The ideal loudspeaker is a single point source (i.e. small compared to all wavelengths of interest) that reproduces all frequencies. Such a driver is not possible with any technology currently available, so (as always) we must compromise.

The most common compromise is to use two (or more) loudspeakers, each optimised for the frequency band it must cover. Since it is highly undesirable that drivers intended for high frequencies be subjected to low frequencies (and vice versa), the audio signal is separated into bands by a crossover network - either electronic or passive, or a combination of the two.

In this article, I have concentrated on a two-way crossover network. Three-way (and above) will become a nightmare if you must use passive crossovers all the way through. My recommendation is that all low frequency crossovers should be active, and if you must use a passive network, then it should be for the mid to high frequency section only. The basic principles apply to all drivers regardless of frequency range, so it is not hard to extrapolate the examples given to low frequency networks.

The purpose of this article is to explain how to obtain the best possible performance from a passive crossover network, and avoid the major pitfalls that await us in our endeavours. Crossovers are not simple. Electronic units require us to have a multiplicity of amplifiers (one for each loudspeaker driver), and passive units impose other constraints and limitations - not all of which are satisfactorily addressed by loudspeaker manufacturers (including some 'high end' components).

There is information presented here that I have not seen in any other material on the subject of crossovers, with the exception of my article, "Biamping - Not Quite Magic, but Close". Specifically, this is to do with the shift of filter frequency and alignment that occurs when a voice coil is hot. Since a stable operating temperature will never be achieved with music signals, there will be a constantly shifting crossover frequency, and a peak in the frequency response where the amplitude is dependent on the power at any instant in time. This cannot be considered a satisfactory situation, and is quite possibly one of the most compelling reasons to use active crossovers whenever possible.

The article that follows requires that you are very familiar with the use of a spreadsheet or scientific calculator. There are many calculations and measurements to be made to get it right - but the end result will be well worth the effort.

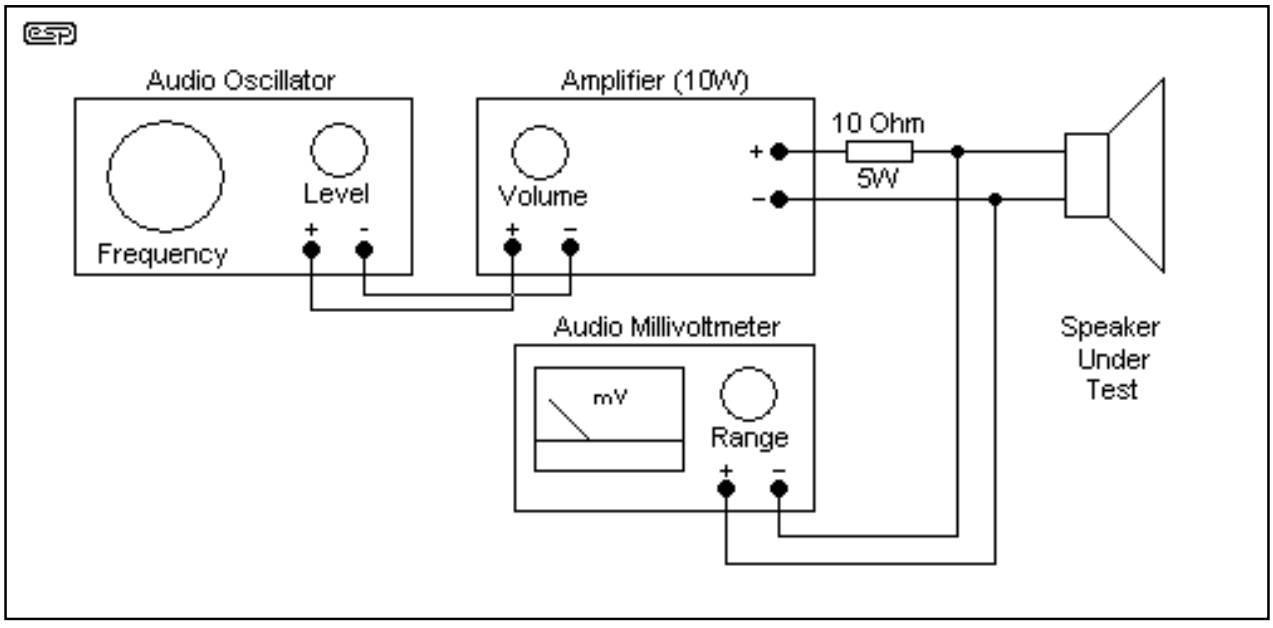

Figure 1.1 - Speaker Test Setup

You will need to set up the equipment shown in Figure 1.1 to carry out any tests on the speakers. The millivoltmeter may be a digital, if you are sure that it has a good enough frequency response. A frequency meter is also very helpful, but is not essential if the oscillator is well calibrated. If an amp larger than 10W is used, make sure that you keep the volume right down - most tests will require a maximum of 1V RMS, so even a 1W amp will be enough.

A spreadsheet is now available to perform the maths for you. You still need to measure the drivers, but once measured, you can simply insert the values into the spreadsheet for a complete starting point. The spreadsheet cannot compensate for all possibilities, and some experimentation will almost always be needed to arrive at the optimum solution.

Passive Crossover Design Spreadsheet

Ideally, when you use the spreadsheet, you should use the *actual* measured impedance of the loudspeakers at the frequency of interest, rather than the quoted nominal impedance. Using the test set shown above makes this quite easy.

Remember that once a Zobel or notch filter has been determined for a driver, that becomes *part of the driver*. The network and driver must be treated as one, since the network's purpose is to remove some objectionable characteristic of the attached driver - most commonly unwanted impedance variations.

To use the test set, follow these steps ...

- Disconnect the speaker, and set the voltage to a convenient level (say 1V)
- Connect the speaker, and sweep the frequency to locate the centre of the "flat" range, where the voltage does not change appreciably
- Measure the voltage

Impedance may be calculated, based on the known input voltage and the voltage measured across the loudspeaker. Using the long way (because it is easier) ...

Vr = Vin - Vs

Where Vr is voltage across resistor, Vin is unloaded voltage, Vs is voltage across speaker

I = Vr / R

Where I is current, and R is the value of the resistor (10 ohms is suggested)

Z = Vs / I

Assume an input of 1V, R = 10 ohms and Vs = 400 mV

Vr = Vin - Vs = 1 - 0.4 = 0.6 V
I = Vr / R = 0.6 / 10 = 0.06 A
Z = Vs / I = 0.4 / 0.06 = 6.67 Ohms

This calculation is also done by the spreadsheet.

2.0 Filter Types

A comparison of filter alignments is in order, so that the reader not experienced in such matters will know what I am on about. There are three primary filter alignments that can be used, and they differ only in the damping (or "Q") factor. Q, or "quality factor" is an abstract term that is applied to many passive components in many applications, and is effectively the inverse of damping. Thus, Q=1/d or d=1/Q. Fascinating stuff (if you happen to be a mathematician :-)

Filter	Main Characteristic	Other Characteristics	Q
Butterworth	Maximally flat amplitude	-	0.707
Bessel	Maximally flat phase	Fastest settling time	0.5 to 0.7 (typ) *
Chebyshev **	Fastest rolloff	Slight peaks / dips	0.8 to 1.2 (typ)

Table 1 - Filter Characteristics

* A true Bessel filter has a Q of 0.57, however there are many 'almost Bessel' alignments in common use
** also spelled Tchebychev in some texts

One of the "magical" number in electronics is √2, or 1.414, and its inverse, 0.707 and the latter can be seen in the table as the figure that provides "maximally flat" frequency response. This means that the response in the pass band is as flat as it can possibly be, until the cutoff (-3dB) frequency is reached. This forms the classic Butterworth filter that has been the mainstay of nearly all crossover systems in common use.

A Bessel filter has a slower and "sloppier" response, that starts to droop well before the cutoff frequency, but has the minimum phase shift (and best transient response), and one that is comparatively gentle. 6dB/octave filters are neither fish nor fowl - i.e. they may be thought of

as a poor Bessel, Butterworth **and** Chebyshev all rolled into one, and have a Q of 0.5 - this cannot be changed by any topology, regardless of whether electronic of passive crossovers are used.

The Chebyshev filter is characterised by peaks and/or dips in its response, and usually has a (slight) rise in amplitude just before the cutoff frequency, the magnitude of which is determined by the Q. The higher the Q, the greater the peak in the response. Depending on the order of the Chebyshev filter, it may have dips as well as peaks. Many vented subwoofers use a Chebyshev response for the port tuning, as do quite a few sealed enclosures. The Q will typically be about 0.8, so the rise in amplitude is less than 1dB, but some will use a Q as high as 1.0 to make the loudspeaker sound as if it has more bass.

Chebyshev filters are rarely used in crossovers - some electronic crossovers have used them, but these are most uncommon. This alignment will not be discussed further (except where it happens by accident due to impedance variations).

3.0 Speaker Effects on Filter Response

The amplitude and phase of a filter is easily plotted by means of circuit simulation. Amplitude response may be measured using a simple signal generator, small power amplifier (for loudspeaker crossover filters) and an AC voltmeter, which must have a bandwidth that covers the audio spectrum - not all do, especially cheap analogue and digital meters. Phase shift is very difficult to measure without an oscilloscope. Digital oscilloscopes have the added advantage of cursors that can be used to obtain accurate readings of time delay at any given frequency, and phase shift can be calculated from this.

Fortunately, once armed with enough information, phase shift measurements are not generally needed. This simplifies the design process considerably, since the phase shift of any given filter type will be known in advance.

In this section, we shall examine some of the possible influences that have (or may have) an adverse effect on the performance of a crossover network. Some of these are well known and are catered for in many (but by no means all) commercial and hobbyist (DIY) loudspeakers. Others are less well known, and are ignored completely by virtually all loudspeaker builders - perhaps with good reason, perhaps not.

3.1 Speaker Impedance

One area where measurement is essential when designing passive crossovers, is the loudspeaker driver itself. There is usually very little information in the makers' data that will prepare you for the behaviour of a loudspeaker / crossover network combination, and these data are usually derived empirically. In some cases the voice coil inductance will be quoted,

and if so, this may be a bonus, as will be shown shortly.

3.1.1 Woofers and Midrange Drivers

In almost every case, the crossover frequency selected for the woofer and midrange driver will be at a frequency where the voice coil inductance is significant. As frequency increases, the effect of the voice coil inductance is to increase the driver's impedance, and this plays havoc with the crossover network's performance.

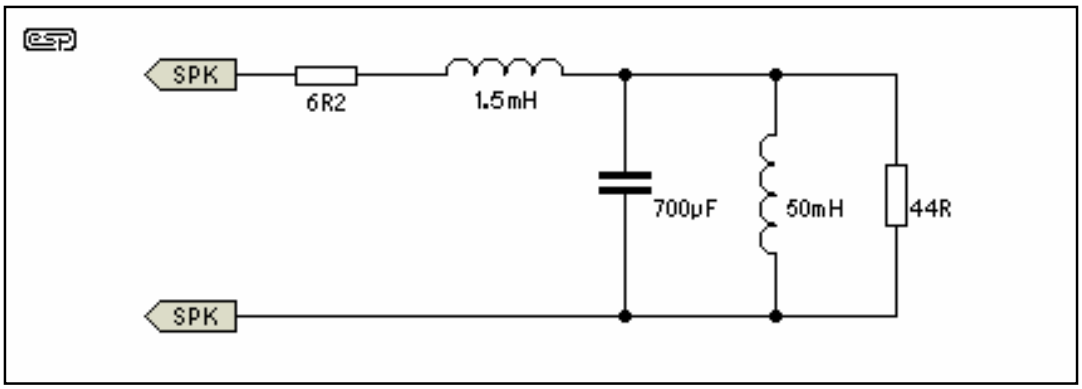

Figure 3.1 - Equivalent Circuit of a Loudspeaker

Examination of a simulated low frequency driver depicted in Figure 1, shows a large peak at resonance, and a relatively small section where the impedance is flat. This equates to the nominal impedance of the speaker, but as shown below, this covers a limited frequency range. The biggest problem for the crossover is not resonance (for a woofer, at least), but the rise in impedance as the voice coil inductive reactance starts to become significant relative to the nominal impedance.

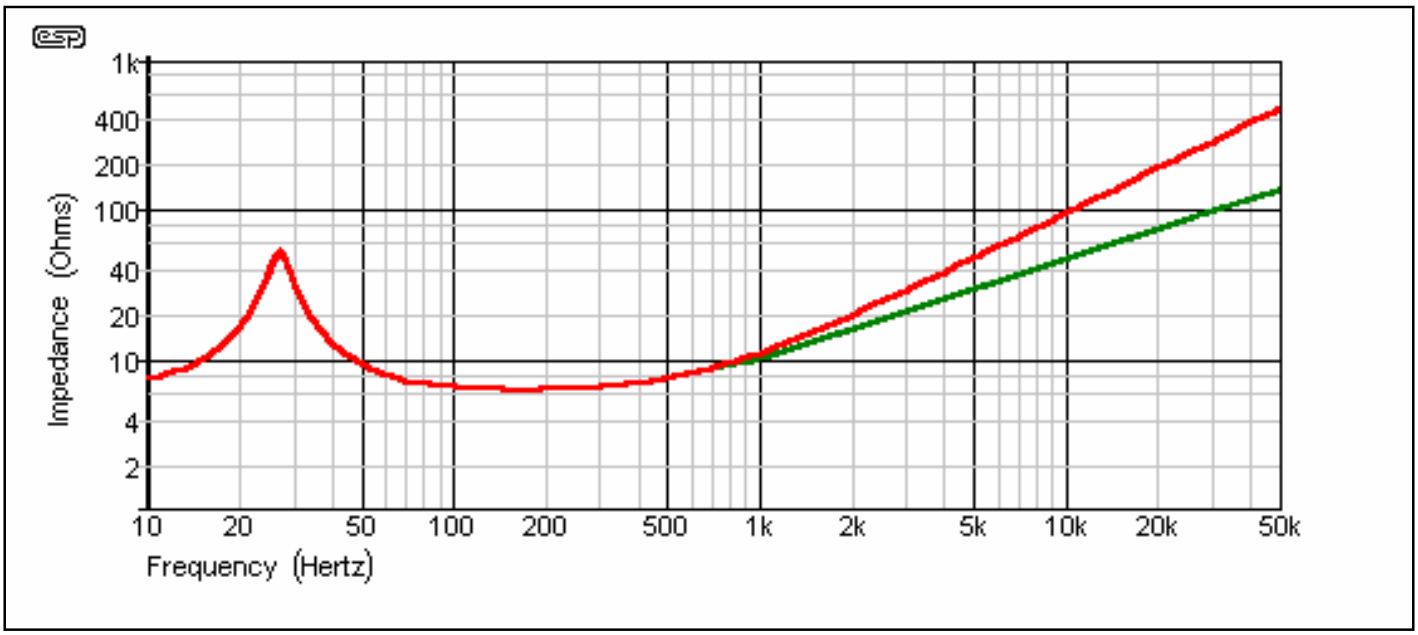

Figure 3.2 - Impedance Curve of "Simulated" Loudspeaker

The green line on the above graph represents the 'semi-inductance' of the voicecoil. Because

the coil is surrounded by conductive metal (steel), its inductance is not linear with frequency. This creates a lossy inductor, and as such it cannot actually achieve the 6dB/ octave (20dB/ decade) impedance rise that one would normally expect. The actual rise varies from one driver to the next, and cannot be simulated in general terms - it must be measured. The real impedance rise due to voicecoil inductance (or semi-inductance) is usually between 3 and 5dB/ octave. For the range of frequencies that we need to be concerned with for a crossover network, the error introduced into the formulae that follow is minimal, and can be ignored.

This is most commonly corrected with a Zobel network (Figure 3.3), connected in parallel with the speaker. As the inductive reactance rises, the capacitive reactance falls, and the resistance is typically made equal to the DC resistance of the voice coil. The net result is a flat impedance curve, as shown in Figure 3.4. This is absolutely essential for proper behaviour of the crossover network, but sadly is not used in a great many designs. The result is a shift in the crossover frequency, and phase response that is not exactly ideal. The crossover may be designed to work with the impedance actually presented by the driver, in which case it will be asymmetrical, having different inductance and capacitance from the theoretical values that one might expect.

In the case of the speaker shown above, at a typical crossover frequency of perhaps 3kHz, the impedance (as simulated) is a little over 28 Ohms, or about 22 Ohms for semi-inductance - imagine the error if a crossover designed for 8 Ohms were used without correction!

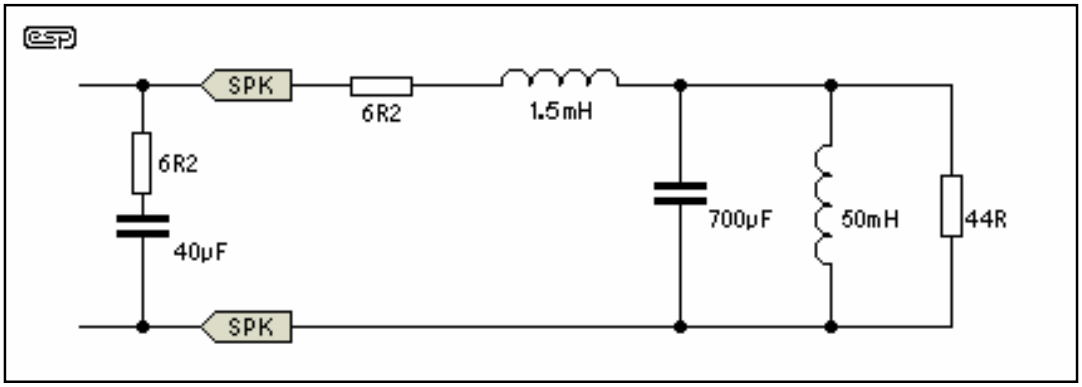

Figure 3.3 - Addition of an Impedance Correction Zobel Network

The Zobel network will flatten the impedance of the speaker, but at the cost of power dissipation, and a slightly lower than expected overall impedance. Naturally, the power dissipated by the resistor is turned into heat, not sound, reducing effective efficiency. The lower impedance may cause some stress to certain amplifiers, but most should be able to cope with the slight extra loading. It must be understood from the outset that the flattened impedance curve does not make the speaker perform any better at the higher frequencies - the sole purpose of the Zobel network is to ensure that the impedance presented to the crossover network remains essentially constant over the frequency range where variations would cause an unacceptable frequency response variation in the filter network. The determination of the required values for the Zobel network is most easily done by

measurement and experimentation.

Once determined, the Zobel network must be treated as part of the loudspeaker. All measurements or calculations for the crossover network *must* include the Zobel network and loudspeaker driver combined. If correctly done, the combination of the two will give an acceptably flat and very usable impedance across the entire crossover region. This will result in a crossover filter with the minimum error possible.

If the voice coil inductance is known, then a suitable value of capacitance may be calculated quite readily. The first thing to determine is that frequency where the inductive reactance is equal to the DC resistance of the voice coil ...

$$f = Rvc / (2 \pi Lvc)$$

Where ...

f = frequency
Rvc = Resistance of voice coil
Lvc = Inductance of voice coil

Once this figure is found, it is a simple matter to calculate the capacitance for the Zobel network ...

$$C = 1 / (2 \pi f Rvc)$$

Using the simulated speaker above as an example, we already know that Rvc is 6.2 ohms, so ...

$$f = 6.2 / (2 * \pi * 1.5 * 10^{-3}) = 658Hz$$
$$C = 1 / (2 * \pi * 658 * 6.2) = 39 * 10^{-6}F = 39uF$$

It should come as no surprise that this is almost exactly the value found by simulation, so we can safely assume that the formula works, and is easy enough to use. The resistance will nearly always be approximately equal to the voice coil resistance - in some cases it may be found that a small variation is needed, but this is unlikely to be significant.

Although the capacitor does not have to be "audiophile" quality, and a bipolar electrolytic could be used, the main problem with bipolars is that they are not stable over time. I recommend that polyester, polypropylene or oil filled paper cap be used, and suggest that you will be faced with a not inconsiderable expense to implement this scheme properly. Is it worth it? ***Absolutely!***

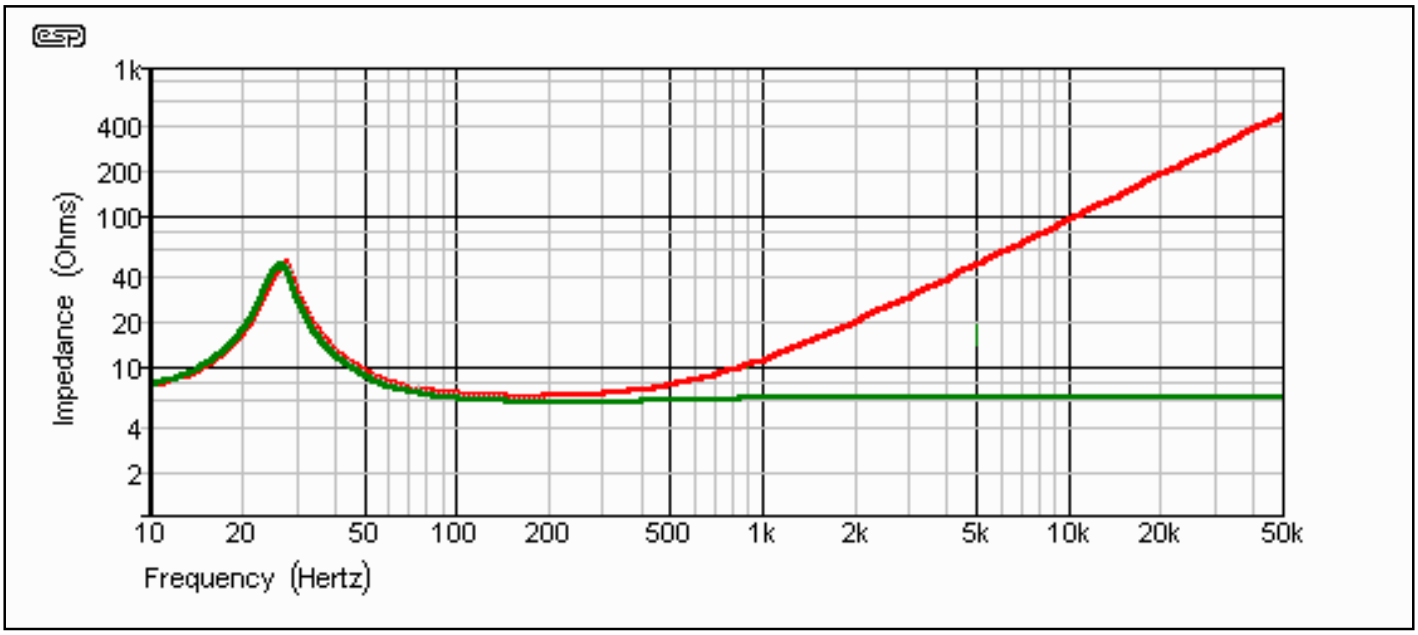

Figure 3.4 - Resulting Loudspeaker / Zobel Impedance Curve

The red trace shows the uncorrected impedance, and the black trace shows the impedance with the correction network in place. Naturally, it is important that the crossover is designed for the actual (rather than the nominal) impedance presented by the driver at the crossover frequency. An 8 ohm speaker will rarely be 8 ohms in reality, and this is especially true when an impedance correction circuit is used.

As noted above, one could also design the crossover for the impedance actually presented at the crossover frequency, but this varies with frequency. Unless the impedance remains reasonably constant for at least 2.5 octaves (and preferably more) above and below the crossover frequency, the network cannot be expected to provide a predictable response. As a direct result of this, a 6dB/octave passive crossover at (say) 300Hz is barely acceptable, because of the impedance peak of the woofer. Although it is possible to equalise the woofer's impedance peak, the components needed will be very large (electrically and physically), and will be very expensive.

If the loudspeaker is installed in a vented enclosure, then there will be two impedance peaks to equalise out - this can become very tedious, and will be costly to implement. There is usually little to be gained by equalising the woofer impedance peaks, and if an electronic crossover network is used, there is absolutely no reason to do so.

When you have completed the network, connect it (and the speaker) to the test setup shown in Figure 1.1 and measure the response. It should be quite flat (within 1dB) up to the highest frequency of interest.

3.1.2 Midrange and Tweeter Drivers

Most tweeters and midrange drivers can benefit from using a compensation circuit at their resonant frequency when a passive crossover is used. This is especially true if you are using

a crossover network with a slow rolloff, or the frequency is too close to the resonant frequency of the driver. With a 6dB/octave filter, I suggest an absolute minimum of about 1.5 octaves between the driver resonance and crossover frequency. A tweeter with a 900Hz resonance should therefore be crossed over at a minimum of 2,500Hz, but preferably higher. If you use the minimum possible frequency separation, there will be a small peak at tweeter resonance - this is a combination of the tweeter's resonance itself, and the fact that the crossover cannot maintain the correct rolloff if the load impedance changes.

Although there are allegedly formulae to calculate the values needed to make a network whose impedance is the exact opposite of the resonance peak, I suggest that they are of minimal use in practice. One I have seen requires the Thiele/Small parameters, and these are rarely available for tweeters in particular. One could measure the parameters, but the effort of doing so is equal to (or greater than) the effort needed to experiment with a few selected values. With experience, this will become quite easy - albeit a little tedious.

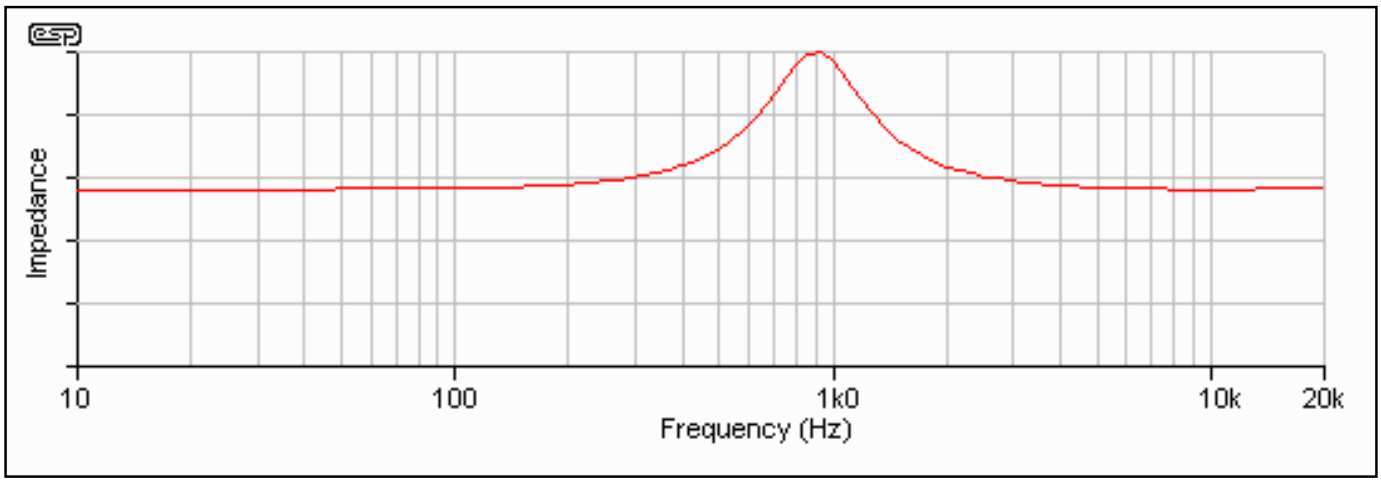

Figure 3.5 - Tweeter Resonance

Experimentation is made easier with the following procedure. The first requirement is to plot the impedance of the tweeter or midrange driver, which should be done with reasonable accuracy. The resistance used in the network will be equal to the DC resistance of the voice coil - that much at least is quite straightforward. With the procedure explained below, I eventually arrived at the network shown in Figure 3.6 - this is hardly a trivial circuit to implement, especially with a relatively large capacitance. Again, the capacitor does not necessarily have to be "audiophile" quality, so a bipolar electrolytic could be used in this circuit as well - but the same caveats apply as with the woofer inductance compensation circuit. A bipolar electrolytic will change value over time, and the compensation circuit's performance will deteriorate as capacitance is reduced with age.

There is a strong case for manufacturers of midrange and tweeter drivers to offer a compensated version of their drivers, which would simplify the process considerably. At the very least, the needed parameters should be supplied to allow us to calculate the values needed. Regrettably, I have never seen the parameters or a suggested circuit with the

specifications for any tweeter - IMHO this is the very least the manufacturers could do to help us all out on this. Instead, we are left to our own devices to determine the network by trial and error. I find this to be somewhat irritating.

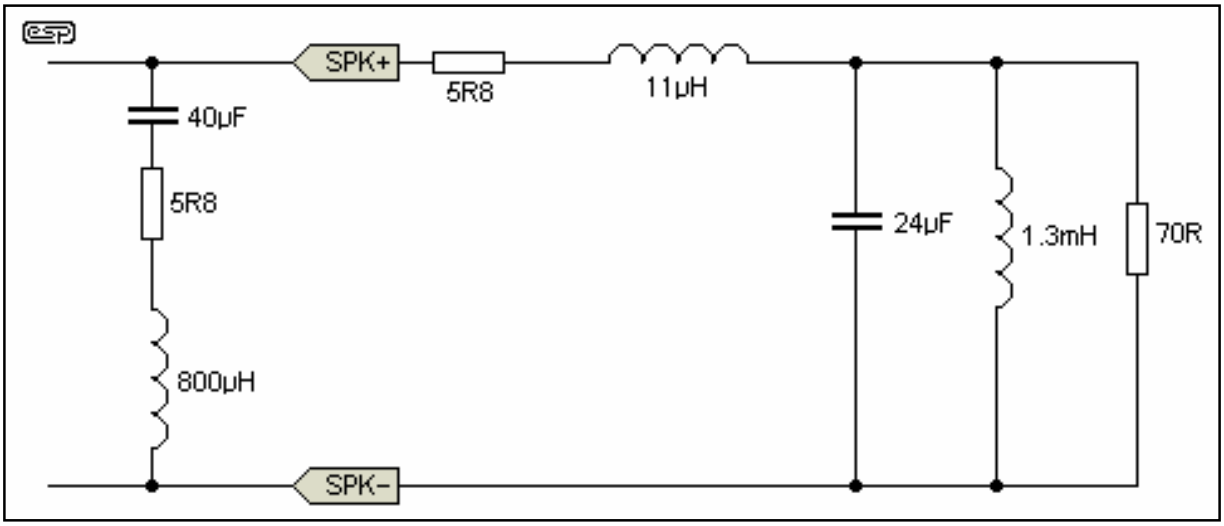

Figure 3.6 - Compensation Circuit, and Equivalent Circuit of Tweeter

Unfortunately, it is extremely difficult to get the required details for most tweeters. The resonance is almost always quoted, but most of the time it is difficult to find the voice coil inductance, let alone the Qts and Vas, which would enable one to calculate the required network. The values I used in the simulations are assumed, and gave a resonance at about the right frequency - the reality will (of course) be different, and will differ even further from one tweeter to another. Some basic measurements on a selection of tweeters confirmed that the simulation is not too far off, although it may be a little broader than some tweeters.

The Q of the compensation circuit must be the same as the resonance Q, or it will simply form a sharp notch in the middle of the resonance peak (Q too high) or a broad notch that spans the resonance (Q too low). Unfortunately, this is not as easy as it may first appear, but it is not actually difficult once you know what to do.

As a first approximation, find the (actual) resonant frequency of the tweeter. You will need a small amplifier, and a resistance of about 10 ohms. Wire the 10 ohm resistor in series with the amplifier output and the tweeter. Keep the output voltage as low as possible (less than 1V RMS). Change the frequency of the audio oscillator slowly and note the frequency where the voltage directly across the tweeter terminals is at its maximum. Reduce the frequency slowly, until the level has decreased by 3dB (i.e. 0.707 of the previous level). From this, you can calculate the required capacitance that will null the inductive component of the resonant peak.

Measure the DC resistance of the voice coil, and note the resonant (Fo) and -3dB (F3) frequencies - you will need both for the next steps.

Capacitance and inductance are calculated from the formulae ...

C = 1 / (2 * π * Rvc * F3)
L = 1 / (4 * π² * Fo² * C)

The details of the simulated tweeter are ...

Rvc = 5.8 Ohms
Fo = 907 Hz
F3 = 635 Hz

Substituting our tweeter, we will obtain the following ...

C = 1 / (2 * π * 5.8 * 635) = 43uF
L = 1 / (4 * π² * 907² * 43 * 10^{-6}) = 716 uH

These values will be difficult to obtain, and substituting 40uF and 800uH caused such a small error that it is of little consequence (it actually improved matters very slightly).

Note that this procedure is intended as a starting point only, and you will almost certainly need to experiment if you want the flattest possible impedance. Small variations will not cause significant errors, so it is not beneficial to go to extremes.

Again, when you have completed the network, connect it (and the tweeter) to the test setup shown in Figure 1.1 and measure the response. It should be quite flat (within 1dB) across the resonance frequency.

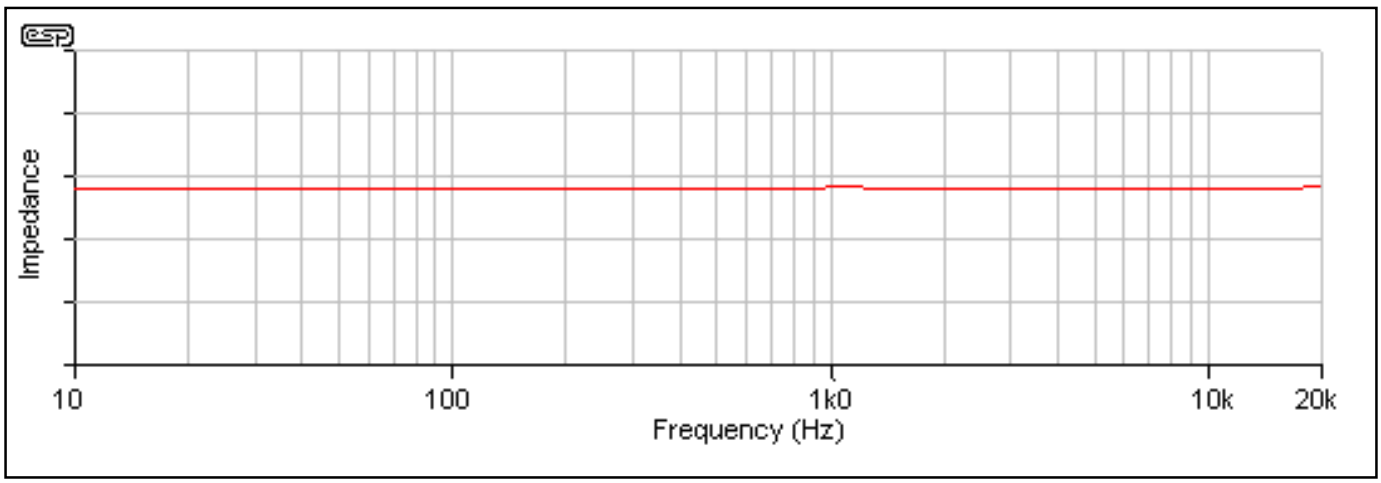

Figure 3.7 - Tweeter Impedance With Correction Circuit

The impedance is now commendably flat, but at the expense of overall impedance, which is reduced from the nominal 8 ohms to the real impedance of the tweeter - in this case, about 6 ohms. This figure must be used when the crossover network is designed - ***not*** the nominal 8 ohms impedance. This is a very common mistake made by the novice, and from what I have seen, quite a few professionals as well. The nominal impedance is just that - nominal. When

designing the crossover, the actual measured impedance must be used - ***always!***

Figure 3.8 shows the result of the crossover with and without the correction network. This was simulated with a 12dB Bessel filter, and as you can see, there is a profound difference. This is the AC amplitude response only - the actual frequency response (dB SPL) will be quite different in most cases, but will reflect (to a modest degree) the problems that are immediately apparent from the diagrams.

An uncompensated (or partially compensated) tweeter can actually be used in a 12dB filter with little audible difference, provided there is sufficient "distance" between the crossover frequency and resonance. However if you are going to go to all that trouble to build the "ultimate" speaker system, you might as well go the extra mile (kilometre?) and get it right.

Ferro-fluid damped tweeters will usually have an impedance that changes so little that compensation is not required. Regardless, the tweeter should be measured to make sure it will not upset the crossover network.

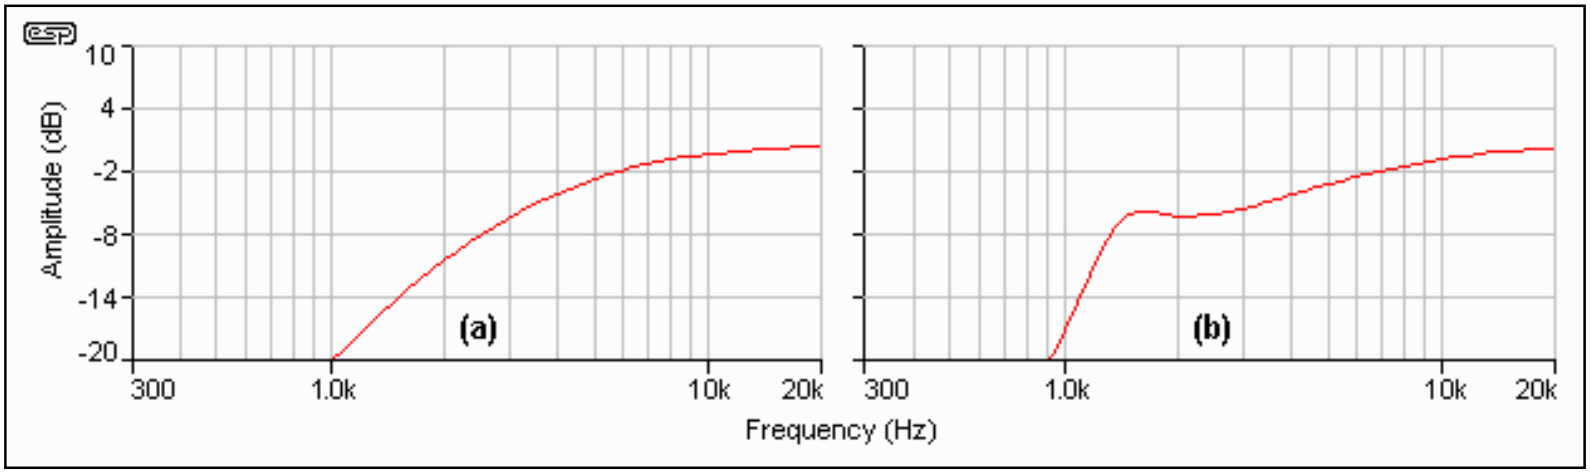

Figure 3.8 - 12dB Filter Response With (a) and Without (b) Compensation

The effect is much worse with a 6dB filter, and this is shown in Figure 3.9. Note the tweeter resonance - it is completely undamped, and the attenuation of a 6dB filter is obviously not sufficient to reduce power to a respectably low level, even though the crossover frequency is set to 3kHz.

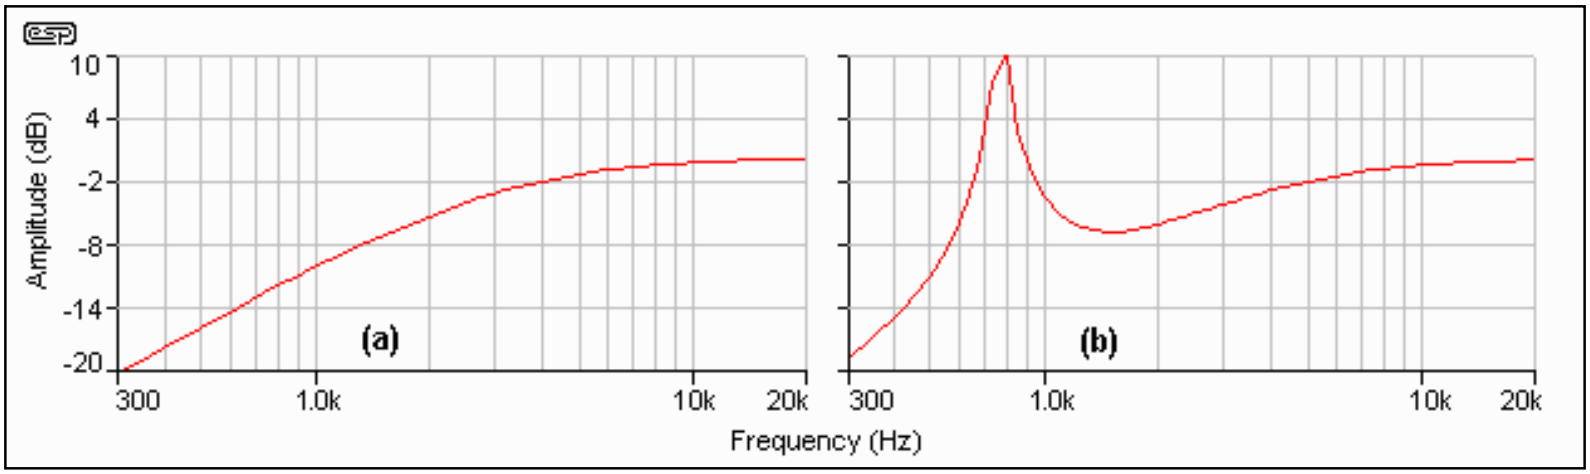

Figure 3.9 - 6dB Filter Response With (a) and Without (b) Compensation

As you can see in (a), the tweeter signal is down by only about 10dB at resonance, and the uncompensated version is very much worse. Somewhat surprisingly (somewhat ??), the audible effect is not as bad as these diagrams indicate, but there is no doubt that for a high quality system, the effects are there to be heard - you just have to know what to listen for.

3.2 Amplifier Impedance

If the speaker impedance has an effect on the crossover performance, then it follows that the amplifier's output impedance will also have an influence. With the majority of transistor amps, this is not an issue, but a valve amp is very different indeed.

Most valve amps have an output impedance that is at least a few ohms, and for the sake of the exercise, we will assume an impedance of 4 ohms.

In a crossover that was previously completely flat when driven from a zero ohm source (a 12dB 'sub-Bessel' filter with a Q of 0.5), there is a 1.5dB (approx.) peak at the crossover frequency when the source impedance is increased to 4 ohms. The effect is less pronounced than with a variation in loudspeaker impedance, but may be considered objectionable nonetheless.

Again, this is not allowed for in any speaker that I know of. If a speaker is to be able to be driven with either a valve or transistor amp, then a switch is needed to modify the crossover to suit the source impedance. Any claim as to "audiophile" performance is negated if the speaker cannot be accurately matched to the amplifier that will be driving it.

This also rather destroys the "audibility of cables" argument, since those who can "clearly hear a difference" between two equivalent quality cables, rarely seem to hear the peak in response that occurs when they use a valve vs. transistor amplifier. One of these effects is far more pronounced than the other - I shall leave it to the reader to decide which is likely to be more audible 😀.

*A word of warning is worthwhile here. **Never** operate an amplifier into a crossover network with the drivers disconnected. It may be tempting to look at the response, but at a frequency equal to the series resonant frequency of the inductor and capacitor, the network may present almost a dead short circuit to the amplifier (depending on the filter type - second order filters are the greatest risk).*

Current is limited only by series resistance, and dangerous voltages can be developed across the capacitor and inductor. These can be sufficient to damage the capacitor (due to over-voltage), and can give you a very nasty electric shock. The amplifier may not survive this abuse either, so it could be a very expensive temptation indeed.

With only 10V RMS applied at the resonant frequency of the 3kHz filter shown below (and assuming a total series resistance of 1 ohm), the amplifier will be supplying 8.3A RMS, and there will be 98V RMS across the inductor and capacitor. Provided the Zobel network is left in place, the resonance is damped so heavily that any risk is eliminated.

3.3 Temperature

In case you were wondering, the voice coil temperature used in the examples below (150°C) is not as outrageous as it may seem. Since loudspeakers have an efficiency of typically 1% or less, this means that 99% of all the power going to the speaker must be dissipated as heat. Although there is some air movement through the voice coil gap, it cannot keep the temperature down low enough to ensure that the effects described will not disturb the behaviour of the crossover network. An efficiency of 1% indicates just over 92dB/m/W, which is quite a respectable figure in the world of loudspeakers!

Copper has a thermal coefficient of resistance such that its resistance increases by 0.395% per °C (variously listed as anything from 0.39% to 0.43% on different websites). We can safely assume that the impedance is based on "room temperature", which will generally be in the order of 20°C. When power (in the form of music or test signals) is applied to a speaker, the voice coil temperature must rise. Given a typical 6.6 ohm (DC) voice coil for an 8 ohm nominal speaker, at 150°C, the resistive component alone will rise to 10 ohms - and naturally the impedance must be somewhat greater than this figure.

The loading on the crossover network is then radically different from the basic design figure of 8 ohms, or any corrected impedance obtained by using a Zobel network. The real issue here is that there is virtually *nothing* you can do about it, so the loading on the crossover network will vary depending on how loud the speakers are playing!

You may have read reviews where a loudspeaker system was described as becoming "edgy" or "brittle" at higher levels. This may be because the amplifier was clipping, but it could also be the result of what is called "power compression". Woofers are particularly susceptible to this phenomenon, since they are expected to handle more power than tweeters. Many

tweeters use ferro-fluid in the voice coil gap, which not only improves damping and reduces resonances, but also gives a higher power handling. This means that the voice coil temperature rise will often be much lower than for the woofer, so the relative efficiency (in dB/m/W) from the tweeters remains the same, and that of the woofer falls (as it must if the impedance increases).

Of course, some speakers may have been optimised for a higher than average listening level, and these are likely to sound somewhat dull at "normal" listening levels.

That the impedance varies with power level is not conjecture, it is a fact, and the effects can be proven in demonstrations and by measurement - this variation is as dictated by the laws of physics, and no speaker manufacturer has been able to break those laws.

> The question remains - what can be done about it?
> The answer (regrettably) remains - virtually nothing!

It would be possible to use a thermistor (a special resistor whose resistance varies with temperature), but matching its thermal characteristics to the voice coil would be a formidable task. Since a thermistor is by definition a non-linear device, it may also introduce distortion of its own - a less than desirable outcome.

It is not only the power compression of relative levels that has an effect in this case - the crossover frequency will shift with volume! It really has no choice, since the voice coil will change impedance, and the crossover frequency (and filter damping) is determined by the load - the loudspeaker, and any additional network you use to equalise its response.

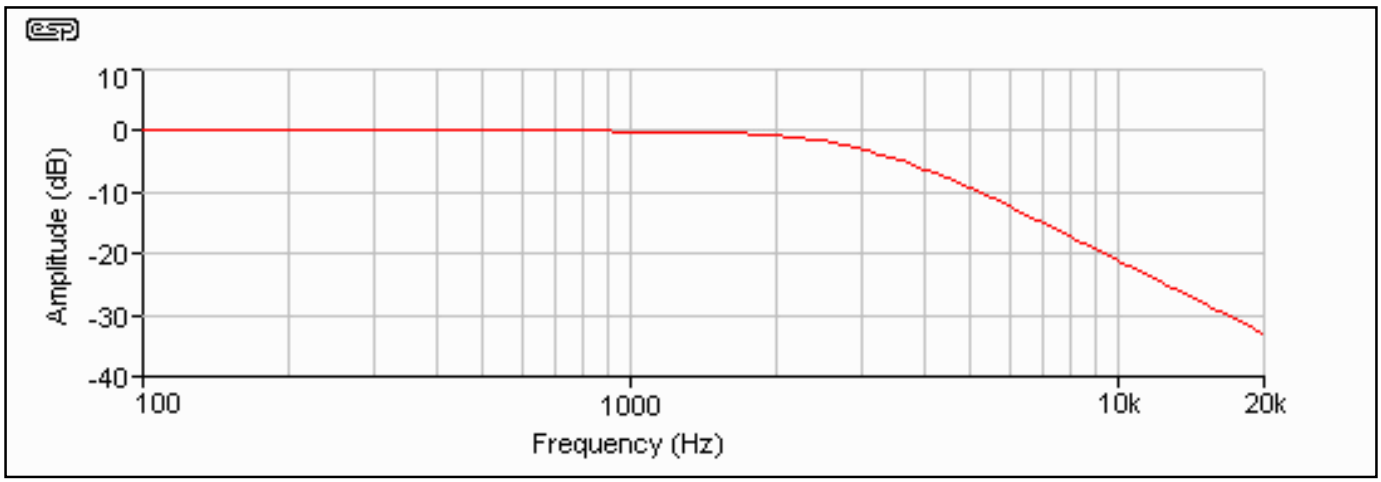

Figure 3.10 - Filter Performance at Ambient Temperature (Z = 8 Ohms)

As an example, let's assume that a loudspeaker has a flat impedance curve, and is exactly 8 ohms. A Butterworth crossover may be designed that will have a -3dB frequency of 3kHz (Figure 3.8). Should the impedance rise to 11 ohms (as in the above example of a 150°C voice coil temperature), the -3dB frequency will increase to over 3.8Hz, and the filter shape is

changed. A Bessel filter will become Butterworth, or a Butterworth filter will now be Chebyshev! This is shown in Figure 3.11, and the typical peak before rolloff of a Chebyshev filter response is easily seen - as is the frequency shift.

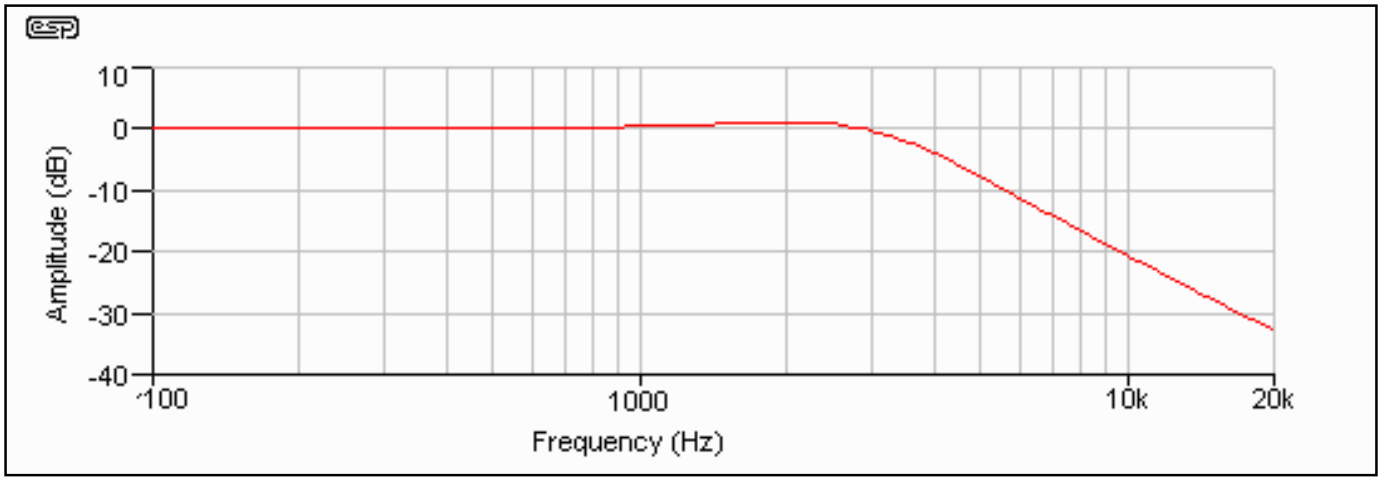

Figure 3.11 - Filter Performance at Elevated Temperature (Z = 11 Ohms)

Meanwhile, because of the relatively low power in the tweeter, and possibly due to the effects of ferro-fluid, its temperature rise may have caused the impedance to rise to only 9 ohms (example only). Even this is sufficient to cause the crossover frequency to fall to about 2.7kHz, and will also change the filter shape (but to a lesser degree).

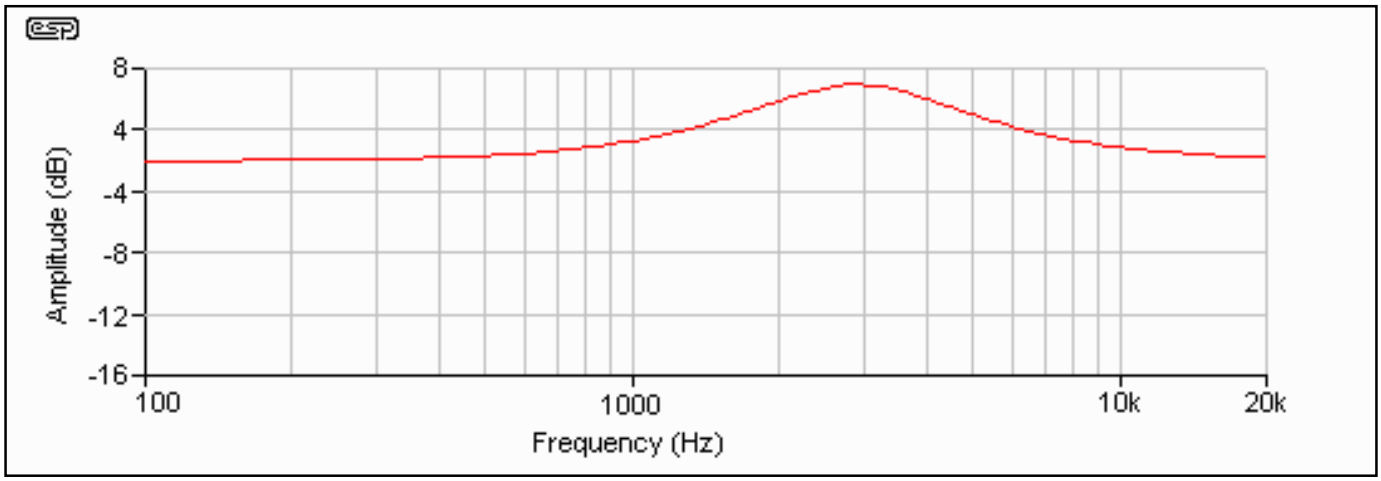

Figure 3.12 - Combined Crossover Response at Elevated Temperature

A crossover that at ambient temperatures had a nice stable (and well defined) crossover frequency of 3kHz, now has a 1.1kHz overlap! The audible effect is a disaster, since there will be quite a prominent peak (almost 5dB) at around 2.8kHz - the approximate centre frequency of the overlap region. Needless to say, if the tweeter had an equivalent temperature rise (due to the use of an aluminium voice coil, for example), then the overlap region becomes greater, and the peak is worsened - the amplitude will be relatively unaffected, but the peak will be wider as the two speakers are reproducing the same frequencies. The effects on relative phase and dispersion are less predictable, but we can safely assume that the outcome will be undesirable! (To put it mildly.)

A further consideration (although probably of minor consequence except in extreme circumstances) is that the tweeter will now absorb a little more power, causing its voice coil temperature to rise further, thus lowering the crossover frequency and allowing more power, thus raising the temperature even further (etc.). Whether this would reach destructive levels is doubtful - but the possibility exists! An amplifier pushed into distortion for extended periods could conceivably lead to this self destructive behaviour (assuming that the tweeter survives the high average power to start with).

This behaviour could be made to disappear completely when an electronic crossover is used. Although the details are not relevant to this article, a signal processor can be adapted to adjust the level to compensate for power compression in the drivers. To my knowledge this has never been done. The truth is, this is far less of an issue when an electronic crossover is used - the power compression still occurs, but there is no shift of the crossover slopes, so the effect is only on relative levels, and not the designed crossover frequencies. It is a simple matter to adjust the relative outputs of the electronic crossover to match the average power that will be used, so one could have a switch, marked "Soft", "Normal" and "Loud" if desired :-)

3.4 Atmospheric Changes

The loading on a loudspeaker cone, and therefore its Thiele/ Small parameters, will also vary with changes in the atmospheric conditions. High humidity, altitude or temperature make air less dense - such variations will cause changes to the loading on the cone, and thus the speaker's parameters.

In reality, these are relatively small, except at extremes. Even at the extremes, the physiological effect on the listener will probably be far greater than the atmospheric effects on the loudspeaker, but I know of no tests that have been performed to measure the changes experienced by any driver with differing atmospheric conditions.

I doubt that there are vast differences, but it is an additional consideration worthy of further investigation - preferably by someone with access to an environmental test chamber. Relying on the vagaries of the weather and quickly taking some measurements is unlikely to yield meaningful results.

Fortunately, it is unlikely that the performance of a passive crossover will be affected to any audible degree by normal variations in atmospheric conditions.

4.0 Selecting the Filter Slope, Alignment & Components

Having digested the above, you now bravely decide to go ahead regardless. The next task is to select the filter slope and alignment. Again, there are compromises that must be made, and

it is important to select the most appropriate crossover to suit the drivers you are using.

4.1 Slope

Selecting the best slope is important, both to protect the tweeter (in particular), and to ensure that the drivers are all operated within their optimum frequency and power handling ranges. A first order (6dB/octave) filter has the most predictable response, and is affected less by impedance variations than higher orders. On the negative side, the loudspeaker drivers will be producing sound at frequencies that are very likely outside their upper or lower limits. At low powers (less than 10W or so), this is usually not a major issue, but it becomes much more important when amplifier powers of 50W or more are considered.

Second order filters (12dB/octave) are better at keeping unwanted frequencies out of the individual speakers, but are more complex, and are affected by impedance variations to a much greater degree. The tolerance of the components used will also have a greater effect, so it is not uncommon for designers to make the inductors specifically for the job, rather than attempting to use "off the shelf" coils. The capacitance used must also remain predictable and constant over time and power, which specifically excludes the use of bipolar electrolytics (well apart from any other failings they may have - either real or imagined).

The design task becomes more complex and the tolerances more exacting as the order is increased. A third order (18dB/octave) filter requires closer tolerances than a second order, and is again even more susceptible to any impedance variations than the 12dB filter. Fourth order (24dB/octave) increases the complexity and tolerance requirements even further - a point must be reached where the requirements versus the complexity and sensitivity will balance out. With passive crossovers, I now believe that anything over 12dB is a waste of time, especially when the effects of voice coil temperature are considered.

Even with the second order filter, the possible variations (especially those caused by voice coil temperature) can totally ruin the sound - regardless of the quality of the components or care in making the crossover. I shall leave it to the reader to determine for him/her self where to draw the line.

4.2 Filter Alignment

The traditional passive crossover is (and for the most part always has been) the Butterworth - at least for second order filters and above. Although this may seem the ideal, it is not, since there is a 3dB peak at the crossover frequency when the outputs are summed. It is now commonly accepted that this peak is also present in almost all speaker systems when the loudspeaker outputs are summed acoustically - i.e. in normal operation. Many (reputable and/or higher priced 'audiophile') loudspeaker manufacturers will modify the crossover to compensate for this effect, but most of the formulae you find on the Net (and even in books and magazines) will simply use the nominal impedance of the drivers, and work out a pair of conventional Butterworth filters. IMO, this is not usable as a crossover for high quality reproduction, but it remains firmly entrenched regardless.

Again, this is a world of compromise. My preference is for a sub-Bessel alignment with a Q of 0.5, since it provides a close approximation to a Linkwitz-Riley alignment, and has zero peak or dip at the crossover frequency. Since the Q is lower, it is also marginally less sensitive to variations in loudspeaker driver impedance, but this is not something that should be relied upon.

As I mentioned above, a first order filter has a Q of 0.5 as a matter of course, and this cannot be changed.

Second order filters have an overall phase reversal, and this must be accounted for. In a two-way system, the tweeter is usually connected out of phase - the negative terminal is connected to the "positive" or hot output of the filter network. In the case of a three way system, the midrange driver is most commonly reversed in phase, with the woofer and tweeter connected normally. This maintains the overall phase integrity of the crossover for all drivers. A deep notch is created at the crossover frequency if the phase reversal(s) is/are not done properly - this is objectionably audible!

4.3 World's Worst Passive Component

Inductors

It is worth pointing out that inductors are, in general, the worst passive component imaginable. This is particularly true for use in crossover networks. Because it is not possible to use a core material without introducing audible distortion, the coils used for crossovers are nearly always air-cored. This means that many more turns than might otherwise be needed must be used to get the needed inductance, and that means either a very large, heavy and expensive coil, or a smaller and lighter coil with significant resistance.

Because inductor coils use magnetic coupling, they are sensitive to stray magnetic fields, or any source of variable magnetic flux. This includes cross-coupling from other inductors in the network, or even speaker magnet flux modulated by cabinet vibration. The latter is unlikely in a well constructed enclosure, but it is sensible to keep the coils well away from strong magnets.

Coils also have inter-winding capacitance, and this causes them to have a self resonant frequency that may fall within an amplifier's pass-band ... although rarely if ever within the audio band. The possibility cannot be discounted that an amplifier may be confronted by a very low impedance at some frequency determined by the inductors in the system.

The biggest problem is resistance. Some people will spend a huge amount on 'special' low resistance cables, and/ or an amplifier with a very high damping factor. A typical loudspeaker

crossover inductor will undo all of that instantly, adding perhaps 0.1 to 0.5 Ohm resistance in series with the bass driver (which is the very one that supposedly needs maximum damping). Resistance also causes power loss, and heat. For a crossover inside the cabinet, the last thing needed is another heat source!

So, the world's worst component is the inductor, with those used in crossover networks generally being the worst of the worst. Adding a core to reduce losses simply increases distortion (usually dramatically), so there is no easy way out (other than to use a fully active system, of course ... hint, hint).

Because of the losses, inductors should be wound with the highest gauge wire that you can - within reason of course. To prevent mechanical noise (rattles, buzzes), it is worth impregnating the finished coil in varnish. Soak the coils in a suitable varnish for an hour or so before draining and drying. The varnish doesn't need to be electrical grade, because the voltages are small and the final temperatures should never get high enough to cause thermal damage.

To avoid unwanted interactions, inductors should be mounted at right angles to each other (see below for more on this), and should also be located at a 'safe' distance from ferrous (iron/steel) materials. What is a 'safe' distance? That depends on the size of the ferrous material, and large pieces (such as loudspeaker driver motor assemblies) should be considered potentially hostile. A (measured) 460uH air-cored coil I tested increased to 480uH at 10mm from a smallish sheet of thin (0.8mm) steel plate, so I would expect a minimum distance of 50mm would probably be acceptable in most cases. This inductor has a DC resistance of 0.38Ω, and this gave a dissipation factor of 0.24 according to my meter.

Capacitors

By comparison to inductors, capacitors are positively benign. Their series (internal) resistance is usually extremely low, and self-resonance is influenced more by lead length than by the component itself. Even high loss capacitors will dissipate far less power than the best low loss inductors. There are some capacitors that should be avoided though, most notably bipolar (non-polarised) electrolytics. When they are new, they work very well, but if they handle appreciable current they will lose capacitance (and gain distortion) over time.

In nearly all domestic systems, all film caps will be quite alright - there is no real need to insist on film and foil types unless there are very high currents involved. Metallised film caps will usually have more than sufficient current carrying ability for systems rated at up to a couple of hundred Watts, and often a lot more. Much has been made of the dielectric material, but this is generally wishful thinking, perpetuated by a fringe area of audio that insists that no reasonably priced component can ever sound any good. In many cases, you may *pay* the top price for polypropylene, but get polyester anyway, and few people know how to tell the difference between them.

Capacitor Type	Typical Temperature Coefficient
Polyester (Mylar®)	600 to 900 ppm/°C
Polypropylene	-200 ppm/°C
Polystyrene	-125 ppm/°C
Polycarbonate	+100 ppm/°C

Table 2 - Capacitor Dielectric Characteristics

From the above table, you can see that only polypropylene and polystyrene dielectrics have a negative temperature coefficient, so when heated (a hot air gun is one easy way), their capacitance will fall slightly. Polyester and polycarbonate will show an increase in capacitance when heated. All capacitors used in crossovers should be located away from any extreme heat source.

A perfectly ordinary 2.2uF polyester cap measured a dissipation factor or 0.02 - vastly better than the inductor. Although this can be improved upon, the change is unlikely to be audible in the vast majority of cases.

Because capacitors have a small variation with temperature, it is sensible to ensure that they are well separated from any resistor expected to get hot in normal use.

Resistors

Resistors are again benign, although they will always contribute heat if dissipating any power. While non-inductive resistors are available and are recommended, the error introduced by a normal (slightly inductive) resistor will typically be far smaller than the normal production differences between supposedly identical loudspeaker drivers. Any errors introduced will generally not be apparent within the audio band. The inductance of most power resistors is such that the wiring may introduce greater errors than the resistors themselves, given that each 10mm of (straight) wire adds about 5nH of inductance to the circuit.

It is important to ensure that the power rating for all resistors is well above (preferably double) the expected power or which they will be subjected. This is much lower than a full power steady state (sinewave) analysis might indicate, but it may be necessary to experiment a little during the final tweaking phase.

Naturally, any resistor that gets hot cannot be glued to the crossover board with hot-melt adhesive, and ideally should be clamped with a metal bracket to help dissipate heat and ensure that vibration cannot move the part - this may cause the lead(s) to eventually fracture.

5.0 And Now ... Some (more) Maths

The formulae for calculating the various filter component values are not at all complex, although they may appear so at first glance. There are quite a few variations, depending mainly on the slope and alignment. I have included those for 6dB and 12dB variations only, as I don't feel that there is anything useful to be gained by using higher order passive filters - especially in light of the discussions above.

Since it has been shown that the speaker impedance will rarely be 8 ohms - particularly when impedance correction has been applied - I will use 6 ohms for all calculations to follow. You will need to determine the exact impedance of your impedance corrected drivers yourself. It is unlikely that they will exactly correspond to my examples, but you might be lucky .

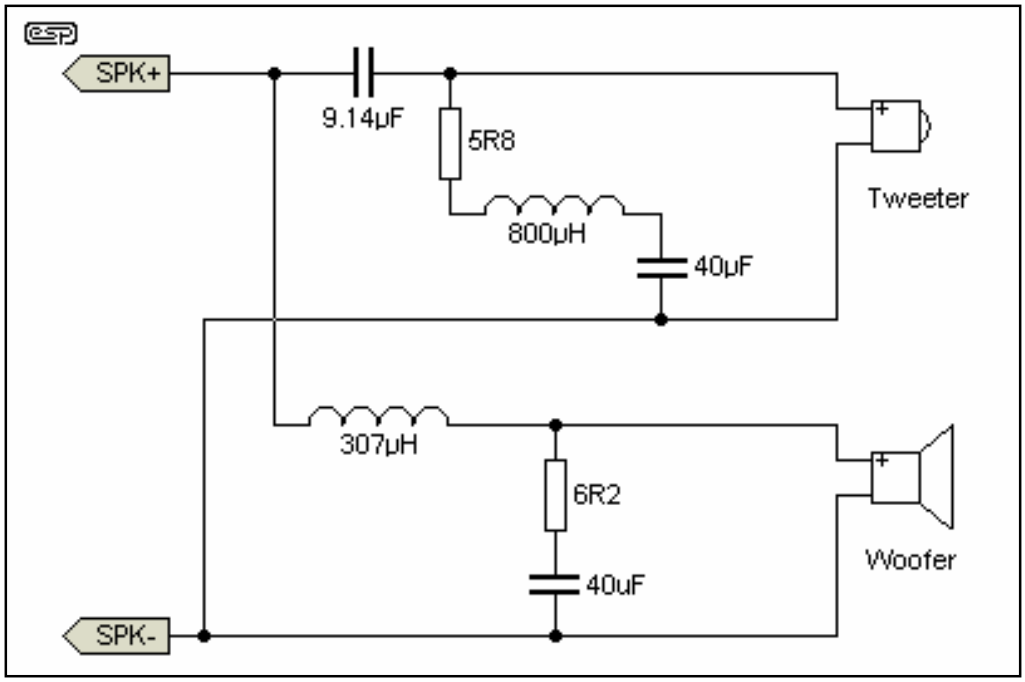

Figure 5.1 - 6dB/Octave 2-Way Passive Crossover

The first filter must be a 6dB two way crossover. This is about as simple as a circuit can get (except that it is actually quite complex when all the parameters are considered). Impedance correction components have been included for reference. I designed this filter using the same drivers used as examples above, and the crossover frequency is 3,000Hz.

$$C = 1 / (2 \pi Z f)$$
$$L = Z / (2 \pi f)$$

Where:

C = capacitance in farads
L = inductance of the coil in Henrys
f = frequency in hertz

Z = (actual) impedance of the speaker in ohms

These can be "simplified", and reduce to the following ...

C = 0.159 / (Z f)
L = (0.159 Z) / f

Thus, for a crossover frequency of 3,000Hz at 6 ohms (a standard I shall use throughout these examples) ...

C = 0.159 / (6 * 3,000) = 8.83 uF
L = (0.159 * 6) / 3,000 = 318 uH

The crossover frequency is the -3B point on the response curve, but since this is a sub-Bessel filter (having a Q of 0.5, or a damping of 2), the response is completely flat across the crossover point.

A schematic for a 12dB crossover using the simulated drivers as used above is shown in Figure 5.2, and again includes the impedance correction circuits. The schematic for nearly all conventional parallel crossovers is the same, only the component values change. Note that the component values have been calculated for the simulated drivers, and should not be used as shown - this also applies to Figure 5.1

Note especially that the tweeter is wired with its phase reversed - this is important, and must not be forgotten. This only applies to the 12dB example.

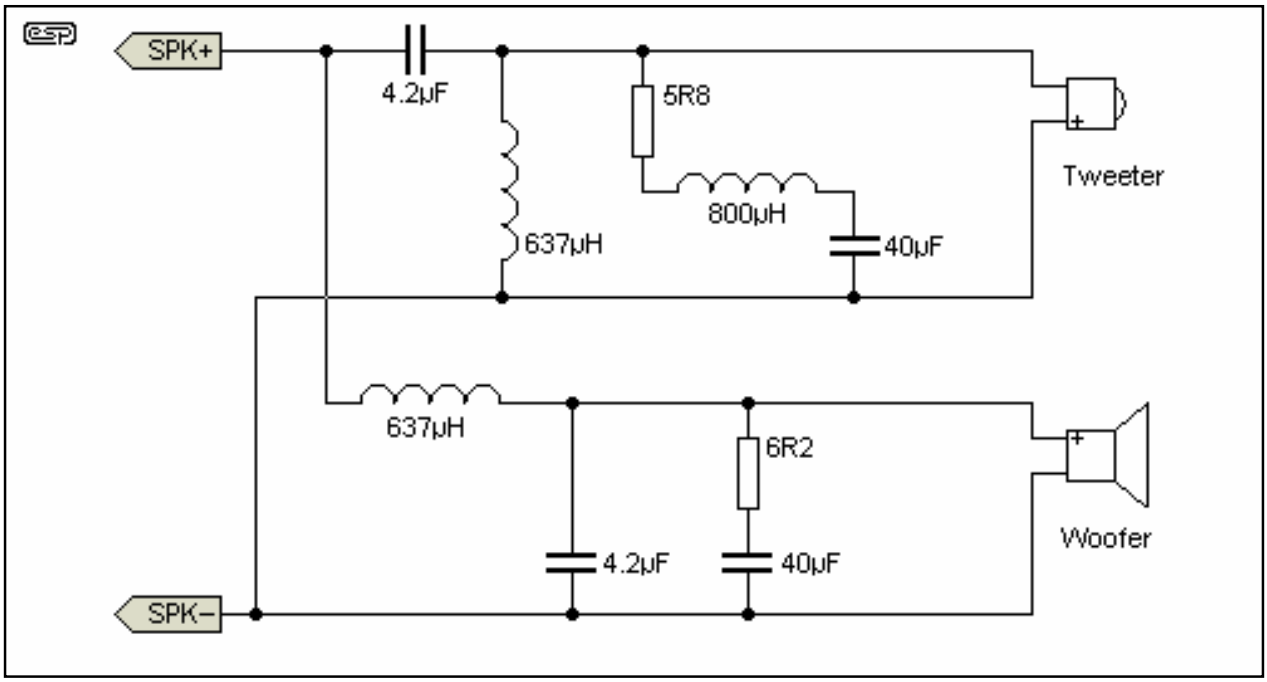

Figure 5.2 - 12dB/Octave 2-Way Passive Crossover

The same circuit is used for all calculations for 12dB filters. Using a 12dB filter network with a Q of 0.5 (which gives an approximation of a Linkwitz-Riley alignment) the following (simplified) formulae will determine the component values ...

C = 0.0796 / (Z * f)
L = (0.3183 * Z) / f

The derivation of these is marginally interesting, and will help you to understand the Butterworth and Bessel alignments a little better. The full original formulae are ...

C = 1 / (2 * π * Z * d * f)
L = (Z * d) / (2 * π * f)

Where ...

d = 1/ Q = 1 / 0.707 = 1.414 (Butterworth)
or ...
d = 1 / Q = 1 / 0.5 = 2 (sub-Bessel)
d = 1 / Q = 1 / 0.57 = 1.75 (Bessel)

A sub-Bessel filter (for our purposes) has a Q of 0.5 or a damping of 2. Note that this has nothing to do with amplifier 'damping factor' which is completely different, and as long as it exceeds about 10, has no influence on crossover performance (although woofer performance may require the amplifier damping factor to be higher than this).

6.0 Attenuation Networks

It is rare that the woofer and tweeter (or midrange driver) will have the same sensitivity (i.e. efficiency). The woofer should have the lowest efficiency, since it will require the most power, and any network that reduces the level to the woofer will absorb a disproportionately high power, and will adversely affect the damping factor.

The driver selection is very important - ideally, all drivers will have the same efficiency, and no attenuation will be needed. In the real world, this will rarely be the case. Attenuator networks are a necessary evil - it is immeasurably better not to use them at all, but they cannot be avoided unless the drivers have *exactly* the same sensitivity.

For the purpose of the exercise, assume that the tweeter has an efficiency 2.8 dB greater than the woofer/midrange. This means that the level must be reduced by 2.8dB, or the speaker system will sound too bright. Remember that this network can alter the impedance presented to the crossover network, so you either must design for the impedance with the attenuator in circuit, or ensure that the attenuator presents exactly the same impedance as the speaker.

The very first exercise is to determine the resistive drop caused by the low pass inductor (this step is almost always forgotten!). A typical coil of this value, using 0.8mm wire, will have a resistance (Rl) of about 0.53 Ohm. We can calculate the low frequency loss in dB with the formula ...

dB = 20 log ((Rl / Z) + 1)

For our example, this gives ...

dB = 20 log ((0.53 / 6) +1) = 20 log (1.088) = 0.73 dB

We have now found that the woofer's sensitivity is slightly lower than before, so we need an attenuation of 2.8+0.73=3.53dB, which we can safely round down to 3.5dB. The tweeter must therefore be reduced in level by 3.5dB so that it matches the sensitivity of the woofer.

The attenuator must be placed either before the filter (basically not a good idea), or between the crossover filter and the driver - including any impedance compensation. The driver and its associated impedance correction network should be considered as one, and they should not be separated (unless you feel like re-calculating the entire crossover and compensation networks). I have seen a number of design examples that state that the attenuator should be before the crossover - *wrong, wrong, wrong!*

This practice increases power dissipation needlessly, since the attenuator must work over the entire frequency range. If attenuation is after the crossover, then power requirements are greatly reduced.

The simplest attenuator is a series resistor, but this changes the load presented to the crossover network. Unless the network is designed for the impedance presented by the combination of driver and attenuator resistor, this is unacceptable. As a result, the most common attenuator is an "L" pad. This is shown in Figure 6.1, and maintains an impedance of 6 ohms to the crossover, but reduces the tweeter level by 2dB.

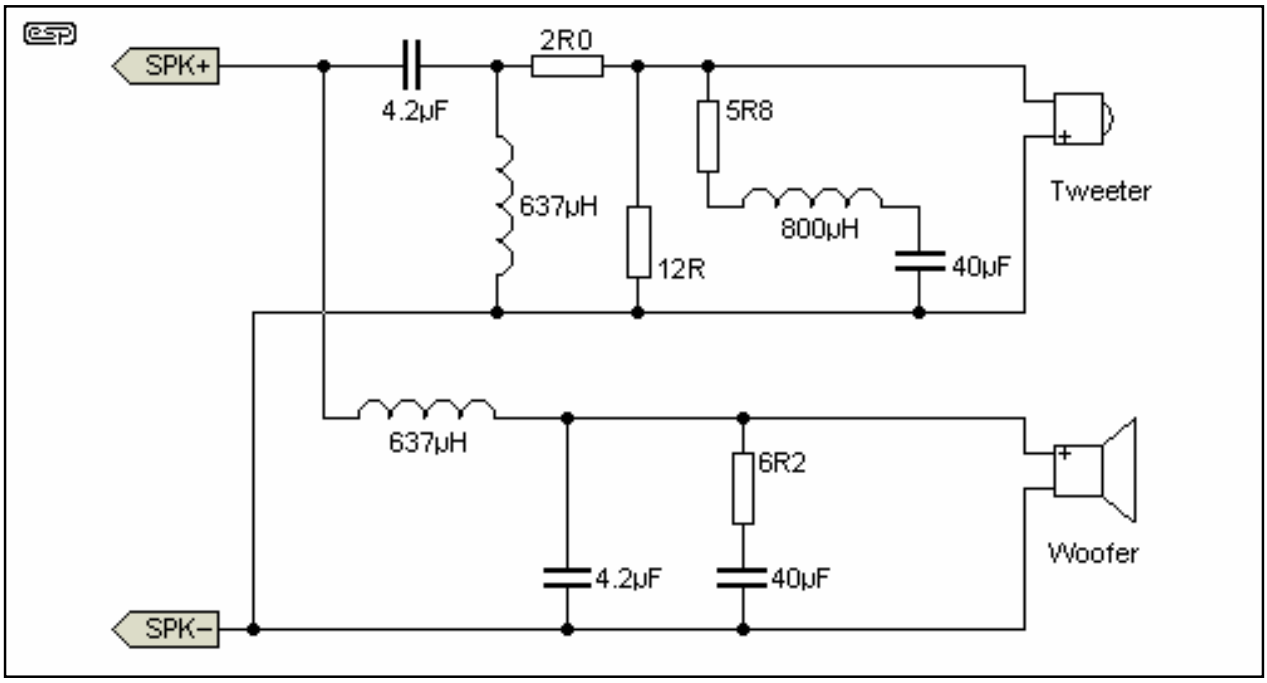

Figure 6.1 - 2dB L-Pad Attenuator

The calculations are quite irksome, and (as always) can be tiresome. The problem is that the resistances are interdependent - if one changes, then so does the other. The idea is to maintain the same impedance we had before, or re-calculate the crossover network. The latter is very much easier, but means that the high and low pass sections will no longer have the same component values. For the purposes of the exercise, I will maintain the crossover, and make the resistors provide the same 6 ohm load as before.

Essentially, there are two ways to calculate an L-Pad - the simple way and the hard way. I am going to use the hard way, because it is simpler! How can this be? If I give you a formula that just spits out the value, that is easy, but you will *never* remember the formula. On the other hand, if I show you how to derive the formula using simple ohm's law, then you will be able to use the basic method, and you will have a much better chance of remembering it.

As suggested, the tweeter in this example is 3.5dB more efficient than the woofer + inductor combination, so must be attenuated by this amount. Please remember that these are examples only, and your situation will probably be completely different. First, we need to convert 3.5dB into a voltage ratio (Vr) ...

> **dB = 20 log (V1/V2) = 20 log (Vr)**, so reversing the formula we get ...
> **Vr = 1 / (antilog (dB / 20))**

For this example, we have 3.5dB, so substituting ...

> **Vr = 1 / (antilog (3.5 / 20)) = 1 / (antilog 0.175) = 1 / 1.496 = 0.668**

The voltage presented to the tweeter will therefore be 0.668 of the input voltage. Since we

want to preserve the impedance presented to the crossover network (rather than redesign the rotten thing :-) this makes the calculations a little harder.

As I said above, it is not impossible to derive a formula for the pad, but it is more convenient to work it out the long way - largely because this provides a better understanding of the process. We will assume an input of one volt - simply because it is convenient to do so.

Firstly, we need to determine the current that will flow into the load (**Z**) ...

I = V / Z = 1 / Z

Now, find the voltage drop across the series resistor **Rs**, then the value of **Rs** ...

Vs = 1 - Vr
Rs = Vs / I

The process is quite simple so far. Now we need to determine the value of the parallel resistor, **Rp**. We already know that the voltage across the parallel combination of **Z** and **Rp** - it is equal to **Vr** (I told you that an input voltage of 1V was convenient, didn't I? . The value if **I** (current) does not change, so we can determine the current through **Z** and **Rp** easily, and then **Rp** itself ...

Iz = Vr / Z
Ip = I - Iz
Rp = Vr / Ip

Now, let's substitute all the values for the example into the formulae. As I said, this is a little tedious, but easily remembered. Recall does not come from rote learning, it comes from *understanding*, and this is just simple arithmetic and Ohm's law.

I = 1 / Z = 1 / 6 = 0.1667 Amps
Vs = 1 - Vr = 1 - 0.668 = 0.332 Volts
Rs = Vs / I = 0.332 / 0.1667 = 1.99 (2.0) Ohms

That was easy enough, so now for Rp ...

Iz = Vr / Z = 0.668 / 6 = 0.111 Amps
Ip = I - Iz = 0.1667 - 0.111 = 0.0557 Amps
Rp = Vr / Ip = 0.668 / 0.0557 = 11.99 (12.0) Ohms

Now we might want to check that the values really will give us what we wanted - I recommend this final check, because there are resistor values that are easily created (or are standard), and we want to use these if possible. As a result, we will substitute 2R (2 x 1R in series) for

Rs, and 12R for Rp, as these are standard values. The first thing we need, is to determine Rt - the total parallel combination of Z and Rp (Z || Rp). We could do that from the current calculated earlier, but that may re-introduce any error made earlier.

Rt = 1 / (1 / Rp + 1 / Z) = 1 / (1 / 12 + 1 / 6) = 1 / (0.0833 + 0.1667) = 4 Ohms
Vd = (Rs / Rp) + 1 = (2 / 4) + 1 = 1.5
dB = 20 log(Vd) = 20 log (1.5) = 3.52 dB

Damn! That was close

An error of less than 0.1dB is completely insignificant, and can be ignored completely, but in this case, we got almost *exactly* the attenuation we determined right at the beginning. In case you were wondering, this was not deliberate - it just turned out that way. If you are careful with your calculations, it will always turn out this way.

The resistors should be wirewound power types, and the actual power is determined by the input power from the amplifier.

7.0 Determining Power Losses

There will always be power losses in a passive system - this is generally referred to as "insertion loss", and all resistors and inductors will create power loss and thus, heat. Capacitors will generally contribute very little loss, and will not get hot - a potentially notable exception being bipolar electrolytics. This is another very good reason not to use them, but the main reason is that their value will change over time, and will upset the crossover frequency.

The power loss is naturally proportional to the input power, and for our example, I shall assume a maximum amplifier power of 100W. Use the chart below to determine how much power will go to the tweeter, using a crossover frequency of 3.0kHz.

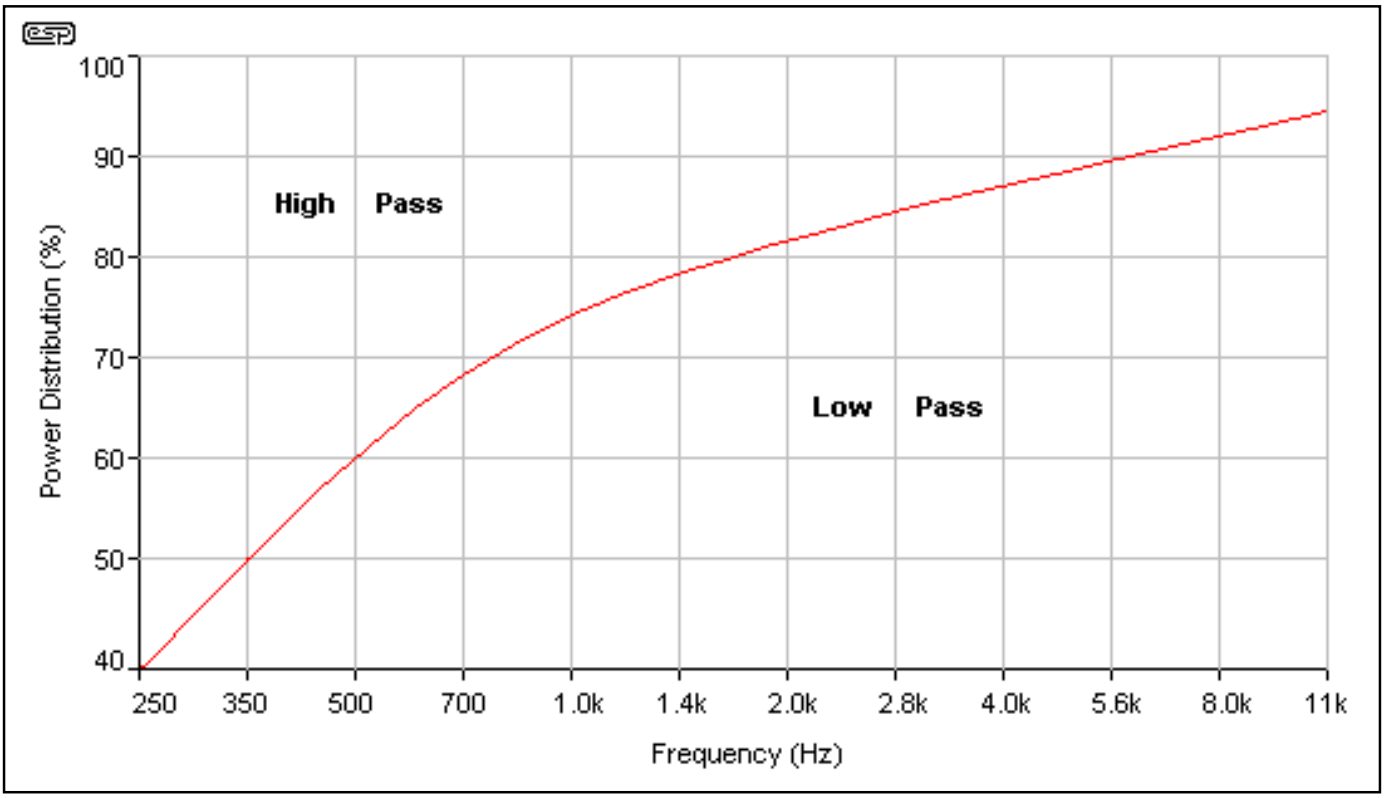

Figure 7.1 - Power Distribution Chart

Working along the frequency axis, we see that at 3kHz, the power in the low pass section will be about 85% of the maximum (85W), so the high pass power level is about 15%, or 15W for our 100W system. We are now in a position to work out some power ratings for the resistors, and can also calculate the inductor losses. Not that we can do anything about losses in inductors, but we can at least decide whether they need to be mounted on fire proof material (just kidding).

We already know that the woofer's Zobel network only needs to operate at over 650Hz, so using the chart again, we see that the low pass section will get about 65% (65W) at that frequency. The Zobel network is a high pass section (yes it is!), so the maximum power will be at above 650Hz, where high frequency energy is less than 35W. Since the power progressively reduces, the resistor will never have to deal with more than about 20W peak. Since no-one (well, no-one who is going to go to all this trouble to make an almost perfect crossover) will listen at 100W continuous, we can safely assume an average power of about 10W - this corresponds to the "typical" peak to average ratio for music of 10dB.

Woofer Zobel resistor ...
I would suggest a power rating of 10W for the Zobel resistor - this provides a very large safety margin.

Tweeter resonance compensation ...
The tweeter power at resonance is more than 20dB down from the maximum level using a 12dB crossover. Since this is the case, a 5W resistor is more than adequate.

Tweeter L-Pad ...
The L-Pad will be subjected to a maximum of 15% of the power, but will dissipate very little of this. 5W resistors are again more than enough to handle the power.

Woofer inductor ...
Since we determined that the resistance will be about 0.53 ohms, so at full power it will dissipate less than 10% of the 100W input, which is about 10W. (0.53 ohms is 8.8% of 6 ohms) The average will be much less than this, and heating will not be a major problem.

Note that all the losses above are wasted power, so in all, only about 90W of the amplifier power will ever get to the speakers themselves, and about 10% will simply be wasted as heat - inside the cabinet! This will eventually cause the air inside the box to heat up enough to change the characteristics of the enclosure - especially sealed boxes. This is added to the heat generated in the loudspeaker voice coil, a good proportion of which will remain in the cabinet, having no means of escape.

Perhaps you would be better off either mounting the crossover network on a heatsink on the outside of the box, or install it in a false (ventilated) base. And yes, I am serious. Apart from the heat (which is actually relatively low compared to that generated in the voice coil), the high sound pressure will cause vibration of the components. While I think that this is unlikely to be audible if everything is well fastened, there are claims from some quarters that microphony at this level is definitely audible. For the small additional effort, external mounting is recommended. It also make minor tweaks and adjustments much easier, since you don't have to remove speakers to get at the crossover.

8.0 Winding The Coils

Using the drivers simulated in this article, and using all the networks that were devised along the way, we have examined the complete 12dB/octave crossover network implementation. The tweeter is 2.8dB more efficient than the woofer (not allowing for the additional inductor loss), and is padded back with an L-Pad that reduces the signal while maintaining the impedance.

Use the examples above to work through your own crossover design - the final result is quite complex, and will not be inexpensive to build. This is the price to pay when the best possible performance is to be obtained from a passive crossover (now, wouldn't it have been easier to tri-amp the system instead?).

All that remains is to explain how to wind the coils you will need. It may be possible to obtain them commercially, but I doubt it, since the values are unlikely to match those you will find at most electronics outlets. You may be able to get coils that are slightly above the values you

need, and remove a few turns until you get it right.

An inductance meter is essential for any of this - many are available in (even relatively cheap) digital multimeters, and these should be sufficiently accurate. It will be virtually impossible to get the coils right without a meter - you can measure their resonant frequency with a known capacitance and calculate inductance from that, but it is very tedious!

If you want to wind your own coils, I suggest you use either of the following the online calculators, available at ...

Shavano Online Music - Inductance Calculator
Barry's Inductor Simulator

Both of these are very much easier than using the formula below. You will still need to measure the final result to make sure that it is within a reasonable tolerance. Much as it might appeal, don't use iron or ferrite cored inductors for crossovers. There are advantages in that they are smaller and have less power loss, but the distortion and risk of saturation (at which point inductance drops dramatically) are not worth it (IMHO).

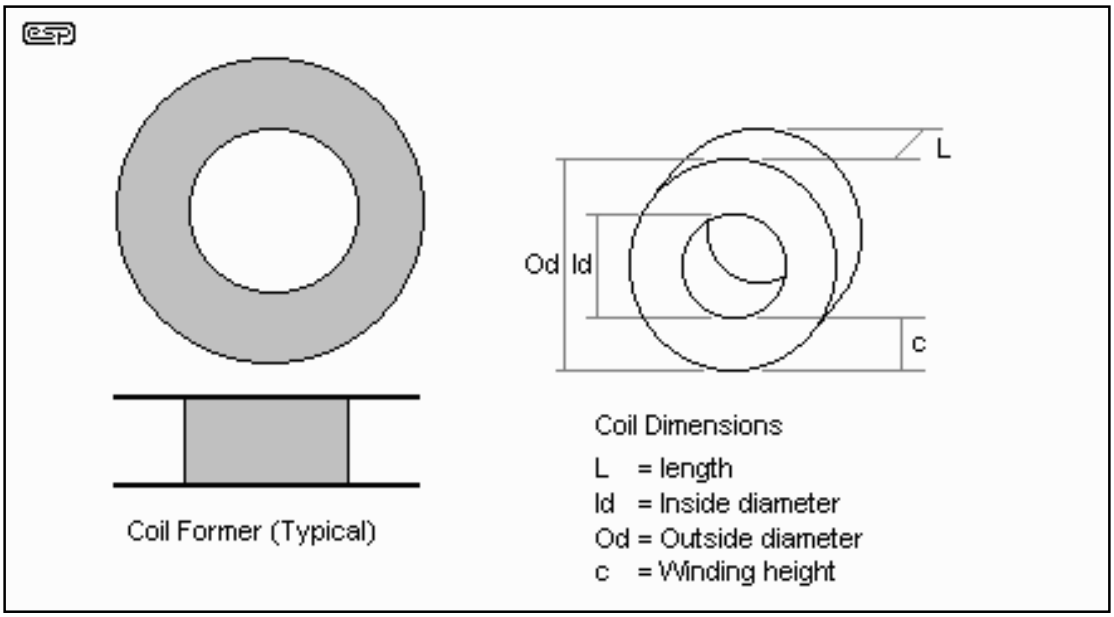

Figure 8.1 - Typical Coil Former and Dimensions

From the above, the necessary dimensions used in the formulae can be easily determined. These apply to the winding itself, not the former (which may be a temporary affair, as it is only needed while winding the coil). There are actually several different formulae that may be used - all are empirical, and require some experimentation to arrive at the correct value (or the correct number of turns for a given inductance and wire size).

Some I found are not worth the paper they are written on - they either don't work, or work only under certain limited circumstances. The formula below is due to Wheeler ("Simple inductance

formula for radio coils" 1928), and is still probably the most accurate so far (which is scary - a formula over 70 years old has never been surpassed). The original (using inches (mutter, mutter)) is ...

$L = 0.8 * a^2 * N^2 / (6a + 9l + 10c)$ uH

Where

N is the number of turns.
a is the average radius.
c is the height of the windings
l is the length of the coil.

All dimensions are in inches. This is easily converted in a spreadsheet or program, but modifying the formula itself is too tedious. For a real example of a coil wound with 0.83 mm (20 AWG) wire, having a design inductance of 637 uH and a resistance of 0.53 ohms has the following dimensions ...

N = 99 turns
l = 11.2 mm (0.44")
Id = 44.8 mm (1.76")
Od = 58 mm (2.28")
c = 6.64 mm (0.26")

These figures were arrived at from one of the Shavano online simulators, and when the data is plugged into the very basic spreadsheet I have done so far indicates that this coil will have an inductance of 635.17 uH. This is a very small error, and will be of no consequence in practice. According to the simulator, power handling is 180 Watts, and it will require approximately 15.9 metres (52.3 feet) of coil winding wire.

Never use plastic coated wire for winding inductors - enamelled winding wire is essential. In most cases, it is probably simpler to buy ready made coils (of higher inductance than required) and remove turns to get the exact value you need.

When the inductance is correct, soak the coil in varnish for an hour or so (most clear floor varnishes are quite acceptable), drain, and let it dry thoroughly before use. This ensures that the turns cannot move - we don't want to add vibration sensitive coils to the already suspect passive crossover. It will also prevent rattles - of the type that will drive you nuts, because you will have no idea where (or what) is rattling! Vacuum impregnation is nice, but few constructors will have the necessary equipment. If desired, coils may have potted centres to facilitate mounting, but you *must* use nylon or brass screws - steel screws will increase the inductance significantly! Brass screws may decrease the inductance ever so slightly, but the error is unlikely to be significant.

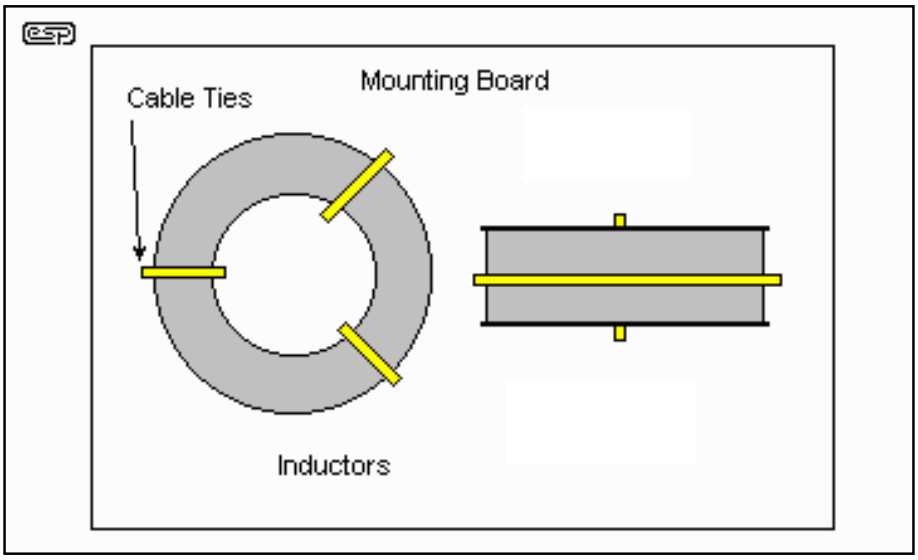

Figure 8.2 - Mounting Inductors to Minimise Coupling

When mounting the coils, keep them well separated, firmly attached to the mounting board, and ensure that there is minimal mutual coupling by placing the axes at right angles to each other as shown in Figure 8.2 - transformers in the crossover you ***don't*** need. Use cable ties and silicone, hot-melt or epoxy glue to make sure the inductors are firmly fastened to the mounting board and cannot move. Any movement will eventually fracture the copper wire if it is rigidly attached, so a loop of wire from the coil (or stranded wire leadouts) will ensure that you don't have electrical failures.

It has been pointed out by a reader that one can economise on the inductor wire if the finished product is going to be installed with a series resistance (to equalise impedances, or provide a level of correction for example). Simply using a thinner wire will make the inductor smaller and cheaper, and if you are very lucky may eliminate the resistor altogether. One must be careful that the coil resistance is the same or lower than any external series resistance - if resistance is too high, there is nothing you can do to lower it again.

9.0 Conclusion

This article has covered the topic in far more detail than you will find in most references, and explains some of the things that most articles don't even touch upon. One thing that should be quite clear by now, is that a full 3-way passive crossover, with everything done properly will be ***very*** expensive to build. It is also time consuming, and the final result will only ever be as good as the effort you are willing to put into getting everything right.

A few generalised recommendations are in order ...

- Sub-Bessel filters are to be preferred for flattest overall response (Similar response to Linkwitz-Riley alignment and easier to design)

- There is a vast amount to be gained by using a biamped system to cover the bass and mid+high crossover. Keep passives for higher frequencies, where their bulk, cost, power loss, and other flaws are minimised.
- A really well designed crossover is of no use if the box is not designed correctly, is inadequately braced, or has drivers mounted equidistant from two or more edges - these cause high frequency refractions that "smear" the stereo image.
- Likewise, voice coil (time) alignment can make a huge difference to the linearity of the system as a whole.
- The crossover will never compensate for a poor selection of drivers, regardless of the work you put into it.
- Some very simple crossovers may appear to give a more "musical" sound reproduction, but are not accurate - in the long term, they cause listener (and driver) fatigue, and are adding things to the music that was never there in the first place.
- Your listening room has more effect on the sound than any of the other points made above! However, a good system has a much better chance of sounding acceptable in a bad room than a bad system (which will sound bad everywhere!).
- A fully active system (using electronic crossovers and separate amps for all drivers) will almost certainly give a better result than the most carefully designed passive system, and may even work out cheaper ... Some passive crossover networks can become very complex and expensive indeed.

A Quick Rant

The "simple" passive crossover is actually vastly more complex than is commonly believed. The "new" Diaural™ "inductor only" crossovers are ***not*** a panacea for the ills of the world (despite *massive* marketing hype to the contrary), but fall into the 'overly simple and grossly coloured' category. There is nothing (repeat - nothing!) about the Diaural system that is new, or will benefit the vast majority of systems. They will probably sound "lively" and perhaps "musical" by initial direct comparison to a conventional crossover, but require very careful driver selection indeed if gross response and phase errors are to be avoided. These are even patented - how in God's name those ratbags got a patent on something that has been done by others for years, we will never know. I have a copy of the patent, and all the variations are shown - so much for the "cone of silence" that was placed on anyone who saw them in the early days. There is absolutely nothing remarkable about the principle, other than the complete and total neglect of almost everything I covered in this article. Especially noteworthy is the fact that they use ... inductors, which as discussed above have more compromises than any other passive component.

So there we have it. I doubt that this is the "last word" on passive crossovers, and I'm equally sure I have left out something that should have been included. I don't profess to be an expert on the design of passives, but my design background and experience (as well as that of a few others) has helped in the analysis of the loudspeaker driver behaviour, in the electrical sense at least.

The mechanical behaviour is something else again, and many excellent papers have been written on the subject. In particular, I suggest Lynn Olson's series of articles (of which I was made aware just as I had almost completed this paper). These are not (IMO) definitive articles, but have sufficient good information to make them recommended reading. Some readers may be mystified that I would include 'subjectivist' material in my reading list, but the fact is that some of the points made are just too important to ignore, and are not often measured by hobbyists and even some manufacturers. That the effects are measurable is not in doubt here ... intermodulation and harmonic distortion are easily measured, but no manufacturer of loudspeaker drivers is going to do so until this is demanded by their customers.

The material presented is mainly to do with cone break-up effects, but some mention is given to impedance correction as well. There are obviously many others, and an enormous amount of research has been done by a vast number of people, all striving for the same thing - the perfect loudspeaker. We don't have it, and may never get it - but when (or if) we do, there will always be someone who says it stinks. Such is Hi-Fi.

Introduction

One only needs to look at a few web sites to realise that there is actually very little useful information on phase in audio systems in general, and loudspeakers in particular. There are a great many conflicting claims and counter claims, but little real data. There is naturally a great deal of rubbish, mostly describing why "Brand X" loudspeaker (for example) is demonstrably superior to every other speaker on the planet (which is why no-one has ever heard of them). Expect to see claims that "this speaker is the only design that will accurately reproduce a square wave" or something similar. As we shall see, this is realistically possible, but has (or should have) a huge "who cares" factor that will be

discussed in greater detail a little later.

This article is not for the faint hearted, as it discusses amplitude, phase and delay, and the complex interactions between them. There is only so much that can be accomplished by diagrams and graphs, and many of the concepts do not lend themselves to easy analysis. I have tried to keep the information in a logical form, but unfortunately, all of the things discussed occur simultaneously. This is not always easy to visualise, and is even harder to write.

The many diagrams and graphs were produced using SIMetrix, an excellent simulator available from Catena (formerly Newbury Technology) in the UK (Catena Software). It is available as a free demo system, and is the best simulator I have used so far. All images are reduced for speed - to see the full version, just click on the displayed image.

Since I am going to be using a 6 dB/ octave filter for many of the examples below, Figure 1 shows the response of a conventional 1st order (6 dB) filter. This is normalised to 1k ohm and 1uF, which gives a crossover frequency of 159 Hz. Although most discussions will revolve around higher frequencies, this is of no consequence. The graph is designed to show the rolloff slopes of the high and low pass sections - not the absolute performance at any specific frequency.

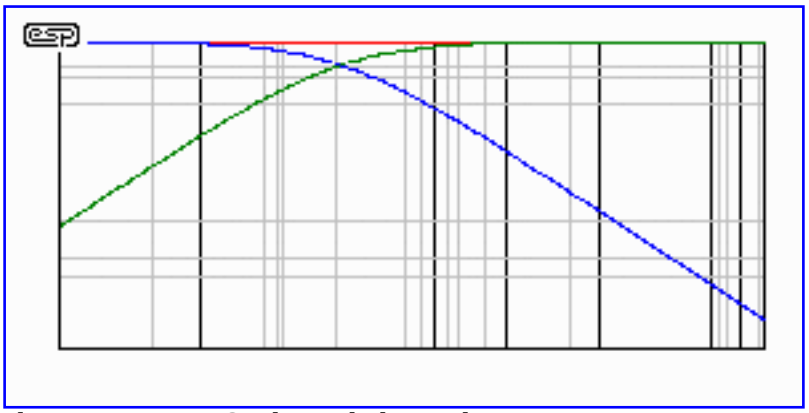

Figure 1 - 1st Order High and Low Pass Response

Note that *all* graphs on this page are shown as reduced size. For the full sized version, click on the image - this uses Java Script to open a new window for the full sized graph.

The line labelled "1-Input" is the input applied to the filter, and is also equal to the electrically summed outputs from the two sections. Both are flat, and are at 1 Volt relative level. Note that the simulator claims slightly different -3 dB frequencies for the two signals - this is not a simulator aberration, but the result of the simulator calculating to the absolute limits of accuracy. The crossover frequency is in fact 159 Hz as calculated, and at that frequency, the level is exactly 0.707 volt. If expressed accurately, -

3 dB is in fact 0.7079, and not 0.707 as is commonly used. This is a small error, and may safely be ignored.

All filters come with some pretty rigid rules - these are determined by the laws of physics, and are not open to discussion, although some of the snake oil vendors will still try. Filters are described in "orders" - 1st, 2nd etc. Each order has an ultimate rolloff (i.e. achieved at some point distant from the cutoff frequency) that increases by 6 dB steps for each successive order, so 6, 12, 18, 24 dB/ octave is a common way to describe the filter's response. They are further divided into "even" and "odd" order (even and odd numbers - it doesn't matter much, but is commonly used anyway).

A brief numerical description of each filter type is shown below, along with its rolloff characteristics and power level above the "cutoff frequency", typically defined as that frequency where the response is reduced by 3 dB. This is not always used as the crossover frequency - Linkwitz-Riley aligned crossovers use the -6 dB point instead, and achieve a flat response as a result (not applicable to 1st order filters).

Order	Slope	Voltage	Power	Theoretical
None	Flat	1 Volt	1 Watt	1 Watt
1st	6 dB/ octave	439 mV	193 mW	250 mW
2nd	12 dB/ octave	371 mV	138 mW	64 mW
3rd	18 dB/ octave	195 mV	38 mW	16 mW
4th	24 dB/ octave	122 mV	15 mW	4 mW

Table 1 - Filter Characteristics

Voltage in the above table is the voltage one octave above the -3dB frequency (assuming an input of 1 Volt and a low pass filter), and power at the same frequency, referred to 1 Watt. For example, 138 mW is about 1/7th Watt. The performance of a high pass filter is exactly the same as shown. The "Theoretical" value quoted is the power that should appear in theory - you may even see it quoted by manufacturers who have neglected to actually perform the maths, and have simply used the filter rolloff to arrive at a convenient looking number.

The above is not exhaustive, but it covers the filters most commonly used in audio. For all filters above 1st, the table is based on a sub-Bessel (minimum settling time) alignment

having a Q of 0.5, which is also typical of Linkwitz-Riley designs.

Time Delay

Firstly, there are many ways that the phase of a wave can be shifted, with the most common being time delay. At its most extreme, there is a delay of days to decades between the material being recorded and you listening to it - and no, this is not meant as a marginally humorous comment - this is a genuine time delay. The important thing is that all of the signal is delayed by the same amount, and it doesn't matter if this delay is measured in milliseconds or millennia, the sound will emerge intact and completely recognisable.

The situation is very different if some of the sound is delayed, while the rest is not. The listening experience would not be enhanced if the high frequencies were to be reproduced half an hour later than the bass or vice versa. This is quite obvious, but let's reduce the time to something more realistic. What if the treble were to be delayed by 20 milliseconds? The effect would be awful - this is a time difference we can easily pick, and we use these cues to determine the original sound from reflected sound for localisation.

We can continue reducing the time delay, and the effect will become less and less discernible as the time is reduced. Finally, we get to a point where the delay represents less than a wavelength (in air), and (perhaps surprisingly), the differences are still audible. Consider a 1 kHz sine wave, reproduced from two sources, but with one delayed by 500 us - just 1/2 millisecond. As one source creates a compression, the other creates a rarefaction - the waves are 180° apart, and will attempt to cancel each other. Early reflections and a multitude of other effects will ensure that we still hear the sound (at least at that frequency), but there will be a noticeable drop in level.

Now, there are some who will claim that reversing the phase of one source will bring everything back to where it was, so there is no harm done, and the net result is the same as if the two sources were not delayed at all. While this will obviously work at 1 kHz, at other frequencies this is not the case.

Now, let's look at some of the physics involved here. How would a 500 us delay be introduced in the first place? In reality, this is not uncommon, but we shall reduce the time delay to something more realistic before continuing. Any two loudspeakers that reproduce the same signal at the same time will exhibit this phenomenon, but for our purposes on a smaller scale.

If we look at a midrange driver and a tweeter, in the common vertical alignment in an enclosure, we have a time delay. The "acoustic centre" of the tweeter will most likely be a small distance closer to the listener than that of the midrange driver, and for the sake of this discussion, let us assume a difference of 50 mm, because it is a realistic and typical offset for common loudspeakers.

Before continuing, it is important that the concept of "wavelength" is properly understood. Sound travels at about 345 m/s in dry air at sea level. This changes with temperature, humidity and altitude, but we shall not concern ourselves with this, and there is little we can do about it most of the time. A sound at 345 Hz has a wavelength of 1 metre, at 34.5 Hz the wavelength is 10 metres, and at 3450 Hz, it is 100 mm. This is quite linear, and works for all frequencies. Another useful thing to know is the period (the actual time required to reproduce one cycle at the selected frequency).

wavelength = velocity / frequency
period = 1 / frequency

From the above, we can calculate the wavelength for any frequency we like. 3000 Hz has a wavelength of 115 mm, for example.

If we return to the midrange and tweeter mentioned above, their acoustic centres are offset by 50 mm - this is exactly 1/2 wavelength if the crossover frequency is 3450 Hz. We can account for the 1/2 wavelength by reversing the wires to the tweeter, so it is 180° out of phase with the midrange. The two drivers are now aligned in phase, so in theory, they are time aligned. Unfortunately, this is not the case. Although the signal is in alignment at the crossover frequency, it will not be aligned any more when the frequency changes.

What is really needed is to delay the signal going to the tweeter by 145 us (1/2 of the period of a 3450 Hz waveform), or align the acoustic centres of the two drivers in the vertical plane. Such "time alignment" is commonly achieved by angling the baffle so that at the listening position, the signals are properly in phase and time. Stepped baffles have also been used, but often create more problems with diffraction than are solved by the time alignment.

In short, time alignment is a good goal, but does not necessarily guarantee that the sound will be any better than a conventional flat baffle, with the phase of the drivers appropriately switched to ensure that the signal is in phase at the crossover frequency. It must be understood that with any flat baffle, an octave each side of the crossover frequency will see the phase out of alignment again, so it is essential that a high order

crossover is used to prevent unwanted cancellations and reinforcements at different frequencies.

With a flat baffle and a time displacement, above or below the crossover frequency the signals are in and out of phase - the exact amount can be calculated, and this can be very important in the greater scheme of things.

Octave	Frequency	Wavelength	Phase Angle
-1	1725 Hz	200 mm	90°
-1/2	2439 Hz	141 mm	45°
0	3450 Hz	100 mm	0°
+1/2	4878 Hz	70 mm	90°
+1	6900 Hz	50 mm	180°

Table 2 - Acoustic centre displacement 50 mm
(145 us time delay) 1 driver reverse phase

Expect a dip at an octave above the crossover frequency, since the two signals (from the midrange and tweeter) are 180° out of phase at this frequency - not because of the crossover, but because of the time delay of 145 us. The only way to ensure that this dip is inaudible is to use a steep filter! If a 6 dB/octave filter were to be used, the signal level is only down to 0.447 of the total (7 dB). On the other side, at 1 octave above crossover frequency, the tweeter will only have 0.894 of the full signal (0.97 dB down). These voltage relationships can be seen in Figure 1, above.

Hang on - this is a 6 dB/ octave filter, and it's 7 dB down an octave from crossover frequency. How can that be?

Remember that we are already 3 dB down at the crossover frequency, but because a 1st order crossover has a very low Q (or in other words is highly damped), the rolloff is not as steep initially as expected. It should be down by 9 dB an octave away, but this will never happen.

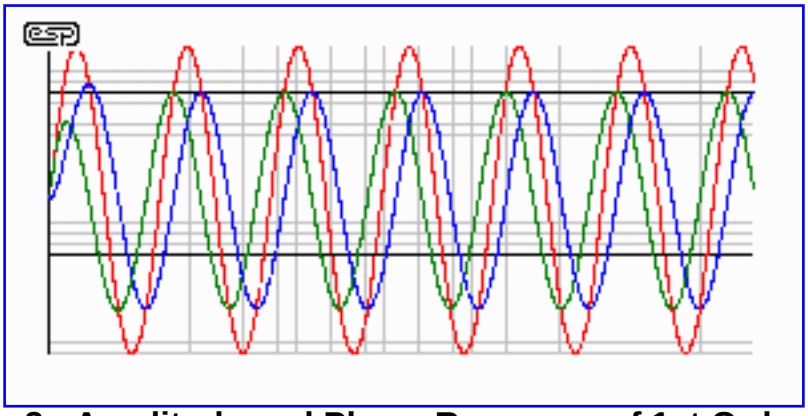

Figure 2 - Amplitude and Phase Response of 1st Order Filter

Ignoring the acoustic centres of midrange and tweeter for a moment, Figure 2 shows the waveform response of the filter at crossover frequency, together with the input signal. The RMS voltages of each are also shown. The waveform at 1 octave above crossover frequency is not shown - the absolute phase will be different, but relative phase (between outputs) remains at 90° for all frequencies. This is the electrical response only - the acoustical response will be different if the drivers are not time aligned!

Now (and this is where it gets tricky), what happens if we sum the electrical signals reproduced by the simple 1st order crossover? Assume an input of 1 volt for convenience. Adding 894 mV and 447 mV electrically (at any frequency) will give an output of 1.34 volts - this is clearly not correct, since the input is only 1 volt to begin with.

Analysis of a 6 dB/ octave crossover shows that the high and low pass signals are in fact 90° out of phase at all frequencies ("Yes but ... isn't the 1st order crossover supposed to be phase coherent?"). Yes and no. It is phase coherent in that all signals at all frequencies are 90° out of phase. I know that you have seen web sites that say that there is no phase shift through a 1st order crossover, but this is simply untrue! At crossover, the high pass section is leading - the signal appears to emerge from the filter 45° before the input, not possible it would seem. This sort of behaviour is standard with all filters with a "steady state" signal - you don't have to really understand it, so I suggest that you just live with it.

The low pass filter has a lagging response, so the signal emerges 45° after the input. This is easier to comprehend, but may still seem a little strange (which I suppose it is for a filter that many claim has no delays).

So, if we make the essential correction, and shift the relative phase of either signal by 90°, we can recalculate the summing of the two signals. Predictably, 894 mV + 447 mV with a 90° phase shift now gives a summed response of 1V - this is as we would expect, and is shown in Figure 3.

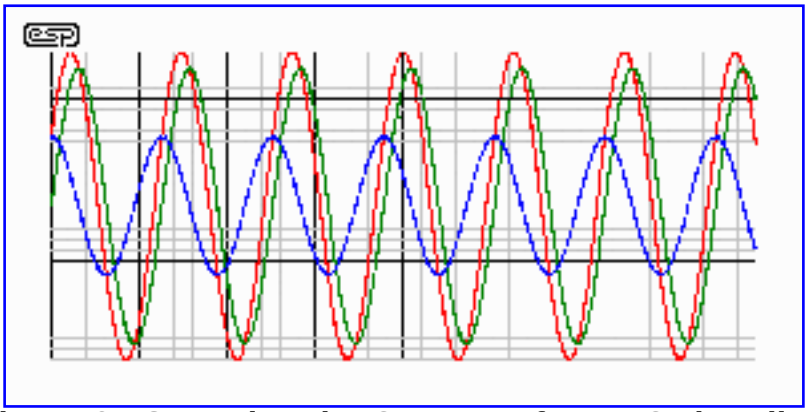

Figure 3 - Summing the Outputs of a 1st Order Filter

You can see the phase relationship between the 3 signals quite clearly. I doubt that this will be terribly meaningful for the most part, but it is essential to the understanding of the relationships - time and phase are inextricably entwined with each other, and cannot be separated.

The electrical and acoustical relationships only coincide if the acoustic centres of the speakers are in exact alignment. As soon as there is a misalignment (introducing a time delay), everything changes. To see the effect, imagine the original setup, with the acoustic centres misaligned by 50 mm. The tweeter's output will now be heard 145 us before that of the midrange. For the purpose of explanation, we shall ignore the 90° phase shift introduced by the crossover, and indeed, this is only present in the 1st order design. In fact, for many of the following explanations I will use signals of equal amplitude, and will ignore the crossover altogether. This provides for a worst case - reality will be somewhat tamer.

If we use two signals of equal amplitude, when summed we get a signal of double that of each signal - after all, the concept of 1 + 1 = 2 is not uncommon (except in corporate financial circles :-) If the level is any different, then there is phase shift (or delay) that causes the error.

Figure 4 shows what happens when the 3450 Hz signal is produced from both speakers simultaneously, but with a 145 us time delay (representing the 50 mm offset). The red line is the combined signal - there is no signal! This is electrical summing, which is much more critical than acoustical summing, so in reality we will still hear something, but nowhere near what we should. This is commonly referred to as a "suckout" by reviewers, and there will be a pronounced dip in frequency response. Now, we know that this is easily fixed by reversing the phase of one driver, and everything will be back where it should be - but (and this is the clincher here) - only at one frequency! At all other frequencies there will be interference effects, and the lower the filter order, the worse it

becomes.

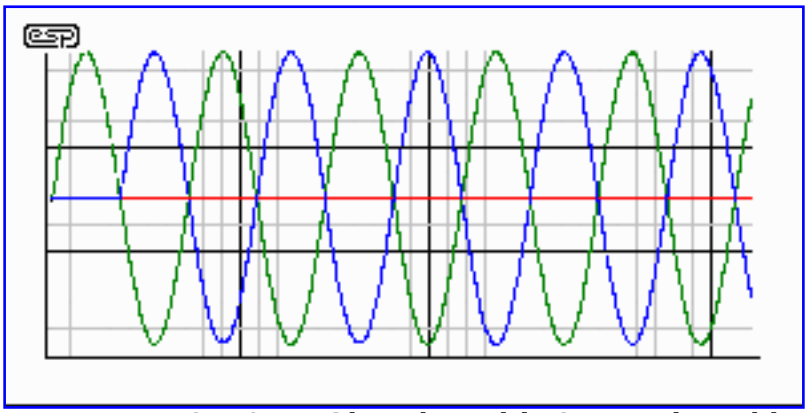

Figure 4 - Two 1V, 3450 Hz Signals, With One Delayed by 145 us

Rather than take vast amounts of bandwidth to display as whole series of similar waveforms, I have tabulated the resultant signal level below, for 2 signals of equal amplitude but with one delayed by 145 us. These are the same frequencies we looked at earlier. In all cases, the result should be 2 volts ...

Octave	Frequency	Amplitude
-1	1725 Hz	1.414 V
-1/2	2439 Hz	0.887 V
0	3450 Hz	0 V
+1/2	4878 Hz	1.195 V
+1	6900 Hz	1.959 V

Table 3 - Summed Signals

Now, bear in mind that the above table is actually meaningless (it looks impressive though). All of the information must be presented in a simultaneous manner for any of it to make real sense. To expand on this a little further, have a look at a frequency scan of two drivers reproducing the same signal, but with one delayed by 145 us. This produces a comb filter effect. Now, in real life, the signals will not be at the same amplitude, so the effect is reduced. The signals are also summed acoustically, reducing the effect even further, but the crucial point here is that the crossover and acoustical summing reduce - not eliminate - the problem. But this is still not real! (It is marginally useful though, just so you can see where all this is going.)

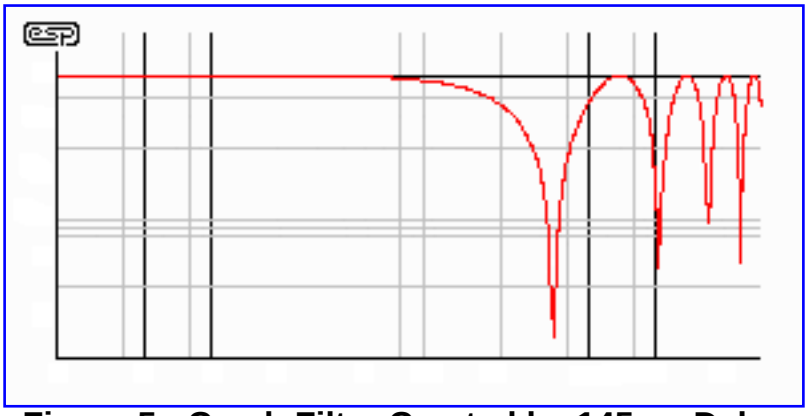

Figure 5 - Comb Filter Created by 145 us Delay

We can see the notch predicted in earlier examples at the crossover frequency of 3450 Hz, but we also see another at 10.26 kHz, and another at 17.4 kHz. The final notch shown is unlikely to be audible for most of us at 24 kHz. If the delay is increased, the effect becomes worse. It is also worth noting that even with the relatively small delay used for this example, the combined signal is down 3 dB at 1737 Hz. Remember that this is worst case, with no crossover network.

The combined effect of the delay and crossover can be expected to be a little less daunting, so the trusty simulator has been stretched a little here, and Figure 6 shows what happens when both the delay and the crossover are used, with the phase of one driver reversed as required to prevent the cancellation at crossover frequency. Oh dear! There might not be a major problem at the crossover frequency, but an 8 dB dip at 2 kHz is less than desirable. The 2.8 dB peak at 5.1 kHz is no bonus either. Less daunting? When all the material is presented, then the whole picture is available.

Note that this was missed in the table above, since I only looked at the 1/2 octave boundaries and with equal amplitudes. Little omissions can leave major gaps in ones actual knowledge! A small (cunningly disguised) trick of calculation or description can leave one thinking that a designer has achieved something special, so always make sure you have all of the information.

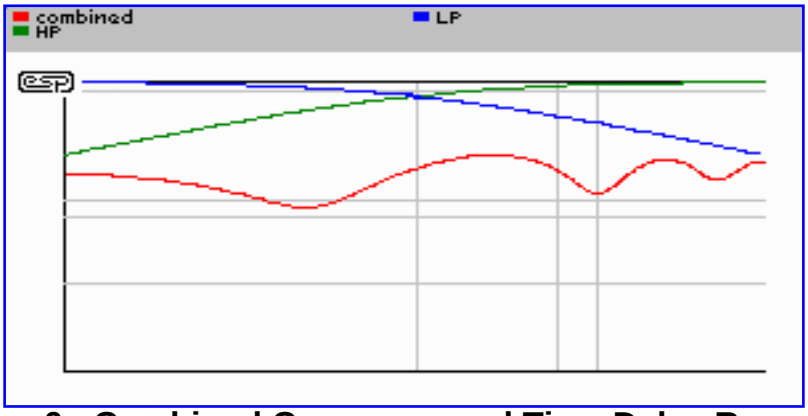

Figure 6 - Combined Crossover and Time Delay Response

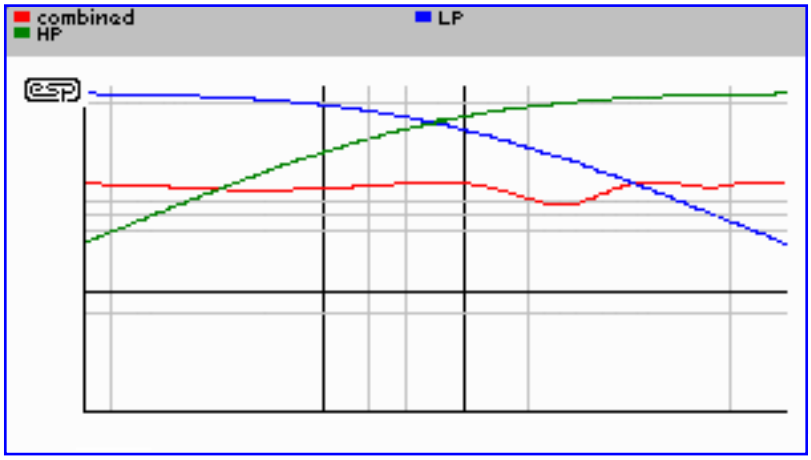
The effect is not as severe (note the depth of the notches - read the voltage levels!), but in quite a few respects it is actually worse than the "fake" graph of the previous example!

Just to make sure, I reduced the time delay to 10 us then 1 us, to verify that nothing was awry with my simulations. As expected, the response was almost flat, and with no delay at all, the response was completely flat.

So, the next question has to be ... What difference does it make if the filter order is increased? Figure 7 shows the response with a 2nd order filter, using a Linkwitz Riley alignment. The ripples have been reduced considerably, but are still quite obvious. Figure 8 shows the response with a 24 dB/ octave L-R crossover. In both cases, the signal to the tweeter is inverted to account for the 145 us time delay, which as we know reverses the effective phase of the driver.



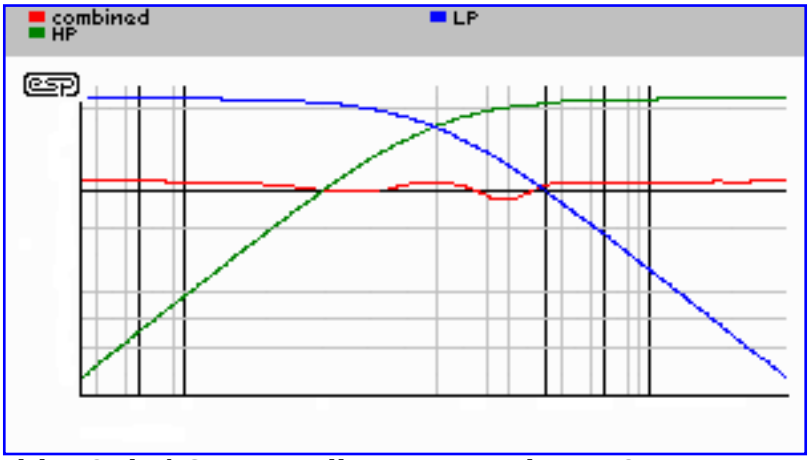


Figure 7 - Response With 12 dB/ Octave Filters **Figure 8 - Response With 24 dB/ Octave Filters**

As can be seen, the ripple is reduced as filter order is increased. Remember that all filters shown will sum electrically and acoustically flat if there is no time delay. All ripple is a direct result of the time misalignment. To put this into perspective, the room and

furnishings (including the speaker box itself) will have a much greater effect on the response than the 12 or 24 dB/ octave filters introduce - however, there is no good reason to muck up the response before the room has a chance.

Using DSPs (Digital Signal Processors), it is possible to delay the signal to speakers to compensate for the physical offset. At present, this is still frightfully expensive, but we can expect digital crossovers with adjustable time alignment delays to become commonplace in a few years. They exist now, but few of us can afford the luxury, and many will be unwilling to insert yet another set of analogue-digital-analogue converters into their system

---

Crossover Filters

I have always liked 1st order filters. Most loudspeaker drivers do not like 1st order filters. The ideal system would use no filters at all. With the partial exception of electrostatic loudspeakers (ESLs), the ideal speaker does not exist. Why "partial" exception? ESLs are bi-directional, and as a result of a relatively small baffle, do not reproduce low frequencies well. ESLs are also hardly a point source - the radiating panel is quite large, and this makes for a small "sweet spot" for listening because of the off-axis response of any large radiating surface.

As always, we must make compromises, and the ideal would be to have a single point source driver that could reproduce all frequencies equally well, and with no distortion. The smaller the driver, the better it will reproduce high frequencies without lobing, most easily described as listening angle dependent response peaks and dips. Low frequencies require that a lot of air be moved, so the small driver will do a very poor job - larger drivers are needed. This is the reason that most high fidelity speakers use at least two, and commonly three different loudspeakers to cover the audible range.

This is where the filters come into play - they are an essential part of the compromise, and separate the signal into ranges that can be accommodated by the individual drivers. The 1st order (6 dB/ octave) filter has the lowest phase shift and the best transient response of all the possibilities. It also has the slowest rolloff, so undesirable effects will be heard from the loudspeakers as they are excited by the signals outside their optimum operating frequency range.

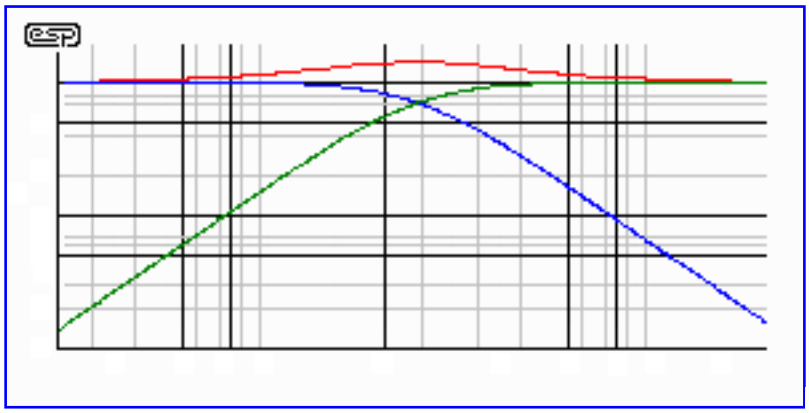
Contrary to what you may read elsewhere, all crossover networks (filters) *bar none* introduce phase shift. This is actually the least important characteristic of a filter, and provided that the low and high frequency waveforms remain in phase with each other,

their absolute phase is not important. Such a filter is described as phase coherent, and this is extremely important to the sound quality obtained.

Since filters introduce a phase shift, they also introduce a time delay. This is not the fixed delay referred to above, but varies with frequency. Perhaps surprisingly, this frequency dependent delay is not overly important to the overall sound, but it requires considerable care to ensure that audible artifacts are not created as a result of the delay.

The conventional crossover of old was the Butterworth. Maximally flat frequency response, a Q of 0.707 (damping factor of 1.414), and 3 dB down at the crossover frequency. It has been shown by many workers in acoustics that this is actually wrong, as a 3 dB peak is experienced at the crossover frequency. It should be noted that this only occurs with 2nd order (12 dB/ octave) filters and higher - a 1st order filter does not have that problem.

The response of this filter is shown in Figure 9, and the peak at the crossover frequency is clearly visible. Figure 10 shows the phase response at one octave below crossover frequency - the signals are perfectly in phase (after inversion of one signal - the 12 dB crossover *always*inverts one signal with respect to the other.



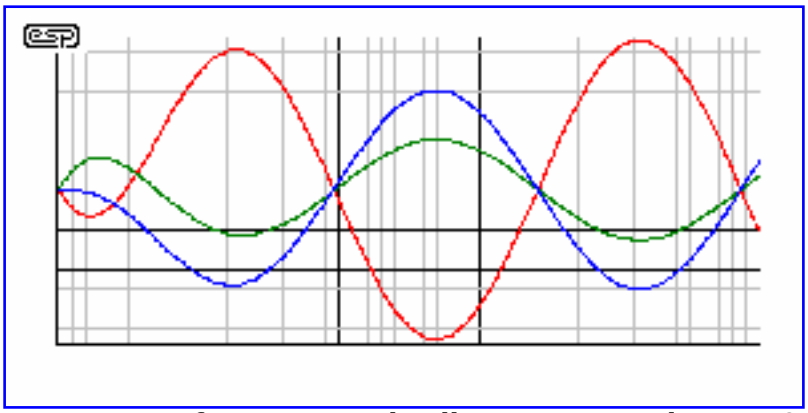


Figure 9 - Amplitude Response of Butterworth Filter ... **Figure 10 - Phase Response, 1 Octave Below Xover**

What about a square wave? This is supposed to be the most telling aspect of a design, which is interesting in itself since a synthesiser is the only instrument that is capable of producing a square wave, and no-one ever uses an unfiltered square wave anyway. Well, the result is shown in Figure 11, and the combined signal looks nothing like a square wave. The fact of the matter is that all frequencies that make the square wave are still present in their exact amplitude relationships, but they are shifted in phase. This is completely inaudible, and that has been proven many, many times. Human hearing is not sensitive to absolute phase, and responds to relative phase only if it causes a peak or dip in the frequency response. I suggest that you treat any claim to the contrary with the utmost suspicion, as the writer has a hidden agenda (to sell you his product being the most common).

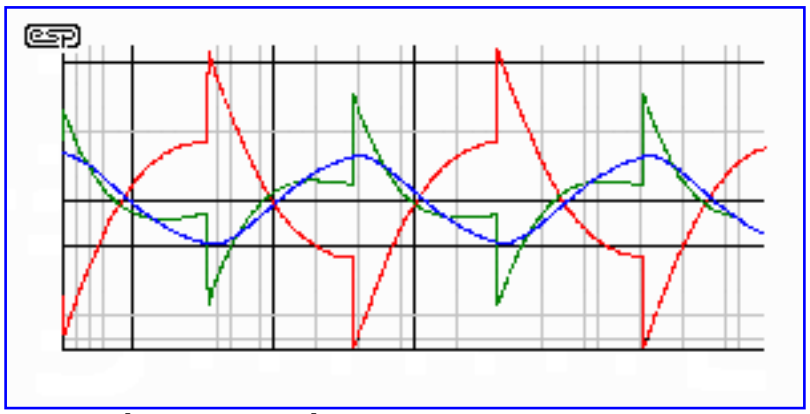

Figure 11 - Phase Response at Xover

Now, for reasons that are unclear (to me anyway), to obtain a license to use the term "Time Aligned", the speaker must be demonstrably capable of reproducing a square wave. Que? License?? Oh yes - the term is trademarked, and one may not advertise speakers as "Time Aligned" unless the appropriate fee is paid (presumably - I have no idea how much this costs), and the requirements are met. The biggest problem faced with getting any crossover to pass a square wave is simply phase shift. 1st order filters do it, but few drivers can cope with the low rolloff. An interesting tradeoff is the so-called "subtractive" crossover. This uses a single filter (of any slope), and subtracts the output of that from the input signal. The result is perfect square wave response, and a flat summed response.

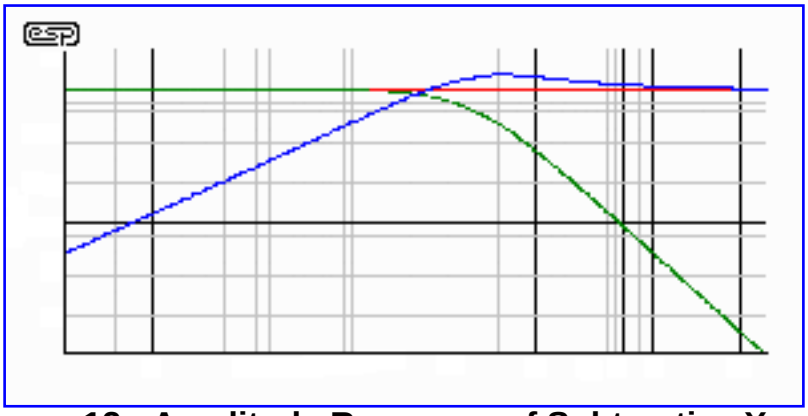

Figure 12 - Amplitude Response of Subtractive Xover

Do you see the anomalies? There is a bump in the high pass response, and although the low pass is 12 dB/ octave, the high pass is only 6 dB/ octave. Even if the "real" filter is 24 dB/ octave, the subtracted one is still 6 dB/ octave. Figure 13 shows the combined waveform and the high and low pass waveforms (input is a square wave).

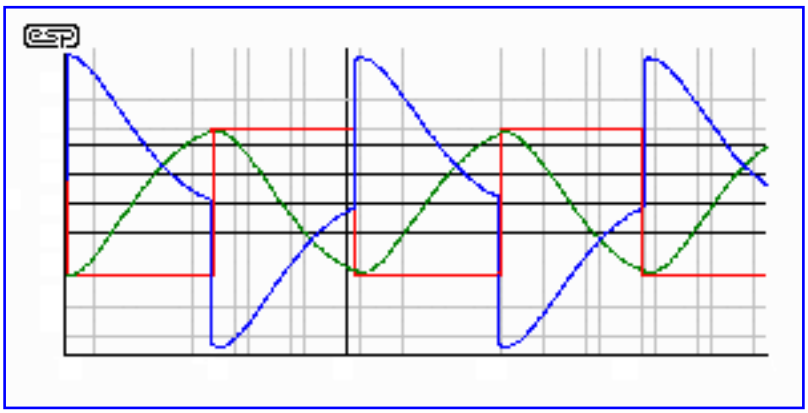

Figure 13 - Square Wave Response of Subtractive Filter

One driver will have an easy enough time, as it will be prevented from entering into the region where it becomes "hostile", with unpleasant lobing effects and possible cone breakup. The tweeter has no such luck! The design frequency is not as expected either (the diagrams shown used the same filter that gave a crossover frequency of 2.8 kHz in Figure 9). When we obtain a crossover frequency of 3450 Hz, the signal to the tweeter is down by only 11 dB at 1 kHz (typical of the resonance frequency of many high end tweeters).

The primary issues that confront the crossover designer are the constraints of the drivers themselves. As soon as the diameter of the radiating surface (the cone) of a driver becomes "significant" with respect to wavelength, you will have problems with lobing. This causes poor off-axis response, and makes the overall sound power output something of a gamble. A safe enough rule of thumb is that no speaker should be asked to reproduce any frequency where the cone diameter is greater than one wavelength. A typical 150 mm (6") mid-bass driver should not be operated above about 2300 Hz, and a

100 mm (4") driver is limited to around 3450 Hz. In addition, all loudspeakers will have cone breakup at some frequency - this can be "soft", causing no gross unpleasant sounds, or "hard", where the sound is quite objectionable. Generally, the more rigid the cone material, the worse it will be when it is finally incapable of true pistonic movement. This is one of the reasons that paper cones are so popular. I do not propose to cover this particular area in detail - further information is available on the Web (right or wrong, subjective or measured - this is up to you to determine).

It is very important that no appreciable power is supplied to a driver at or above the frequency where the cone breaks up or where the cone diameter exceeds one wavelength. The result is almost always a sonic disaster at the high frequency end. A relatively steep crossover is the only way to ensure that this colouration is kept below audibility.

Likewise, no speaker should be operated through its resonant frequency (pity about the bass driver!). For typical tweeters, this is between about 900 to 1500 Hz, and it is imperative that no appreciable power is allowed to get to the tweeter at its resonant frequency - the result is audible, not always insufferably unpleasant, but usually fatiguing and the sound is definitely coloured. With passive crossovers, the resonant peak also changes the characteristics of the crossover network (see High Quality Passive Crossover Design for more details).

This is surely one of the major quandaries facing any loudspeaker designer. To use a steep rolloff crossover, with its attendant transient response problems (and yes, these are real), or a simple 1st order design, that will allow the signal through that will excite the speaker at frequencies it will handle poorly. Despite some of the claims that you may see, there is no evidence that anyone has actually made a speaker that can handle more than about 6 octaves, and most will not come close to managing that. I would normally expect that a driver (other than most tweeters) will handle about 4 octaves reasonably well. The table below shows a few possibilities. A four way system is required to make it across the full audio band if you limit the drivers to 3 octaves, and with 4 octaves per driver, a 3-way system can exceed requirements in theory - the crossover frequencies may not be suitable for a great many drivers. Two way systems will almost invariably miss out on the lowest octave or three.

Table 4 - Driver Frequency Ranges

Distortions

Naturally, if the number of drivers is reduced, the bandwidth they must cover is much greater - ever wondered why some (many?) large 2 way systems just don't seem to cut it? One of the biggest problems (and rarely spoken of) is intermodulation. If a cone is moving back and forth reproducing a low frequency, as well as 'jiggling' back and forth simultaneously reproducing a higher frequency, what will happen to the high frequency?

This is not an electrical system, this is pure mechanics and high school physics. Remember the Doppler effect? As a car (for example) comes towards you, the sound is higher in pitch as the sound waves are 'squashed' together by the forward motion of the vehicle. As it passes directly past you, the pitch falls to normal, and becomes lower as the car retreats from your observation point. Everyone has heard this effect, and many people have equated it with loudspeakers. This is actually not quite correct (IMHO), for reasons that are fully examined (and explained) in an article, but for now, suffice to say that the effect that has been claimed as 'Doppler' distortion is a combination of phase distortion and intermodulation distortion.

The Doppler effect is caused by compression or rarefaction of the wavefront, depending upon whether the object is approaching or retreating from your position. A loudspeaker cone does exactly the same thing! The high frequency tones are phase modulated by the cone movement caused by the low frequency tones.

The real problem is intermodulation, and this is one of the major arguments for using ported enclosures, since it reduces cone excursions at the lowest frequencies, and therefore reduces the tendency of the voice coil to partially leave the magnetic field, and introduce amplitude modulation distortion of the higher frequencies (i.e. intermodulation). The difficult load this presents to the power amp, and the phase irregularities of ported enclosures are well known, and I will not dwell on them here. Other alternatives exist ...

- transmission lines - usually very good performance, but rather bulky and hard to build
- horn loaded enclosures - not to everyone's taste, in size or sound
- multiple speakers to share the load - Ok at low frequencies, but causes problems when the distance between drivers exceeds 1 wavelength
- remove all the low bass from the main speakers and use a subwoofer - often an excellent choice, but not to everyone's taste (and subwoofer positioning can be

almost impossible in some listening spaces)

Other distortion generators have been discussed - cone breakup, tweeters receiving significant power at their resonant frequency, and drivers expected to extend their response way past the point where they become highly directional.

The major effect we hear is simple loudspeaker intermodulation distortion. A loudspeaker driver uses a motor, consisting of a voice coil, which is immersed in an intense magnetic field. The radiating element (usually a cone or dome) is coupled to the motor, and supported by a surround of corrugated material, rubber (usually synthetic) or foam. Additional support is provided by the spider, which is attached to (or near) the voice coil former - this is essential to prevent the cone from shifting, and causing the voice coil to rub on the magnetic pole pieces (poling).

The surround, spider and the motor itself are linear over a limited range. The maximum excursion of a driver (Xmax) describes the maximum physical movement allowed, but usually does not guarantee that this full range of movement will be linear. If it is not linear, the speaker will distort - subtle with some, gross with others. How do you know what a driver will be like at its limits? You can ...

- believe the manufacturer - not always a good idea
- test it yourself - be prepared for the odd damaged driver if you go too far
- ask others for their experiences - expect many conflicting responses
- make sure that your design will stay well within limits, perhaps 25% of the maximum - pay more for the driver
- use a servo system - feedback from the cone to the amp will linearise the movement, but it only works at low frequencies

Now we know that there will be intermodulation products generated when the speaker driver is outside its (often limited) linear range, causing the higher frequencies to be distorted as the bass forces the cone towards its limits. This is similar to amplifier clipping, except that it is progressive, and much more subtle - and therefore more insidious, because it is so difficult to detect reliably. Some musical passages will just not sound right at high volumes, but are fine at lower (often unrealistically low) levels.

The ideal is naturally to limit the excursion to the absolute minimum, but this is not always possible, especially with bass drivers. In this case, it is far better to relegate the bass to its own speaker altogether - a subwoofer is not just for home theatre - it can work absolute magic on normal musical programme material as well, including music that does not appear to have a great deal of low bass.

Phase Audibility

The audibility of absolute phase is nil.

I must explain this further, as this is a somewhat contentious issue. It can be proven in ABX tests that there are some signals where the difference between a non-inverted and inverted signal is audible. Certain waveforms and instruments are highly asymmetrical, and if listened to in isolation *will* sound different if the phase is reversed. The difference is not subtle, either - it can be very pronounced. This is much more likely to be a result of loudspeaker driver behaviour than anything else, and the "correct" phase is anyone's guess - should it be inverted or not? We don't know the answer, since we will be unsure of what the instrument sounded like "live" - it is possible that neither the inverted or non-inverted recorded signal will sound like the original, so the point is moot.

The key issue here is that if we listen to a saxophone (a good example of an asymmetrical waveform) with the phase normal then reversed, all we hear is a difference - there is not necessarily a "right" or "wrong" phase, since it depends on the way the instrument was miked in the first place. If the period between listenings is extended to a few minutes, the chance of us hearing the difference will be minimal, and we still won't know which is "right" and which is "wrong" - all that this proves is that there is a difference, and it only becomes audible with some instruments.

This is probably the only case where an ABX test proves something that is not relevant in the general sense - so yes, absolute phase can be audible, but it is (generally) irrelevant. [Update added 30 Jul 2002]

The net result is that our ears do not care if there is a slight misalignment between the fundamental and harmonics of any instrument known. This is likely to cause howls of protest from people who won't actually bother to read this article in its entirety (if at all), but it has been demonstrated a great many times, and by various techniques.

> **Example:** Let's examine this from another perspective, using live sound as the source (for example, a string quartet). Regardless where you stand or sit, you will most likely be a different distance from each instrument. One could insinuate oneself into the very centre of the performers' space, but this is more likely to lead to your eviction from the venue than to improve your listening enjoyment. If one is a different distance from different sound sources, then the absolute phase of those sources will all be different too. Not only that, but the phase variation changes with frequency.
>
> At 40Hz, a two metre difference in the relative path lengths amounts to only about 42° phase

shift, but the second harmonic is shifted by almost 84° while the 5th harmonic (200Hz) suffers 208° phase shift. Move a little, and it all changes. Do we hear a huge variation in the sound (assuming a reasonable listening environment)? No, of course we don't. No-one will ever convince anyone who has been to a live performance that there is one (and only one) specific location from the musicians where the sound is somehow "right" (ignoring major auditorium problems, of course). The fact is that phase varies with distance and frequency, and this will not change. The complex nature of music using real (as opposed to synthesised) instruments guarantees that things will drift in and out of phase as a matter of course. Yes, the loudspeaker should be able to reproduce this as accurately as possible, but there is only science in the design of a loudspeaker system - no magic.

A simple all pass filter will shift the phase of an audio signal by 180° over a frequency range determined by the component selection, and it is completely inaudible - provided the source is music, and provided the phase sweep is performed slowly enough for our ears and brain to make the necessary adjustments. In fact, I have demonstrated this as the filter is adjusted (very slowly), and the sound quality remains the same. Nearly every (Ok, not nearly - every) recording ever made has been recorded using a microphone, had some equalisation applied, and/ or has had some additional treatment in the recording process. All of these introduce some degree of phase shift, but does it ruin a good recording? No. As the signal emerges from the vast majority of crossover networks, there are huge shifts of phase, as has been described above. A square wave subjected to phase shift still has all of its harmonics present, they are just slightly misplaced in time.

The sort of delay we will experience is dependent on the frequency, but it doesn't matter. Vented speaker boxes do 'awful' things to phase, as do many highly regarded 'feedback free' single ended triode (SET) amps. Any equaliser, be it a constant Q graphic, parametric, or just a simple tone control, will introduce phase shift as well as equalisation. The phase of a waveform changes as you move about - but your best friend sounds like your best friend regardless of your relative positions in a room, even though there are massive changes in phase as we walk around.

If we believe the 'absolute phase' lunatics, this would not be the case, so your wife may sound like your wife in one part of the room, but sound like the milkman in another. We all know that this doesn't happen - the tonal structure of a sound does not rely on the phase integrity of the received sound, only the relative amplitudes of the fundamental and harmonics. So a speaker that has perfectly flat frequency response but is not 100% phase coherent will sound the same as one that is also flat, but totally phase coherent. This does not include colouration caused by the cabinet or drivers - of course these are important. Assume the same enclosure, same drivers, but a phase shift applied to one, and not the other.

In isolation, they will sound the same. Put them together, and you will hear strange

reinforcements and cancellations as you move about. This is *relative* phase, and is very audible indeed. What we need to concern ourselves with is relative phase only. Two amplifiers with different phase responses used as a stereo pair will sound terrible if the shift is sufficient. Use two of the same amplifier, and there is no problem.

Absolute phase is inaudible within reason - a 3,600° phase shift represents a time delay that is significant, but a 360° phase shift will not be heard. Inverting a signal (e.g. reversing the connections to a loudspeaker driver) creates a 180° phase inversion, but this is not the same thing as a 180° phase shift! This is a point missed by many.

Relative phase is audible, depending on the amount, the frequency and the context. Two speakers side by side with 90° phase shift between them will sound dreadful - and the sound will change as you move about. The relative phase of two musical instruments playing in harmony *makes* the sound you hear - take away the phase shifts, and it will sound flat and lifeless.

There have been many tests and experiments to look at phase shifts within the audio band, and whether they are audible. Under controlled laboratory conditions (or using headphones), there is strong evidence that with single (complex) tones, there is an audible change. However, in a listening room with speakers reproducing music, there is little evidence that phase shifts are audible with the vast majority of recorded material.

An example of a pair of very typical all pass filters is shown in Figure 14. These are connected differently so I could show the different behaviour (not actually different, the phase of one is simply reversed from the other).

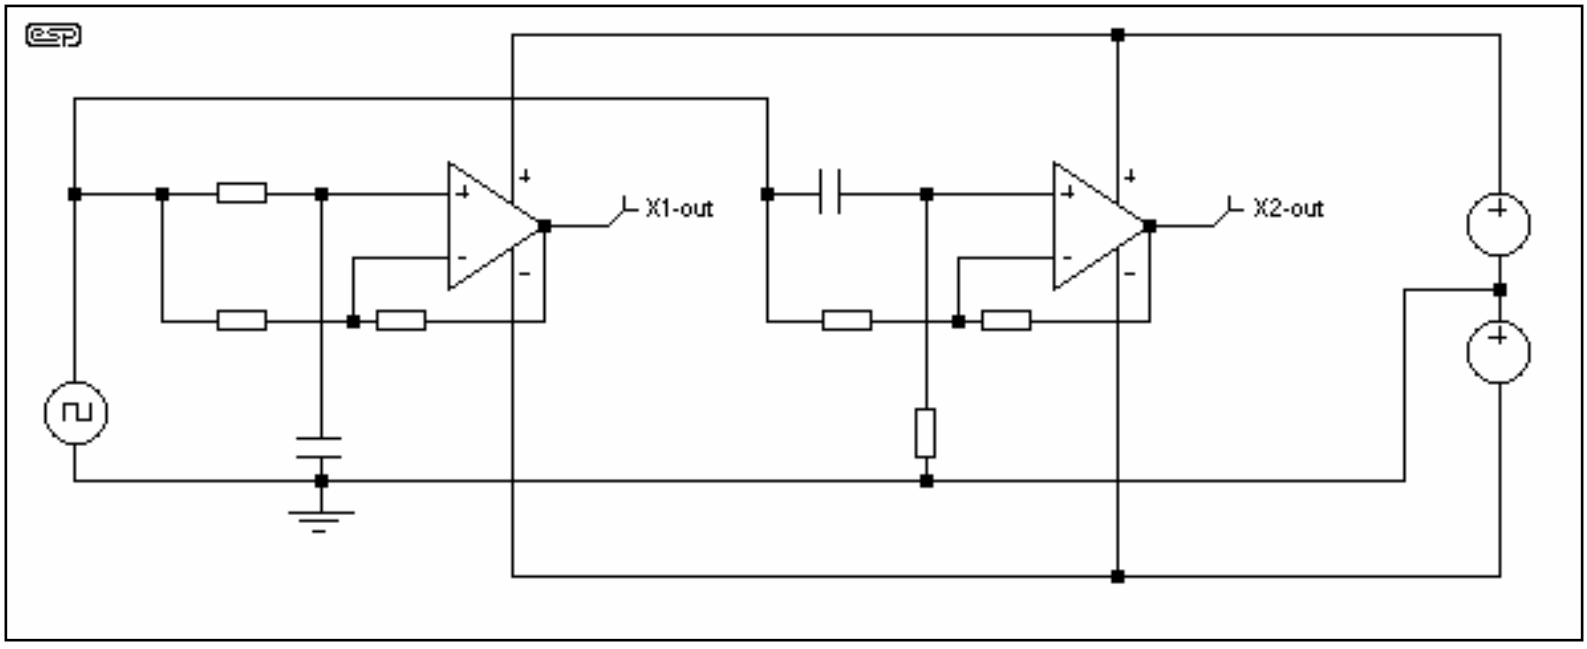

Figure 14 - All Pass Filter Networks

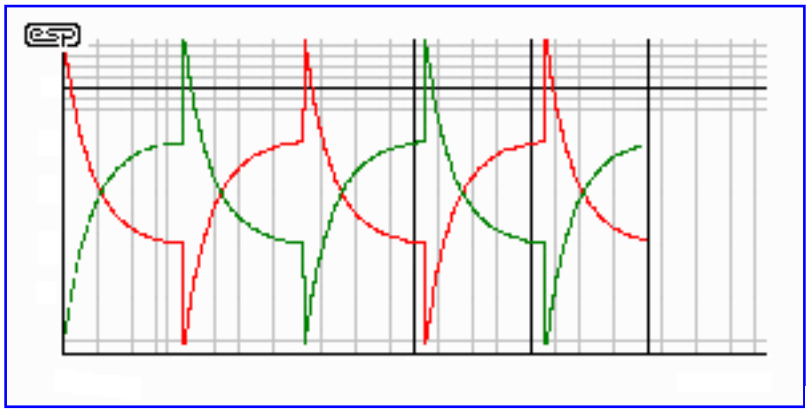
The resulting output and phase response of the filters is shown in Figures 15 and 16 respectively. I only included the phase response graph for one version - the other is simply the reverse of that shown.



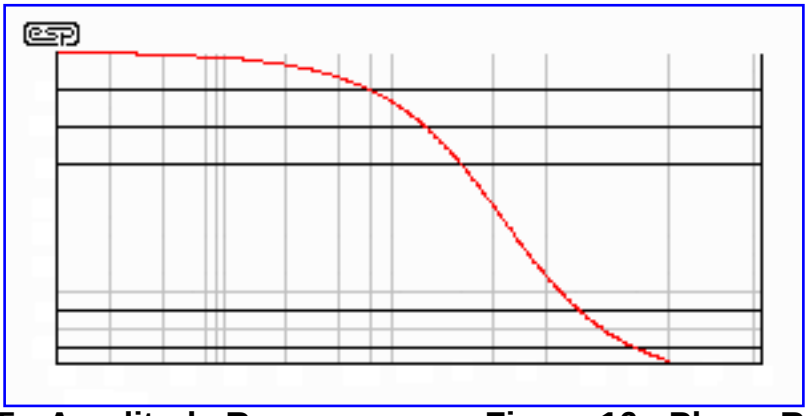


Figure 15 - Amplitude Response **Figure 16 - Phase Response**

Note that this particular filter is called 'all pass' - it passes all frequencies equally (i.e. the magnitude is unaffected). Not much of a filter by normal standards, but a useful tool nonetheless. Interestingly, if the input and output of an all pass filter are summed, the result is an ordinary filter. High and low pass responses are available. Not that there is a great deal of point, since this is vastly more complex than a 6 dB/ octave filter built conventionally. I just thought I'd mention it - someone might be interested :-)

Conclusion

For what it's worth, I originally started this article not to praise, but to debunk the theory that time alignment is the only way a speaker should ever be designed. Having done the research, run tests, and written the article, I confess that I must agree with many (perhaps even most) of the points made by the time alignment proponents. Mind you, there is still a lot that you will hear and read that is either gross exaggeration or a downright lie, and it can be very difficult to tell the difference unless you know exactly

what the real story is.

My overall opinion, based on the research for this article (primarily tests and simulations), is that time alignment is a very good thing, and perhaps all speakers *should* be designed this way. On the negative side, the offset required to achieve time alignment can lead to diffraction effects that may damage the sound quality far more than the misalignment. A sloped baffle means that you are *always* listening off axis from the drivers - not by a great deal perhaps, but off axis nonetheless. This conundrum can be resolved, and it has been by several manufacturers, each in their own way.

Use of 1st order crossovers means that the vertical axis of the speaker is very narrow - the speaker will sound entirely different when you stand up! This means that the signal propagated into the room is uneven, so the natural reverberation of the listening area is not excited evenly at all frequencies. Higher order crossovers are better in this respect, but cause their own problems. Relatively poor transient response is always claimed, but in reality, a great many high end manufacturers are using 24 dB /octave filters, especially with electronic crossovers, and achieve extraordinary results. My own system loudspeakers are triamped using my version of the Linkwitz-Riley 24 dB crossover, and they sound very good indeed. They are not time aligned, but based on the results of my work on this article, I would expect that when (not if) I rebuild the boxes (or just make a new system altogether) they can sound even better.

Reproduction of a square wave is something of a myth. I have received a very passable square wave response from a pair of small hi-fi boxes I use in my workshop. All I have to do is select a good position for the measuring microphone. How many sites have you visited in your quest for "the ultimate loudspeaker", where they claim (or show) the square wave response? How many admitted that the positioning of the measurement mic has a very great bearing on whether a square wave is reproduced or not? From what I have seen, no-one has ever claimed that a square wave is received perfectly, regardless of mic position, nor have they disclosed the actual measurement setup that was used - is this at the listening position in a "typical" room, or 300 mm in front of the speaker in an anechoic chamber? We shall never know.

Indeed, the room itself is still the greatest offender - even a coffee table that is in the acoustic path of the loudspeaker will have a profound effect on the overall response. Very few rooms are acoustically dead enough (IMO), and I have seen a great many photos of people's systems set up on polished marble (or whatever) floors in relatively bare rooms, with almost no acoustic deadening materials to be seen.

Human hearing is very adept at picking the original sound from the reverberant field,

provided the early reflections are not so early that they influence the direct sound. Given the highly reverberant listening rooms of some people, I have difficulty understanding how they can even tell what anything really sounds like - yet they will happily espouse their theories on what makes the sound better, ignoring the fact that their room will destroy the sound of any loudspeaker.

Finally, the quality of much of the recorded material available is absolutely woeful. Equalised to within an inch of its life (so it will sound "good" on crappy systems), compressed, "aurally excited" (ptooey!), and generally mangled beyond all recognition. To be sure, quality recordings are available, but are they available from your favourite artist(s)? Usually not, so you either have to change your musical tastes to experience a decent recording, or put up with the rubbish that is often the only version of the artist/ song available. I have so many CDs and vinyl recordings that I find unlistenable on a decent system that it's not funny - for one CD, I have to switch off my subwoofer or all my windows will fall out!

This article started as a short explanation, intended to dispel some more snake oil, and has become the missive you see due to the vast amount of information I collected as I ran the tests and simulations. I Hope that it has been of value to you - having read this far, I suppose it must have been. Expect an update shortly, after I have had a chance to figure out a way to determine the acoustic centre of typical drivers - perhaps manufacturers could supply this information as a part of their specifications (hint, hint).

Update

1. It was pointed out to me by Geoff Moss (who is still checking my pages regularly - thanks Geoff!) that the all pass filter has been used as a time delay, and this usage is described by Siefried Linkwitz in one of his articles published many years ago in Wireless World (now Electronics World). I have run some simulations of a 4 stage all pass, and it is indeed possible to get a time delay that is reasonably constant for at least a few octaves. Now, while there is no doubt that the principle works, there are not too many people who would actually want to have anything from 4 to 8 stages (all based on opamps) as a series string in line with the tweeter signal. The high frequencies are the most easily damaged, and such an arrangement would generally be considered unacceptable.

Nevertheless, it is a valid usage of the principle, and shows that this is not a new topic - indeed far from it. The original was published in 1978, and was republished in 1980 in Speaker Builder magazine - a copy of the article as published in Speaker Builder can be obtained from ...

www.linkwitzlab.com/sb80-3wy.zip

I do not propose to go into great detail on this topic, but since it has been done (and is described in excellent detail in the article), this will provide you with more information on the topic.

2. I recently saw a posting on a newsgroup referring to a (single driver) speaker reviewer's claims that a single driver is the only way to undo Doppler distortion introduced during the recording process. For various reasons, this is complete rubbish, but mainly because single driver speaker systems introduce vast amounts of intermodulation type distortion, especially if they are expected to cover anything more than a moderate range and at relatively low levels. Even horn loading does not reduce cone movement sufficiently to prevent distortion, but it may reduce it to within acceptable levels (depending on the design of the horn and driver).

By comparison, a microphone diaphragm may move a very small fraction of a millimetre at most, and the distortion introduced is minimal - indeed, with capacitor (aka 'condensor' or 'condenser') mics, the movement is infinitesimal, and distortion can be all but ruled out. In the case of 'heavy' musical styles, there will be separate mics for each instrument, so the most troublesome signals are removed from the equation.

In any case, the claim is fallacious, and highly misleading for anyone without the knowledge to be able to examine the facts properly. This is classic "snake oil" marketing at its very best. I wonder how such a speaker handles electronic music, that has never even "seen" a microphone during the entire recording process? Maybe it is clever enough to know the difference ... no, I didn't think so either :-)

For a speaker reviewer to be spouting this sort of garbage gives some idea as to their overall credibility - would you take any notice of someone who made such absurd claims in any field other than audio? Would you believe it with audio? I certainly don't.

Introduction

Despite many of the myths that surround series networks and their acclaimed superiority over conventional parallel networks for loudspeaker design, both networks can be designed with identical transfer functions if the load impedance remains constant. Most of the claims regarding series networks are either grossly overstated or blatantly wrong and may cause deleterious effects on system performance. As with all aspects of design, there are compromises that must be made, and it is impossible to make an informed decision if you are unaware of the facts.

This article is intended to show that there are no greatly enhanced features in a series or parallel network - if properly designed their performance is essentially identical in terms of response, phase and (by extension) transient response. It is unwise to claim that one type of network is superior to

the other, when simple logic dictates that if amplitude and phase response are the same, then all of the filter's other characteristics are also the same.

There are other factors than just the response, and this is where the differences between the network topologies exist. Each has good and bad points that must be considered.

1.0 - First Order Comparison

First order (6dB/octave) networks have a strong following amongst many audiophiles, and indeed, they have a number of very desirable features. They have the best possible transient response, and are predictable and easy to design, but as with all things there is a down side. The demands on the drivers are extreme, with significant power delivered to the tweeter even at its resonant frequency, and the risk of cone breakup and off-axis lobing for the mid-woofer.

Nevertheless, at low power, intermodulation products can be kept within reasonable limits with careful driver selection, and they can sound very good indeed.

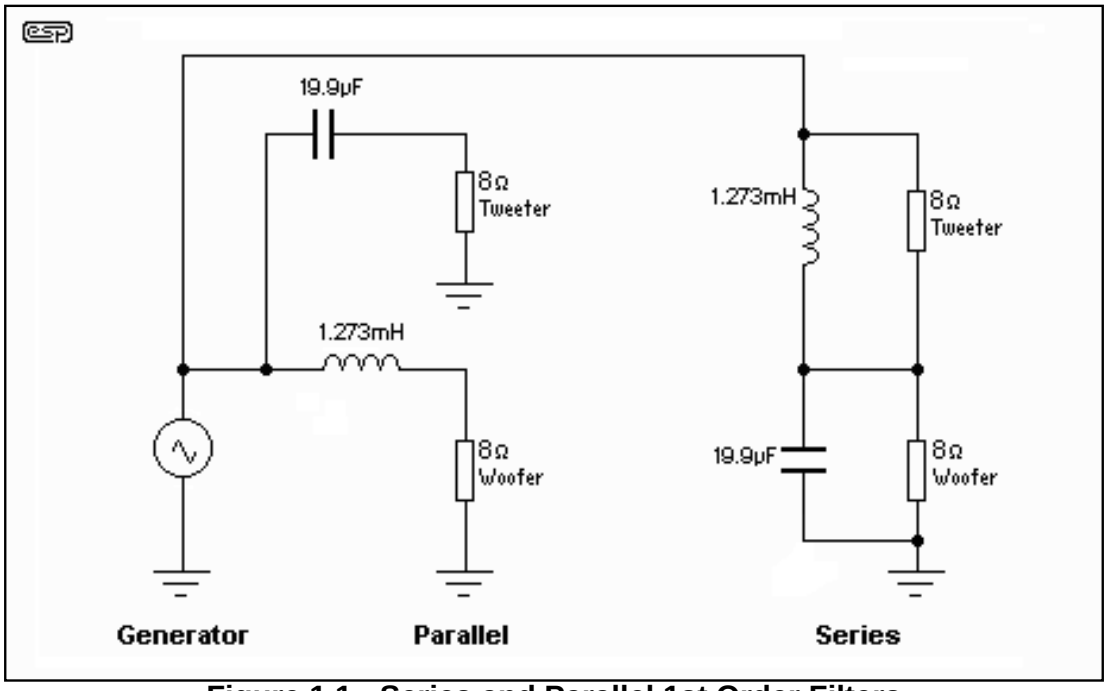

Figure 1.1 - Series and Parallel 1st Order Filters

Illustrated above are equivalent series and parallel first order crossovers with 1kHz crossover points for a fixed load. Note that resistive loads were used in order to minimise analysis variables. There is some material in the conclusion of this article describing further simulations and transient response that encompasses complex load impedances typical of a loudspeaker. 1kHz was chosen for one reason - the crossover frequency is nicely centred in the graphs for best display. The effects shown in this article are identical at any frequency.

Input impedance is exactly the same for each type, and is essentially perfectly flat, with both circuits dropping by 2 millohms at the crossover frequency. This is of no consequence, and may be ignored.

1.1 - Response

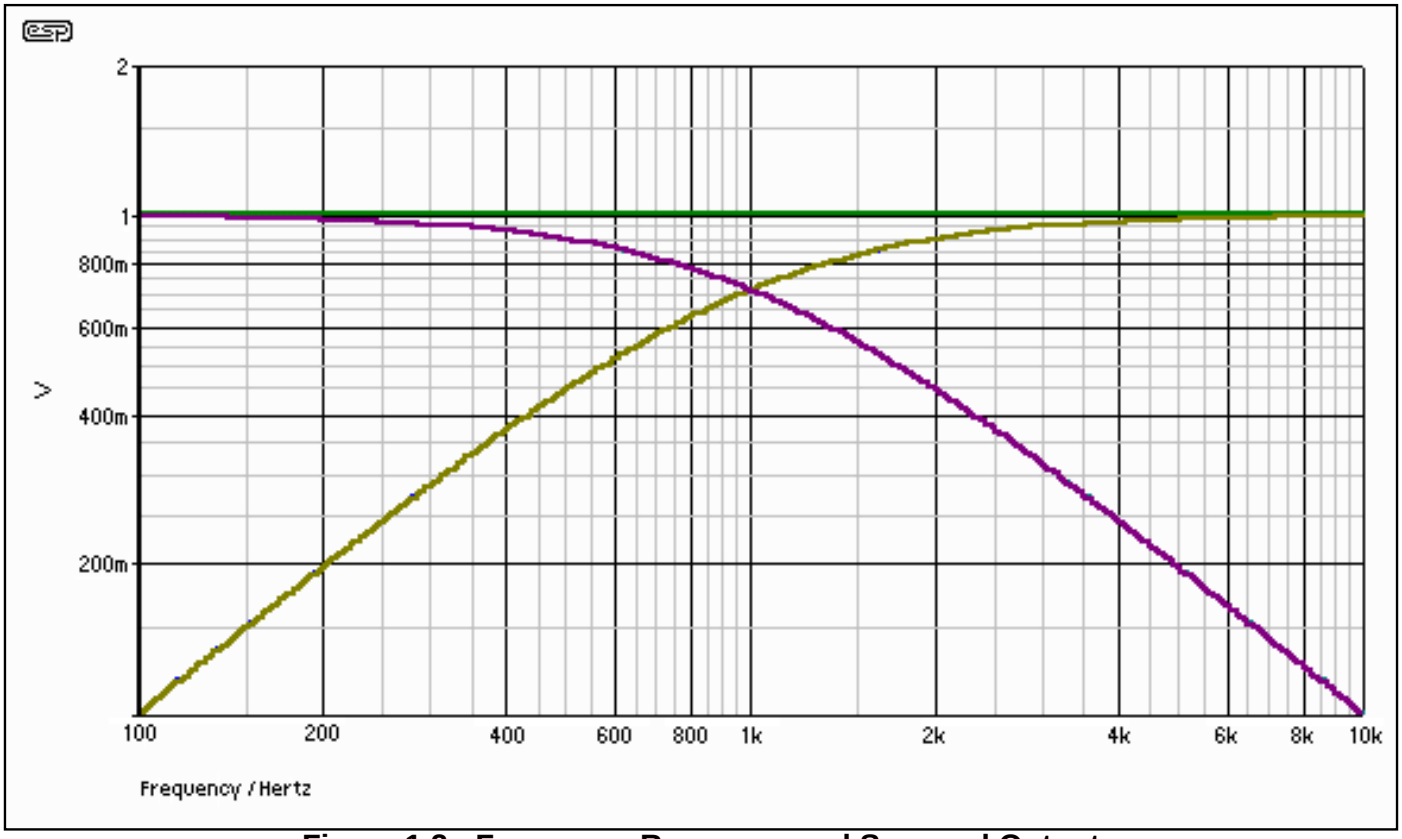

Figure 1.2 - Frequency Response and Summed Output

The frequency response and electrically summed outputs are shown in Figure 1.2 and it is quite obvious that they are identical, since the graphs are perfectly overlayed (there are 6 graphs on the chart, not 3).

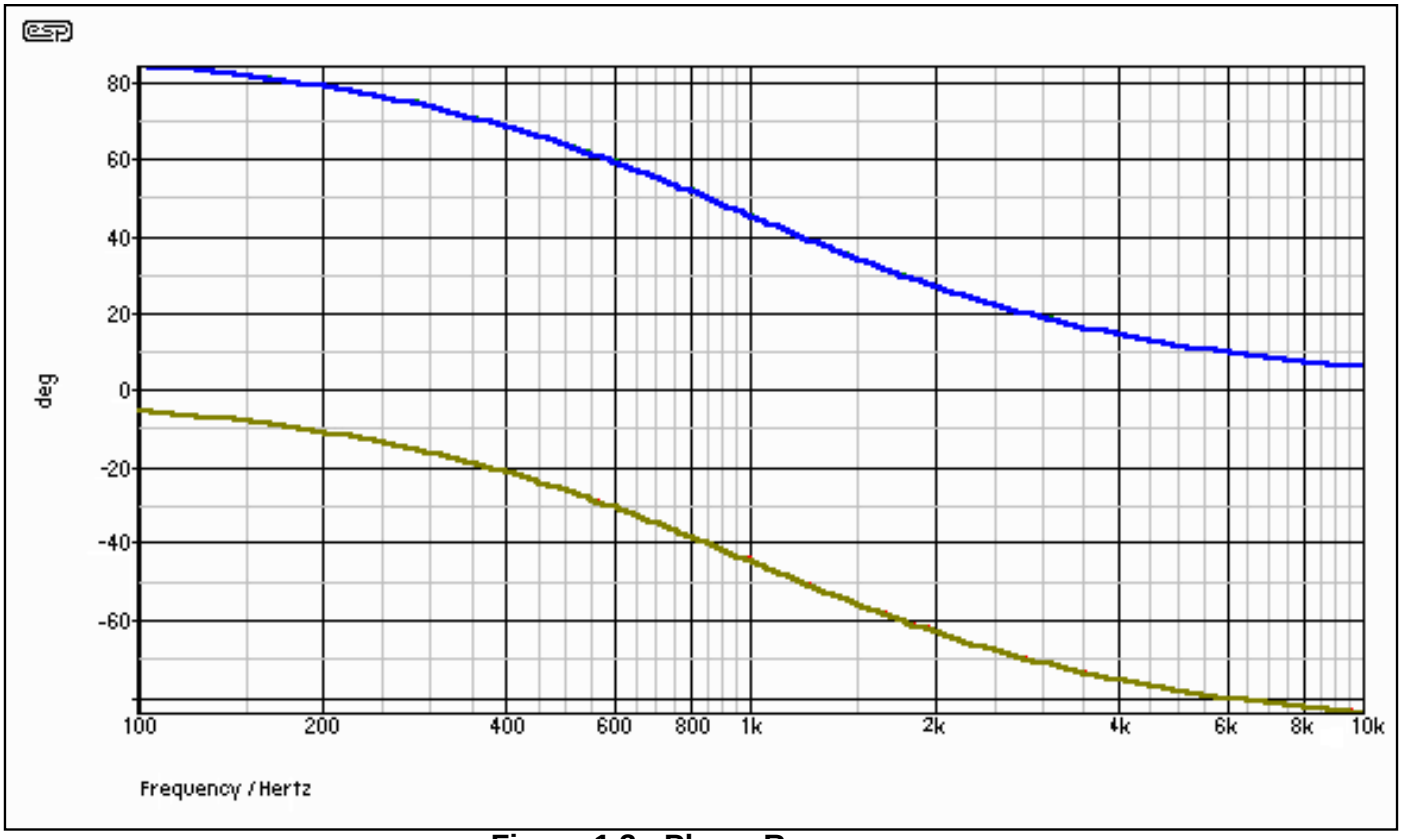

Figure 1.3 - Phase Response

The phase response of the series and parallel crossovers are also identical as can be seen above. There are 4 graphs (2 serial and 2 parallel) and again, they are perfectly aligned.

1.2 - Impedance Variations

Figure 1.4 shows the variation of high and low pass filters and summed response when the woofer impedance is varied by +/-2 ohms. Red shows the electrical sum of the variation with 6Ω impedance, and the green graph is for 10Ω. Note that only the low pass filter response is affected.

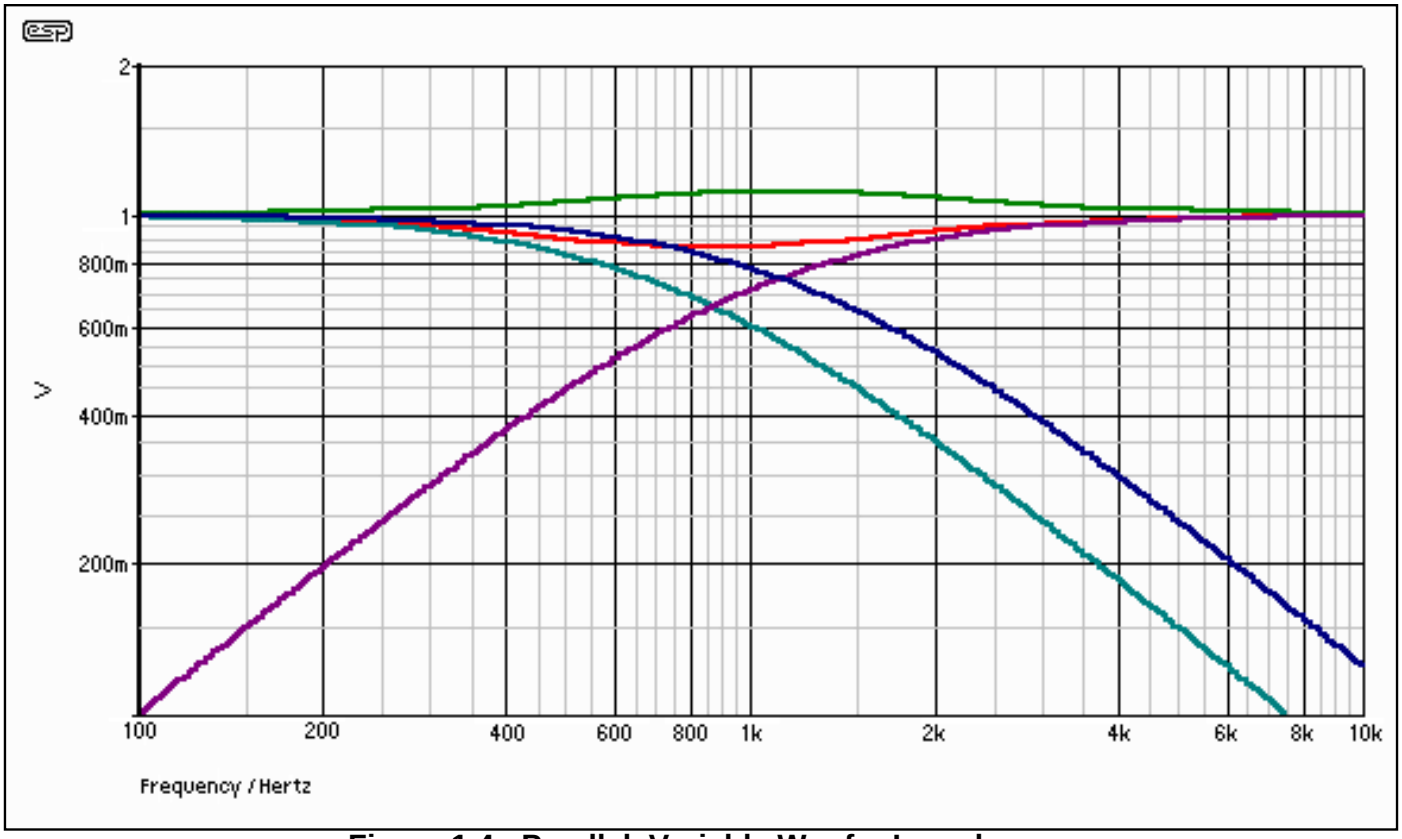

Figure 1.4 - Parallel, Variable Woofer Impedance

The results for tweeter impedance variations are similar (and affect only the tweeter section of the filter), but have not been shown, since the tweeter is far less likely to undergo any noticable change than the woofer.

The graphs below are *very* interesting. The woofer impedance was again changed from 6Ω to 10Ω as was done with the parallel network. Note that although the crossover frequency moves (it becomes higher at higher woofer impedances and vice versa), the summed response remains completely flat.

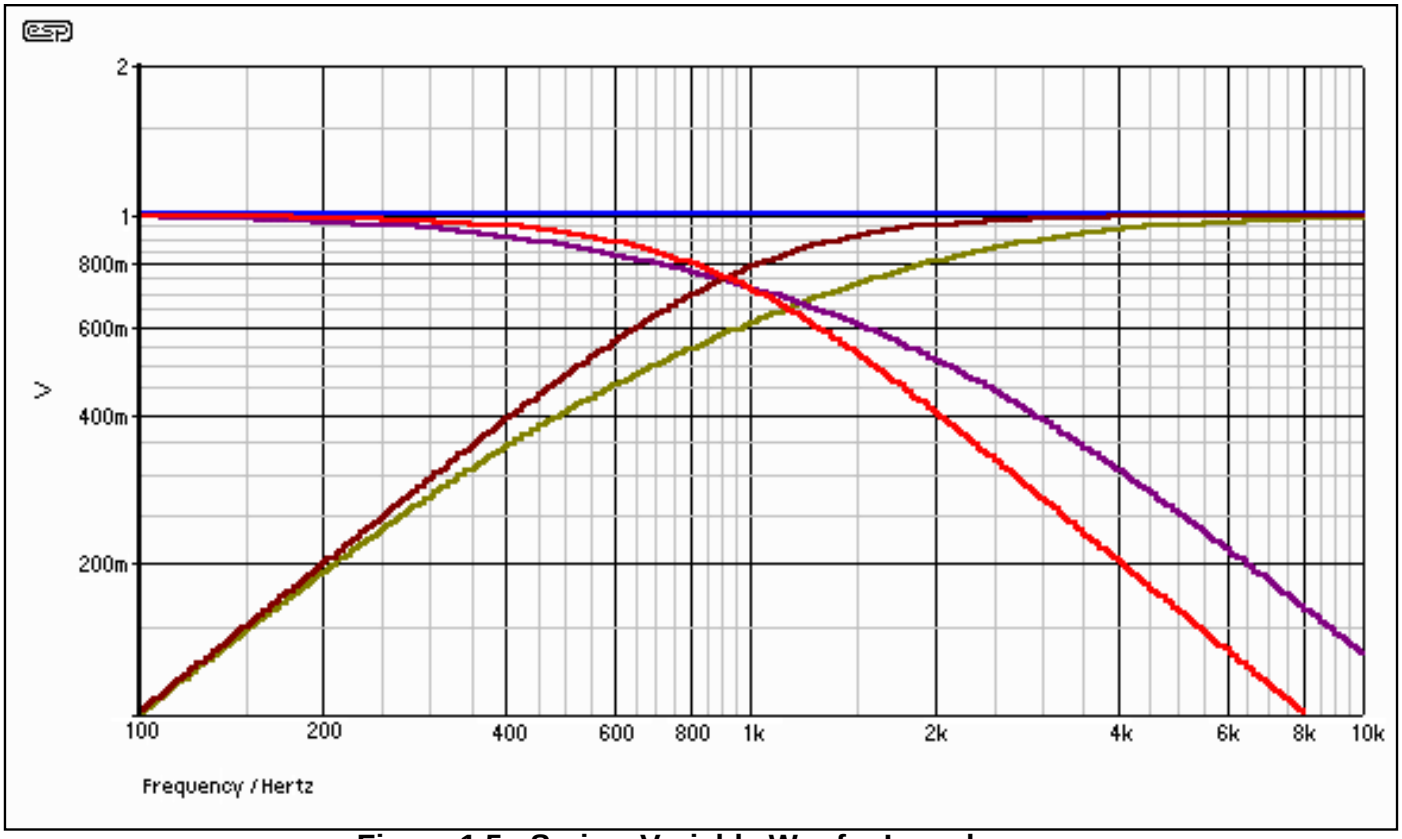

Figure 1.5 - Series, Variable Woofer Impedance

The two sections have a complementary shift - when woofer impedance changes, it effects both low *and* high pass sections, and changes the Q of the filter sections. The result is quite obvious - unlike a parallel crossover, the response remains flat regardless of a shift in the woofer (or tweeter) impedance. If both change in any direction, the same thing happens. In theory, this means that the series network is almost immune from impedance variations in the drivers.

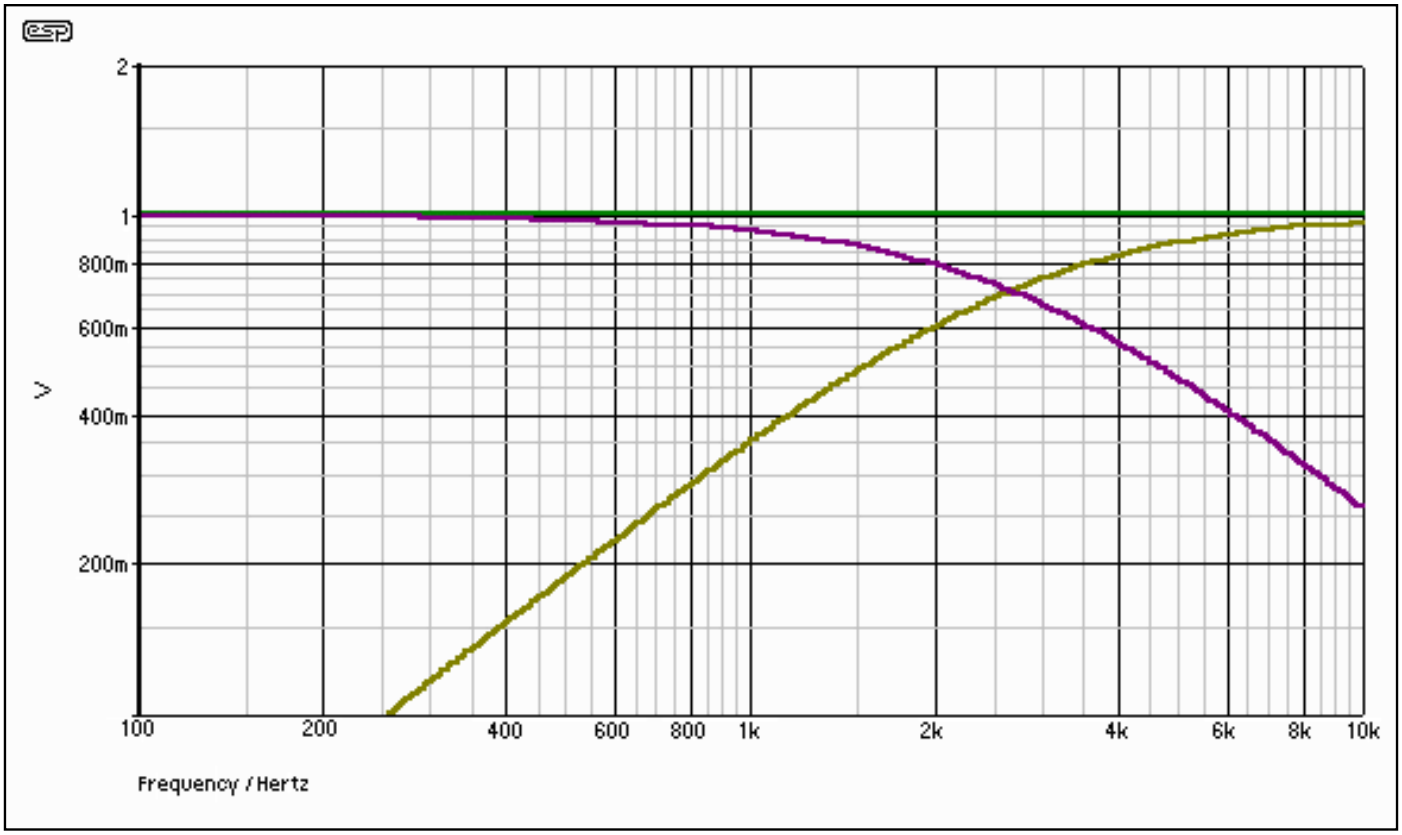

Figure 1.6 - Series, 20ΩWoofer, 3Ω Tweeter

By changing the driver impedances, two things happen. The filter Q changes, and the reflected change affects the behaviour of the other filter section. Although the individual response, Q and phase varies, the net result is that the effective crossover frequency is changed, but nothing more. This is a remarkable property, and the series first order is the only crossover filter circuit that has this ability.

Remarkable though it may be, it is still advisable to design the series network correctly, and maintain everything as close as possible to the design values. Should the woofer impedance increase (with voice coil temperature, for example), the crossover frequency will move upwards, thus providing a small measure of added protection for the tweeter at sustained high power levels.

However, all is not completely rosy. Everything in electronics is a compromise, and the selection of a crossover is no different. There is one final test that needs to be applied, and that is to examine the amount of woofer back EMF that reaches the tweeter. This is an area where the series network is inferior to the parallel.

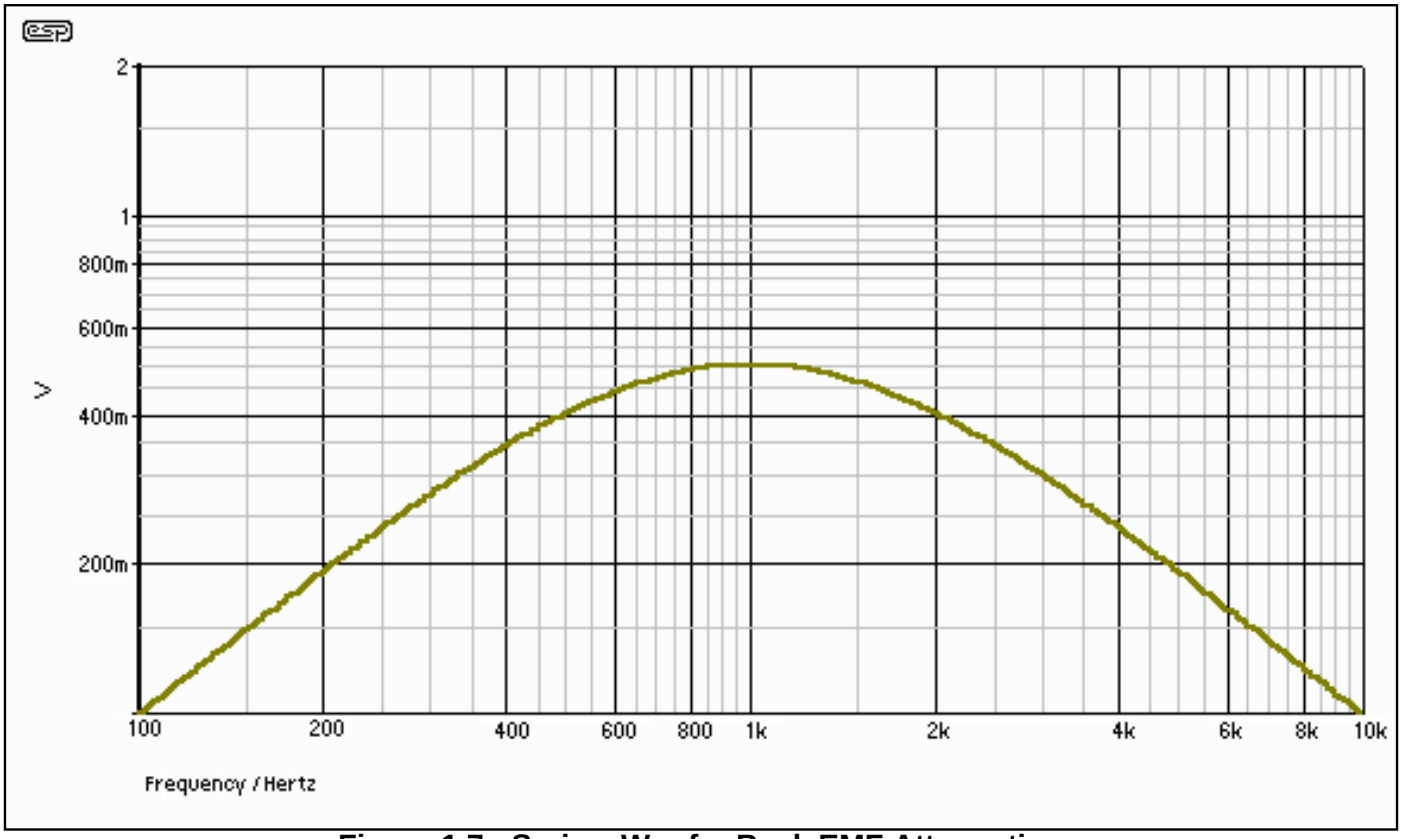

Figure 1.7 - Series, Woofer Back EMF Attenuation

With a parallel network, only the amplifier's output impedance plus the impedance of the cable allows any cross coupling between high and low pass sections. With a zero ohm source, attenuation is infinite, and is not shown above.

A series network relies solely on the isolation of the crossover filters, and as a result, the back EMF from the woofer is not attenuated as well. This may not be a major problem, since the attenuation of back EMF is the same as for amplifier power (actually, it is 3dB better), and the latter is at a far greater amplitude. It is a consideration nevertheless, so be aware that it may increase tweeter intermodulation.

1.2 - Summary

The series network is probably a better choice than parallel for a number of reasons. It retains a flat response even when the driver characteristics change, and is to an extent "self correcting". Implementation is no more difficult than for an equivalent parallel network, and the same component values are used.

On the negative side, woofer back EMF supression is significantly worse than with a parallel network - it is up to the designer to determine if this is likely to cause a problem.

Finally, it must be remembered that any first order network dictates that the drivers will have significant power applied at frequencies where their performance will be rapidly deteriorating, however for a system that will never be operated at high power, the performance can be very

satisfying.

2.0 - Second Order Comparison

The design process for a 12dB/octave filter is completely different for series and parallel implementations of the same design. For a parallel network (assuming a Butterworth alignment for the sake of simplicity), the capacitance and inductance are calculated by …

$$C = 1 / (2 * \pi * f * (Z * \sqrt{2}))$$
$$L = (Z * \sqrt{2}) / (2 * \pi * f)$$

(where Z is impedance, f is frequency, $\sqrt{2}$ is ≅1.414, and $\pi$is ≅3.14159)

A series crossover design is different in terms of the component values …

$$C = 1 / (2 * \pi * f * (Z / \sqrt{2}))$$
$$L = (Z / \sqrt{2}) / (2 * \pi * f)$$

For this exercise, the crossover frequency was arbitrarily selected to be 1kHz, and 8 ohm resistive loads were used. The series network has the advantage of using smaller inductance values, but capacitor values are higher. The difference is unimportant, but capacitors for crossovers are more expensive than inductors. This is a minor point if there is an improvement in performance.

The values used for the simulations were as follows …

Table 1 - Second Order Crossover Values

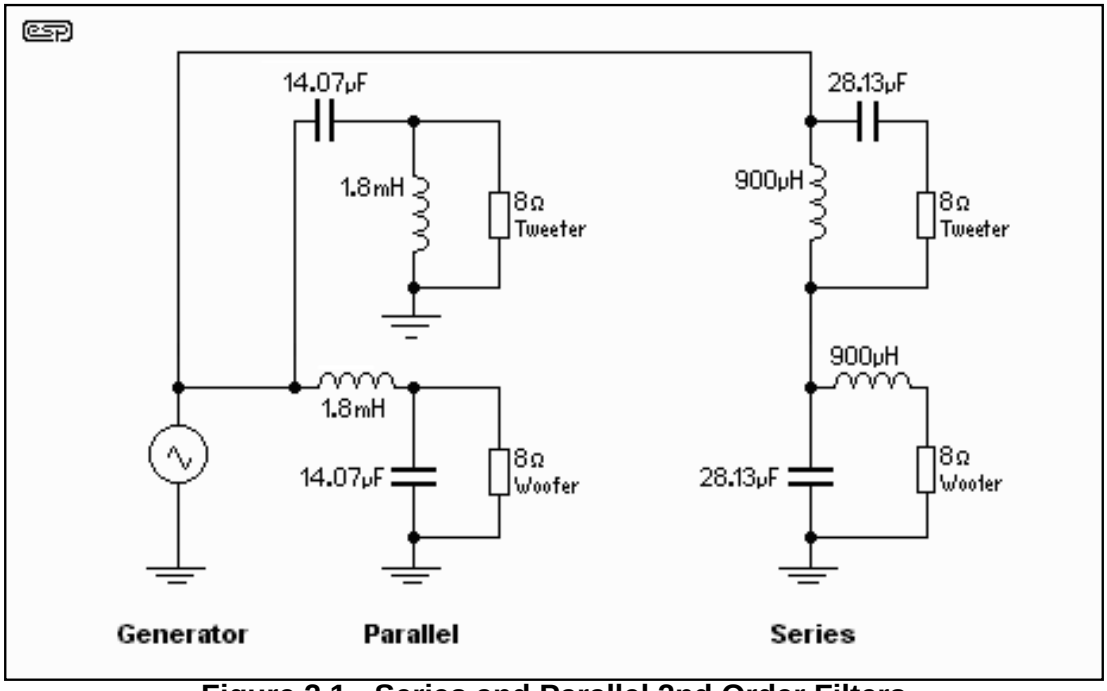

Figure 2.1 - Series and Parallel 2nd Order Filters

2.1 - Response

As with the previous example using a first order filter, when properly aligned, the response is identical. Because the plots look exactly the same as the previous example (other than the rolloff slope), there is little point displaying graphs that show two sets of curves that are perfectly matched.

It can be stated that if two filters, regardless of topology (series, parallel, active or passive) have an identical frequency response, then they must also have identical phase and impulse responses, since these cannot be separated.

Of course, this only holds true as long as the source and load impedances are also identical. Input impedance of both filters is essentially completely flat, having a variation of only 4.6 mdB (i.e. 0.0046 dB). Due to rounding errors in the component values, there is a tiny variance between the two filters, however it is completely insignificant (about 0.17 Hz difference).

One thing that should not be overlooked is the inductor's resistance. While this causes a small loss of level with a parallel crossover network **, it will cause the series network to "shelve" the tweeter rolloff. As a result, a DC resistance of (say) 800mΩ will cause the signal applied to an 8Ω tweeter to drop to a minimum of just over 20dB below the applied signal *regardless of frequency!* This includes DC under amplifier fault conditions.

There is virtually no difference between series and parallel at about 1 decade below crossover (i.e. 1/10th the frequency), but below that the difference becomes apparent. There may be as much as 20dB more level applied to the tweeter at 20Hz with a series crossover vs. an otherwise identical parallel version (with an inductor DCR of 0.8Ω)

** Although there is a small loss of level, the parallel crossover's theoretical response is greatly disturbed by even a 0.8 DCR in the inductor. This will cause a response anomoly of about 1dB, with the woofer output being 0.8dB down at one decade below crossover frequency. Naturally, higher resistance will create more deviation in response. The series network's overall response remains flat. Normally, the inductor's DCR must be factored into the design, regardless of crossover type.

2.2 - Impedance Variations

As was shown to be the case with the first order implementation, by its very nature, the two segments of a parallel crossover are separate, and share only the amplifier’s output impedance, plus the impedance (R, L and C) of the speaker lead. Speaker lead capacitance may safely be ignored as it is insignificant compared to the capacitances within the crossover network.

A series network on the other hand, relies on the integrity of the series elements - all of them. A change in woofer parameters (for example) therefore affects the tweeter, and vice versa. The tweeter is likely to have smaller and fewer changes than the woofer in a practical system.

It is interesting to see the behaviour of the two network types when the outputs are summed electrically. This is a severe test, and in 12dB types, neither crossover is significantly worse than the

other in this respect.

Any change in the parameters of the woofer (the most likely to change) causes a change in the tweeter parameters, and the summed electrical response varies with both types. Since it has been established that the two filter types are identical when all values are at their design figures, there is no point showing this. The following two charts show the extremes - with the woofer impedance at 4 ohms and 12 ohms (the latter value being much more likely).

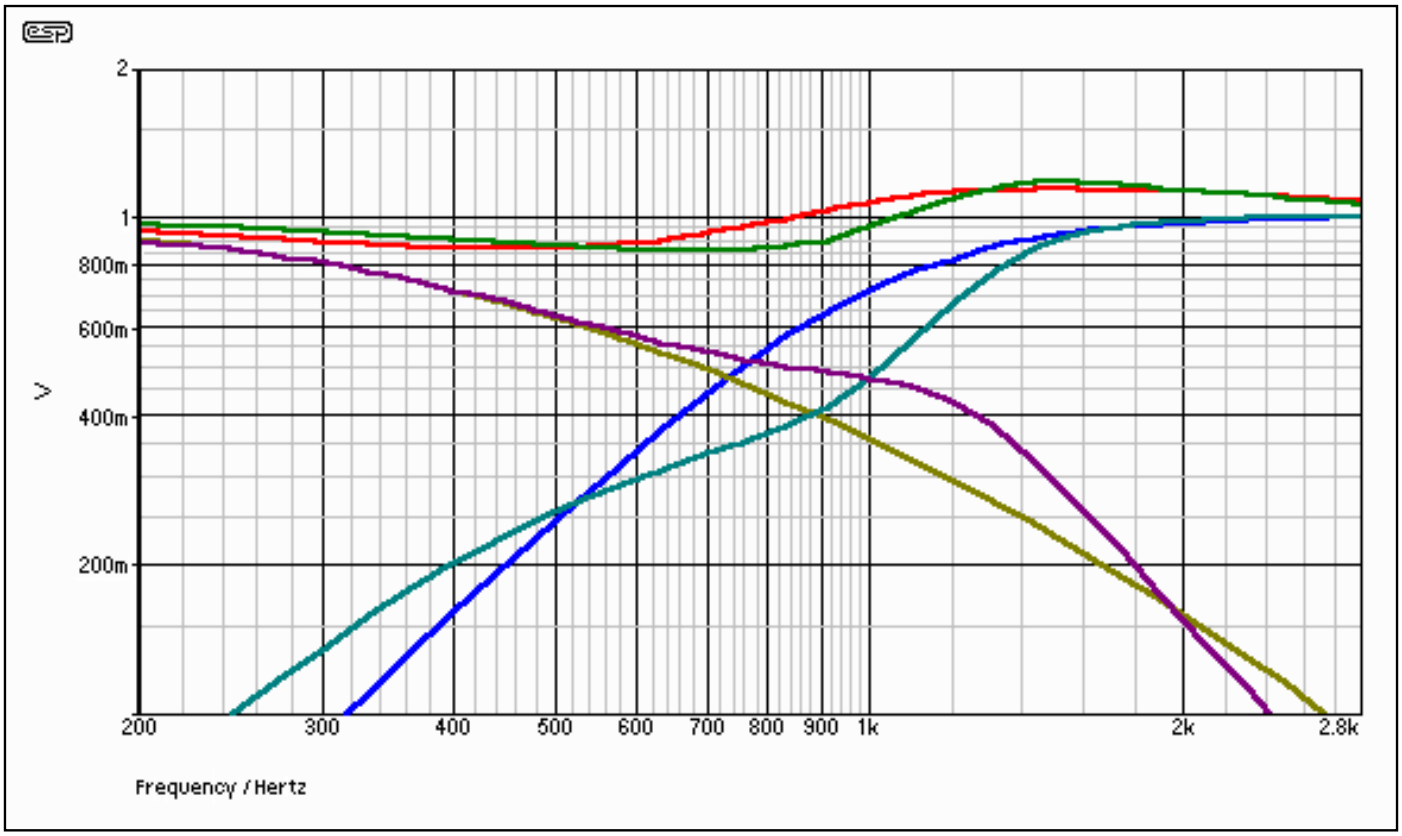

Figure 2.2 - Series and Parallel - Woofer at 4Ω

The red trace is the summed electrical response of the parallel network, and green for series. The dark green and violet traces (with the kinks and bends) are the individual responses for the series network.

Note that although both series and parallel networks have deviated from the ideal, the parallel network has a flatter and less rapid change. Overall, the difference is marginal.

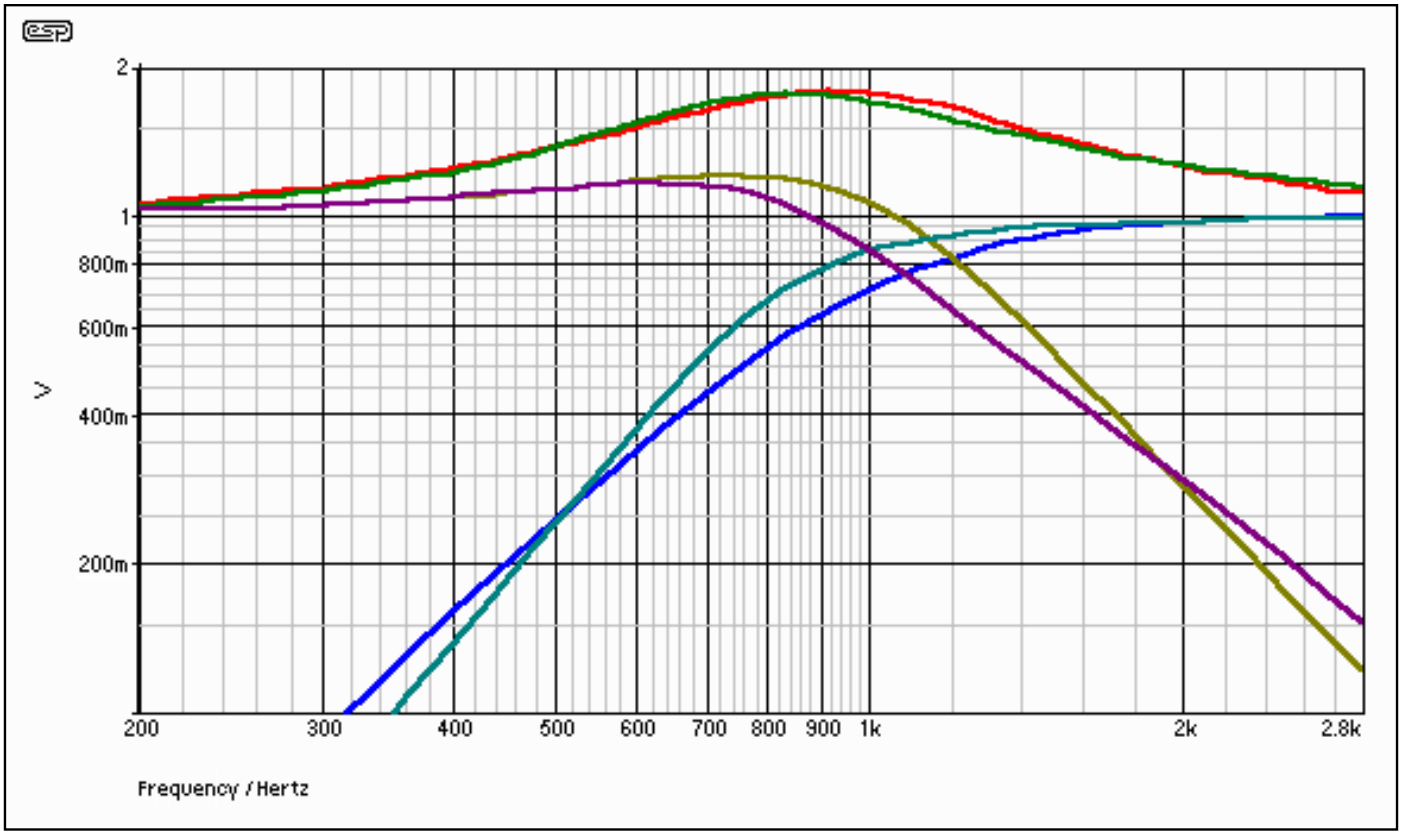

Figure 2.3 - Series and Parallel - Woofer at 12Ω

Here, we see the change when the woofer impedance is increased to 12 ohms. The series network is slightly better, but there is very little between the two. The rise at crossover frequency has changed from 3dB (normal) to 4.9dB - this will be audible in both cases.

The impedance "seen" by the drivers is also important. This may be referred to as "look-back impedance". The woofer is expected to be effectively short-circuited by the amplifier at low frequencies, and both networks achieve this quite well. Interestingly, the parallel network loses control at the crossover frequency. This is shown in the following diagram. The loss of control at this frequency is relatively unimportant if the cabinet is well damped, but may cause colouration with some systems.

In the following graph, each trace indicates the current generated when a 1V source is connected in series with the woofer. This represents the back EMF generated by the cone's momentum when the signal changes. The red trace shows the current in the parallel network, and as can be seen, it drops to a low value (high impedance) at the crossover frequency. A series network maintains relatively good control over this region, tapering off (impedance increasing) gradually.

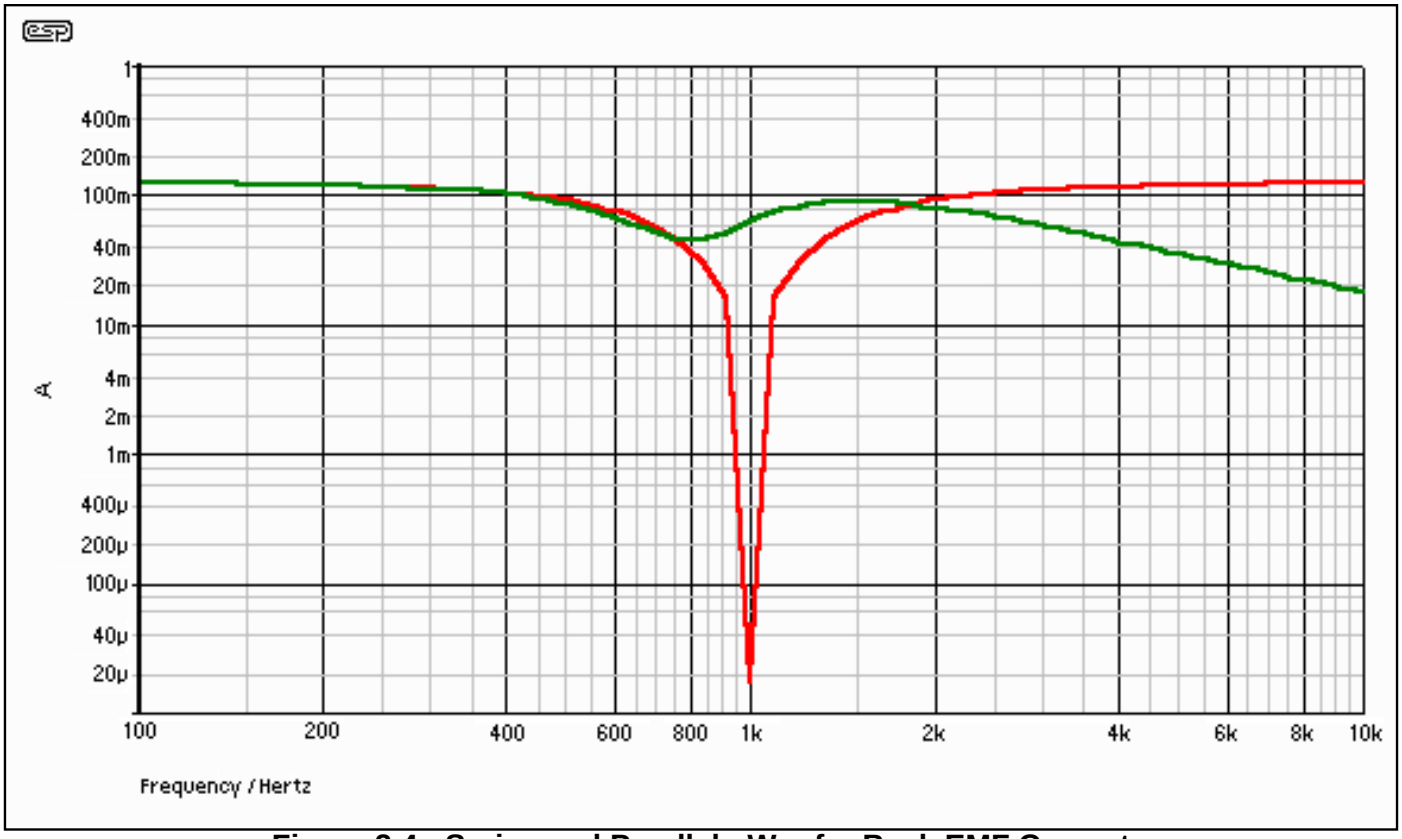

Figure 2.4 - Series and Parallel - Woofer Back EMF Current

The next test is to see how well each network maintains separation of the signal generated by the woofer. It is important that woofer back EMF (in particular) is not seen by the tweeter, as this may create intermodulation. The 2nd order network is the same as a 1st order network in this respect, except that the slope is 12dB/octave as is expected of a second order network.

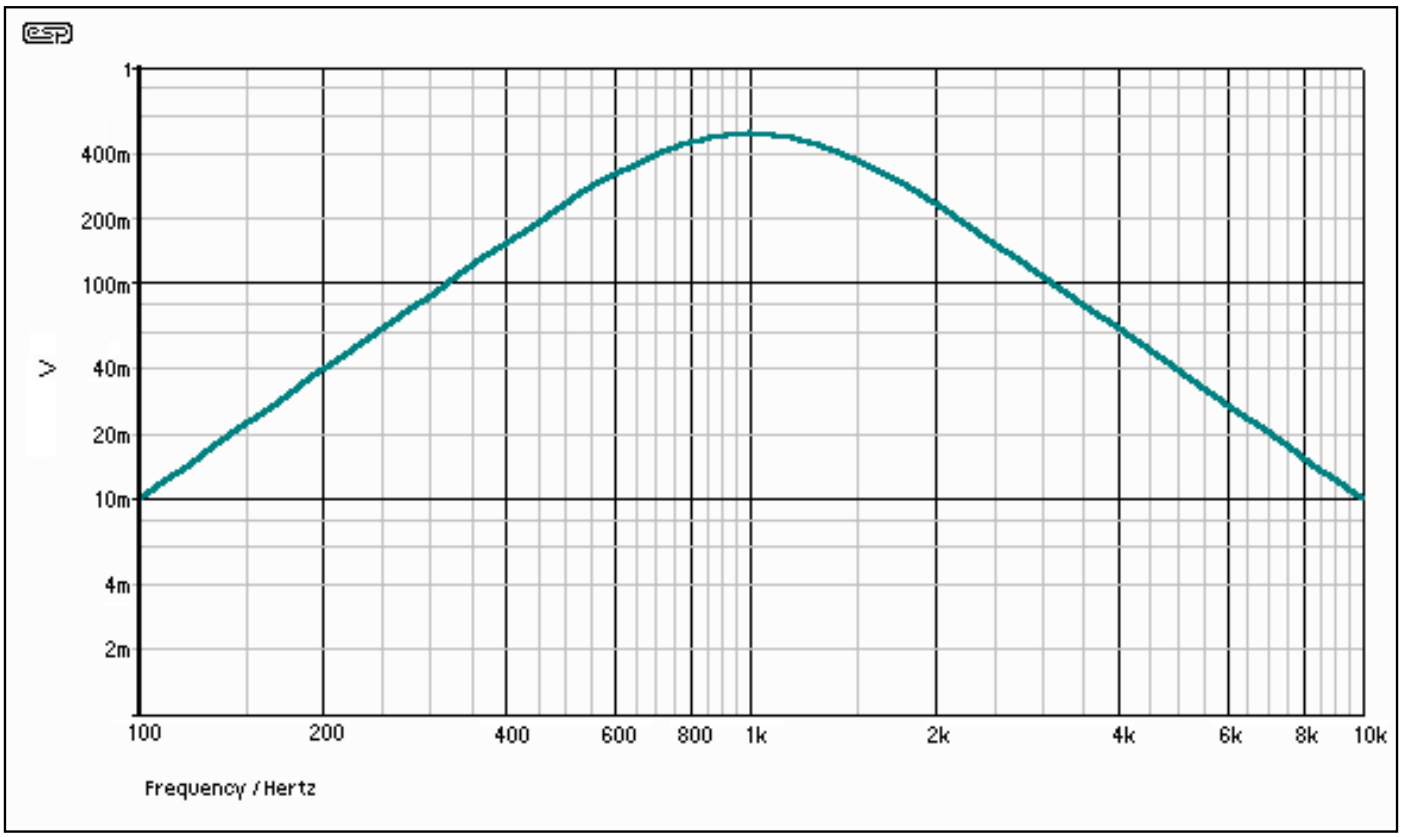

Figure 2.5 - Series, Woofer Back EMF Rejection

The amount of this signal reaching the tweeter should be zero (or close to it). The parallel network is not shown, since it is at zero. Not so good for the series network however, with more than half the generator voltage appearing at the tweeter terminals at the crossover frequency. Even at 300 Hz, the voltage is significant at 100 mV (20dB down from the full 1V applied). As with the series 1st order network, the back EMF rejection is 3dB better than the attenuation of the amplifier signal below crossover frequency.

The levels shown are not a real concern, since woofer back EMF will always be much lower than the amplifier signal. While it would seem ideal to limit such cross-coupling to the minimum possible, the effects are something of an unknown, and back EMF can be expected to be quite low with typical drivers - especially where the box is well damped internally.

Given that valve amplifiers typically have an output impedance of 6 ohms (when operated without global feedback), the differences between the series and parallel configurations become very similar, with the parallel network being only 2.7dB better than its series counterpart.

2.3 - Summary

The differences between second order series and parallel filters are more difficult to rationalise. Each has strengths and weaknesses, but from the above, the parallel version probably has a slight advantage. Both exhibit variations in response when the woofer (or tweeter) characteristics change, and they are quite similar. The parallel filter has better woofer back EMF rejection in the tweeter circuit, while the series crossover has a better woofer "look back" impedance characteristic.

Components for a series crossover will be more costly because of higher capacitor values, but it will have lower losses due to inductor resistance, since they are lower values. For those who feel that capacitors change the sound, the higher values may be thought to have a greater effect

---

3.0 - Conclusion

It is very difficult to make any judgement of series or parallel crossovers as a generalisation. The series first order network is probably a better choice in general, due to its flat response regardless of driver impedance - this can simplify the design, but at the expense of having the crossover frequency shift from the design value.

The choice is more difficult for the second order crossover, since both series and parallel have vices and virtues, with neither standing out as generally superior. Overall, the parallel version is probably a better choice, if only because it is slightly more tolerant of variations, and will probably have marginally lower losses because there is no series connection of the drivers (this adds the resistive losses in the inductors, whereas they are in parallel in the parallel filter - of course).

As for any claims for better transient response or sound quality, this is very doubtful - there is

nothing to suggest that either version if properly designed will outperform the other to any degree. Parallel crossovers are easier to design, and are simple to convert to a (sub) Bessel response with a Q of 0.5 (approximating a Linkwitz-Riley response).

Most constructors who have attempted second order series crossovers have had to spend considerable time tweaking to get it right - they are harder to design than their parallel counterpart, and interactions will always cause problems.

As a final examination, Figure 3.1 shows a series and parallel network, using simulated drivers. There is no compensation applied for woofer inductance or tweeter resonance, yet both effects are present.

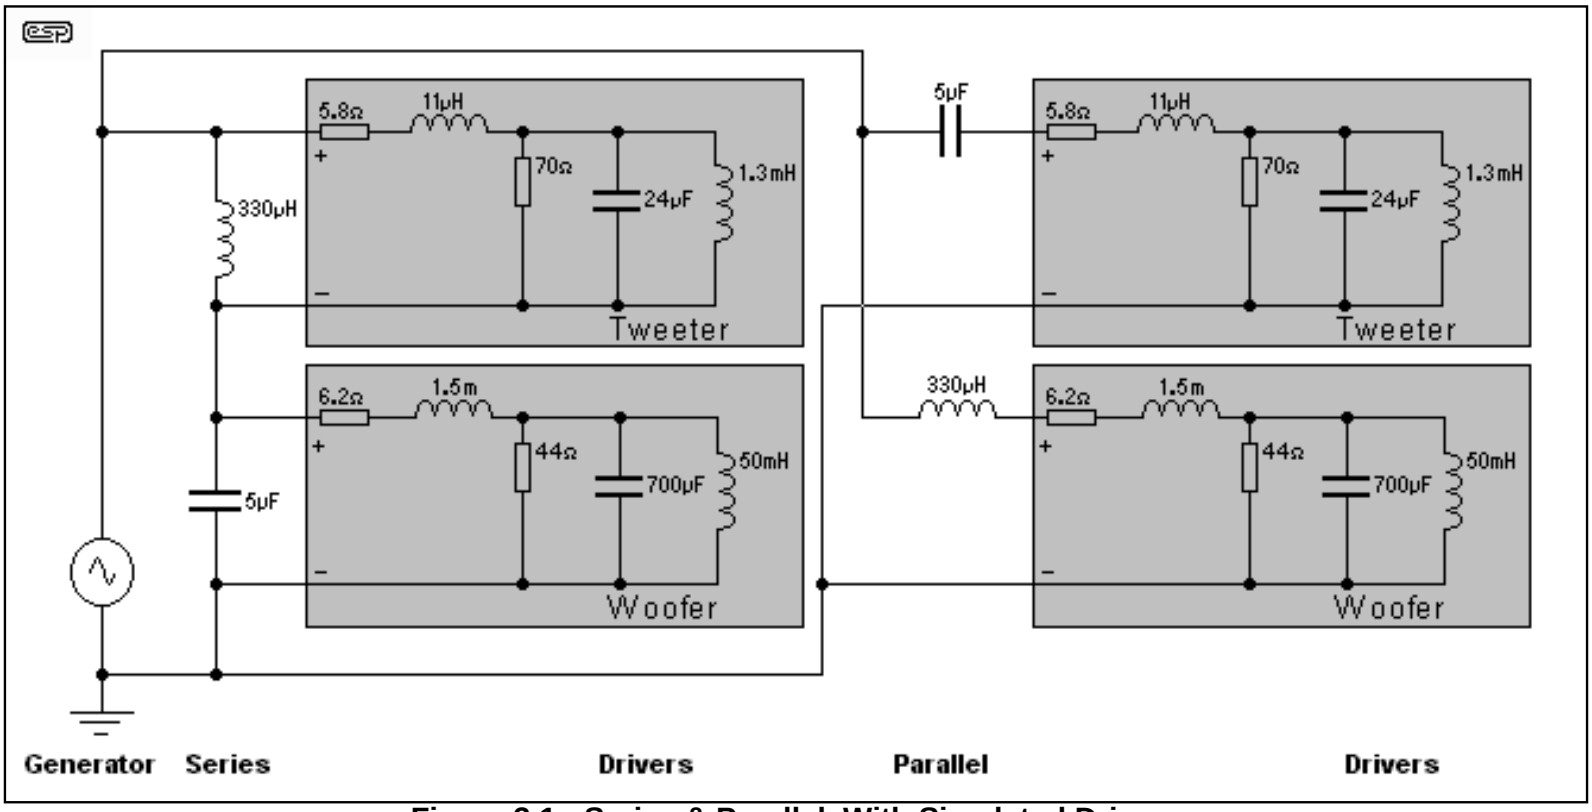

Figure 3.1 - Series & Parallel, With Simulated Drivers

The grey boxes are the drivers (identical in each version), and the area outside the boxes contains the generator and filter networks. As you can see, these are the same in each case, with the values deviating from the previous simulations only in that this design is for a real crossover network (a very similar design is used in my PC speakers, as described in the ESP projects section - see Project 73). The values are slightly different from those shown, but the principle is identical!

A transient analysis shows the following outputs, using a nominal 4kHz crossover frequency (as per the circuits above) and an input signal of 1kHz ...

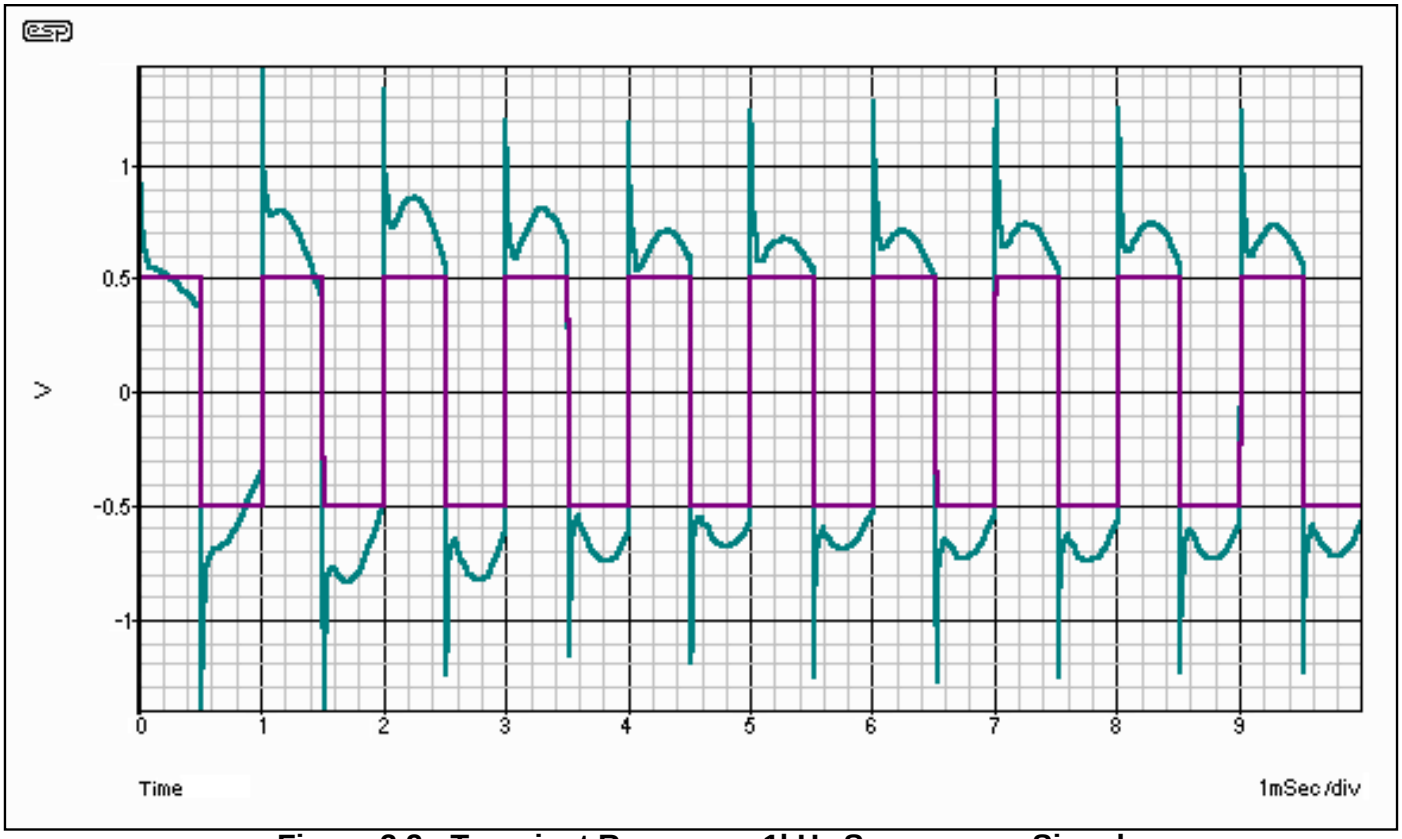

Figure 3.2 - Transient Response, 1kHz Squarewave Signal

The parallel crossover output is shown in Aqua, and the Violet trace is the series network's output. This is an electrical summing, but it shows clearly that the driver characteristics are fully compensated by the series network, and the output is exactly the same as the input. The parallel network by comparison indicates severe waveform distortion, and this implies phase and levels are incorrect - remember that no attempt was made to optimise the driver impedance with zobel or notch filters in either case.

This is fine in theory, so to prove the point one way or another, the following are real impedance and response plots from two identical (inasmuch is possible) boxes, measured under identical conditions, and within a few minutes of each other. The boxes are my PC speakers, as described above, using shielded Peerless tweeters, and small (unbranded) polypropylene woofer drivers.

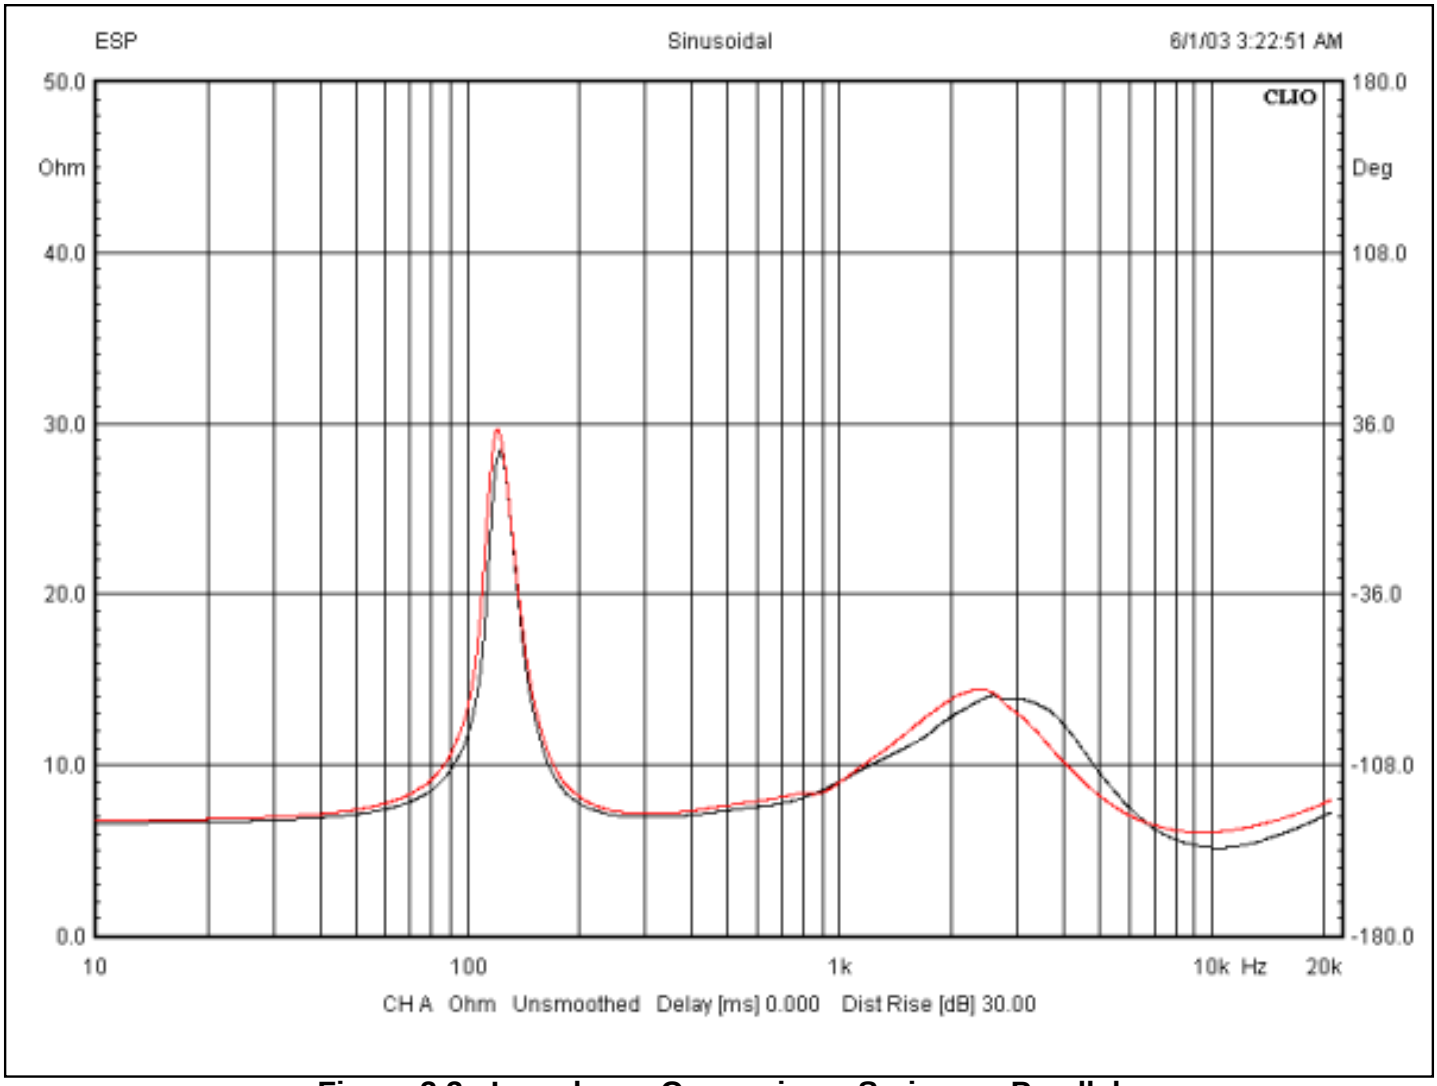

Figure 3.3 - Impedance Comparison, Series vs. Parallel

The measured impedance differences are as likely to be the result of silghtly mismatched drivers as anything else. There is not a great difference at all. The red trace is the series connection, and black is parallel.

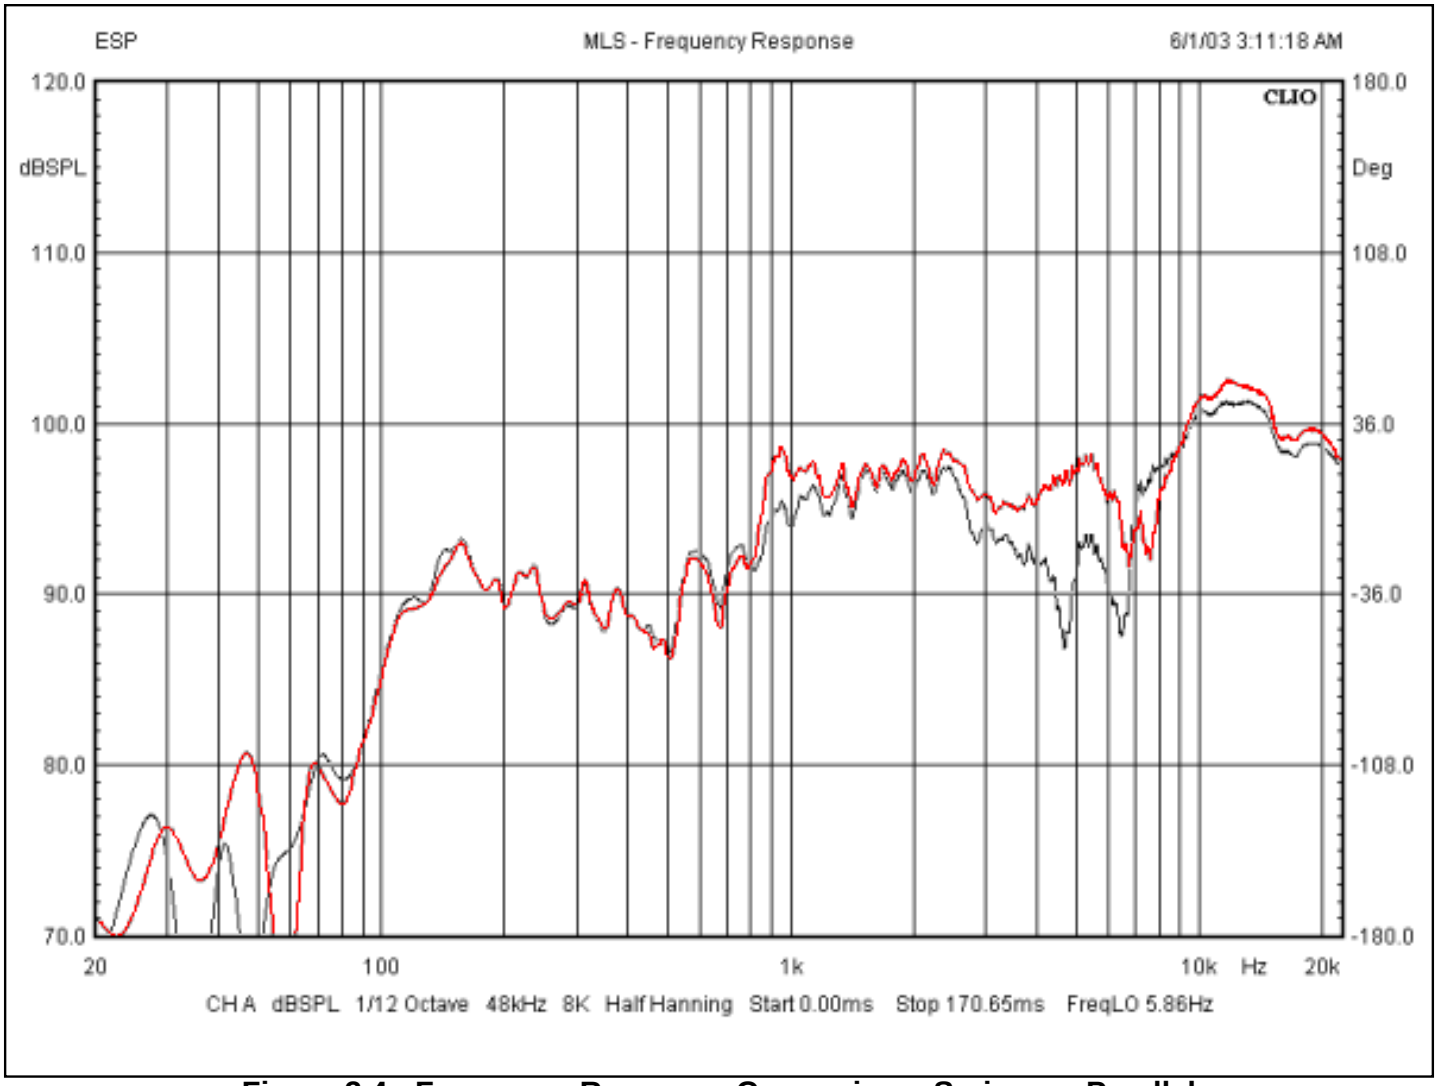

Figure 3.4 - Frequency Response Comparison, Series vs. Parallel

Response differences are a bit more pronounced (again, red is serial and black is parallel), but are not as we should expect based on the simulations. Simulation showed perfectly flat response, but remember that was an electrical signal only, and fails to account for driver behaviour. Note that there *is* a noticable improvement at the crossover frequency of 4kHz - the series network is flatter, indicating that the theory does work (the drivers have no impedance compensation - these are PC speakers, and make no claim to be being hi-fi).

Finally, after converting the second enclosure's crossover to series, I did another response comparison. As you can see, there are still differences between boxes, with one tweeter being more efficient than the other. This alone would account for some of the differences seen in the series-parallel comparison.

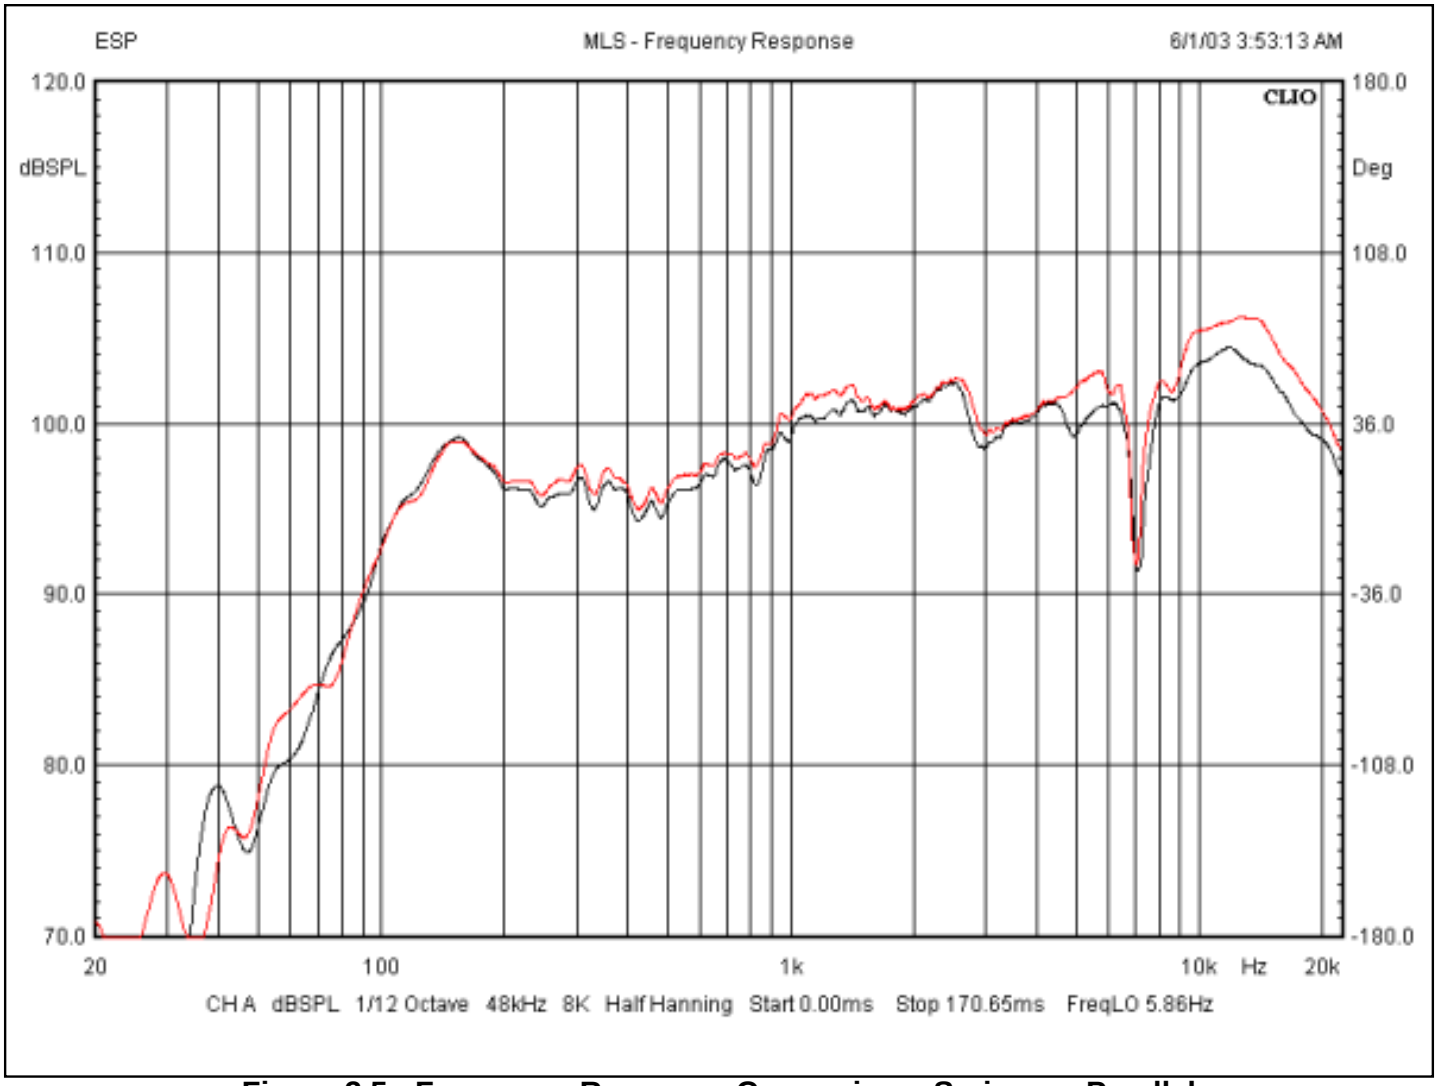

Figure 3.5 - Frequency Response Comparison, Series vs. Parallel

The glitch at 7kHz appears to be caused by a diffraction, probably from the woofer's surround (which projects slightly from the frame, and is at the correct distance for that frequency). As for sound differences between the series and parallel connections, there was very little that I could hear. The microphone is much more sensitive to small variations than the ear, and there are quite dramatic variations in response as one moves around - far greater than the differences measured between the series and parallel connections. This shows up readily if one moves the measurement mic even a small distance, and the fact that the two sets of response graphs look quite different is evidence of this. The mic was moved about 50mm further away from the speakers for the second chart.

Spectral decay plots were also done, but are not shown - there are marginal differences as one would expect from the frequency response variations, but little else.

So, although a simulation shows that a first order series crossover is superior to its parallel equivalent, the fact is that the differences are slight. The evidence was sufficiently compelling for me to change the crossovers in my PC speakers, but the huge difference in sound quality one might expect was not forthcoming. More revealing drivers may well sound better to a critical listener, but the differences are hardly "chalk and cheese" as some may imply.

3.1 - Series & Parallel Networks are (Virtually) Identical ...

Despite the differences that have been shown, the loudspeaker drivers should always be carefully equalised with zobel networks to achieve a flat impedance. Once the impedance is flat, it is resistive, and as has been shown above, the two networks are virtually identical with resistive loads. Therefore, it follows that properly executed zobels (and a notch filter for the tweeter resonance) will cause real-world series and parallel crossover networks to behave in an identical manner, with the (relatively) small difference of woofer back EMF applied to the tweeter.

The phase and transient response of both filters will match exactly with impedance equalisation, so in a *properly designed* crossover network, there is nothing to choose between the two. Certainly, the parallel variant is easier to design, and this alone is probably a good reason to stay with a parallel crossover - and probably also explains why the vast majority of loudspeaker designers use parallel rather than serial. In addition, a serial crossover cannot be biamped or biwired (assuming that you consider this important).

It is safe to say that neither crossover is possessed of any magic (only skill), so be very wary of any claims that a particular crossover design is "vastly superior" or "infinitely more transparent" (or any other hyperbole that may be thrust upon you) in advertising material. All crossovers, and indeed, all loudspeakers, are a compromise. While the "form factor" of the crossover is relatively unimportant, the skill and patience required to execute it properly is what really counts.

1.0 - Introduction

Phase Correction - Myth or Magic? Does it actually work? Although recommended in a lot of designs (especially for subwoofers), you cannot really correct a time delay with a phase shift network, but you can improve performance, albeit marginally some would say. An all-pass filter (aka phase shift network) may be useful in some cases, but it is certainly not the panacea that some would claim.

The best one can hope for (and it does depend a lot on the time delay you are trying to correct) is to convert a deep dip in response into a much shallower ripple at or near the crossover frequency, but it is entirely possible that the end result will not sound as good

as if the dip were just left alone.

This topic has received scant attention at most of the speaker building sites, forum pages and published books on the subject, but is obviously important since it has the potential to make matters worse than they were before you started. A discussion about "time alignment™" has already been done on The Audio Pages - see Phase, Time and Distortion in Loudspeakers for the full discussion.

Unfortunately, it is difficult to achieve true time delay in the analogue domain - it can be done, but requires a large number of components to be placed in the signal path. Since the tweeter is the driver most likely in need of the delay, this means potential degradation of the higher frequencies, something that is commonly quite audible.

2.0 - Time Delay

A time delay is introduced whenever the acoustic centres of any two loudspeakers are different from the perspective of the listener. It is not usually a problem in a three way system between the woofer (or subwoofer) and midrange or mid-bass, but between the mid/ mid-bass and tweeter there is usually considerable room for misalignment in the time domain.

For this exercise, I have used a crossover frequency of 3.0kHz, and the offset between drivers' acoustic centres is 100us (or 35mm, close enough). It is useful to establish the relationship between distance and time, and this may be determined by ...

wavelength = velocity / frequency
period = 1 / frequency

So for any given frequency we can determine the wavelength and period (the time for one complete cycle). For example, at the selected crossover frequency of 3.0kHz, the wavelength is ...

wavelength = 345 / 3000 = 115mm
Period = 1 / 3000 = 333us

It is useful to understand that there is a simple relationship between time delay and effective "phase" shift in terms of wavelengths and the velocity of sound in air (345m/s at sea level, approx 22°C and 50% relative humidity).

For example, if the delay were 166us, a 3.0kHz signal is delayed by exactly 1/2 wavelength, or an equivalent distance of 57mm. This can also be determined by realising that sound travels 0.345mm/us, making calculations rather easier.

2.1 - Phase Shift Vs. Time Delay

While it is possible to make a phase shift network that has a consistent phase shift over a wide range of frequencies, this is not the same as time delay. It can be considered obvious that if two signals are delayed in time by exactly the same amount that the end result is identical to no time delay at all. Likewise, if two signals are affected by identical phase shift networks, the net result is again the same (although there is now a phase shift in the signal which may or may not be audible, depending on many different circumstances).

Having a time delay (in the case of loudspeakers introduced by a physical misalignment of acoustic centres), and attempting to correct this with a phase shift simply does not work as well as one might hope. This should be obvious, but it is still touted as the "proper" way to realign the drivers. This can be shown in the simplest case with a time delay that is exactly 1/2 wavelength. For a 3kHz crossover point, this equates to wavelength ÷ 2, or 57.5mm (which can also be described as a time delay of 166us). The graphs shown below are all done using a 24dB/octave Linkwitz-Riley crossover - the effects with lower orders are very much worse than shown here.

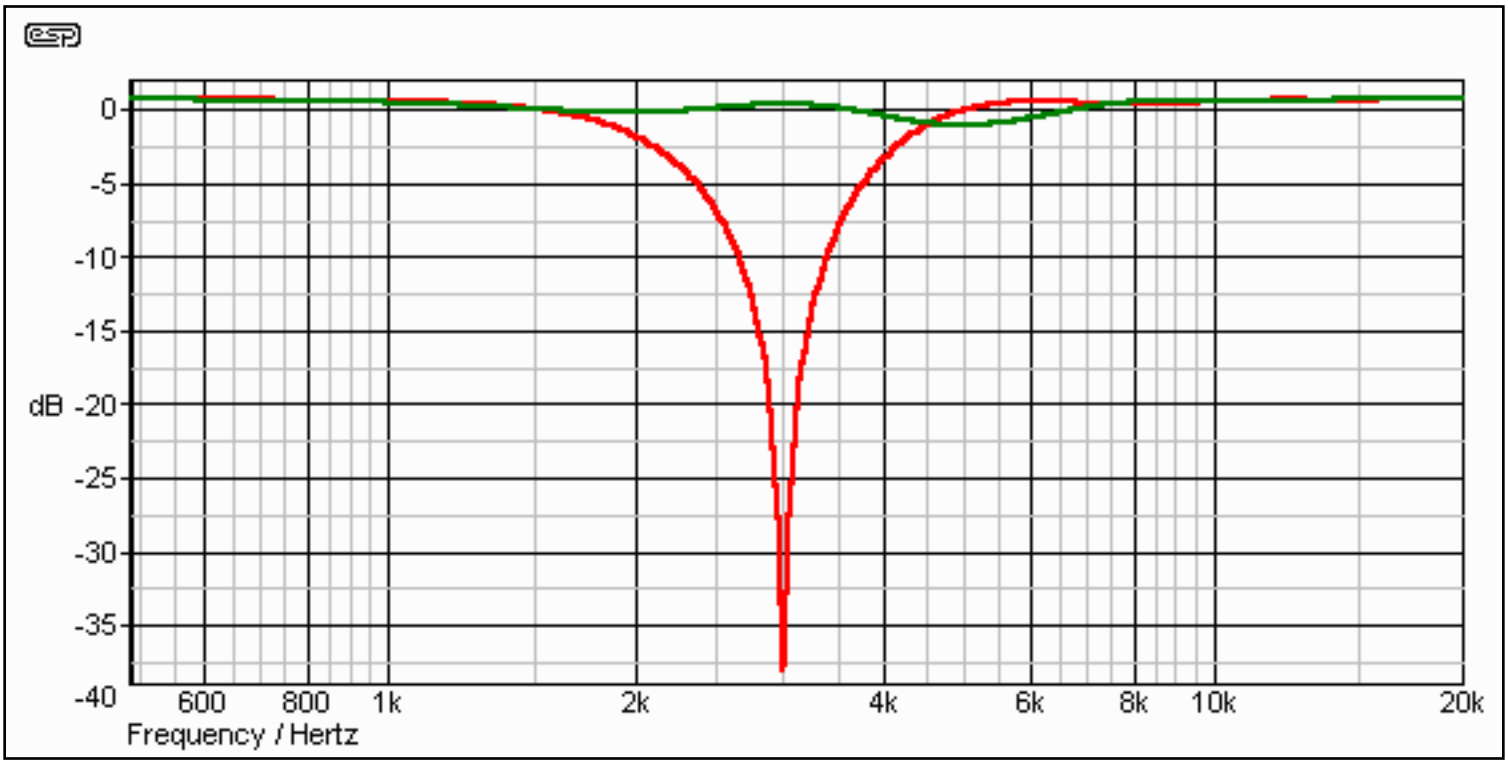

Figure 2.1 - Frequency Response With 57mm Acoustic Centre Offset

The red graph shows the response without phase reversal of the driver, and it is very obvious that there is a significant response dip at the crossover frequency. This was done using electrical summing, which is much more severe than acoustic summing, however the "suck-out" would be very audible indeed.

The green graph is the response with the tweeter reversed in phase, and it looks better than it really is because of the graph scale. However, the response ripple is still within (barely) acceptable limits, at -1.7dB at 4.9kHz. Again, this is with electrical summing - the acoustic response will be somewhat better than shown.

Next, we see the response of the same system, but with a 100us delay. With the tweeter wired out of phase, the response dip is 2.8dB, and when wired in phase it is 5.8dB - the anti-phase connection is better, but neither is acceptable.

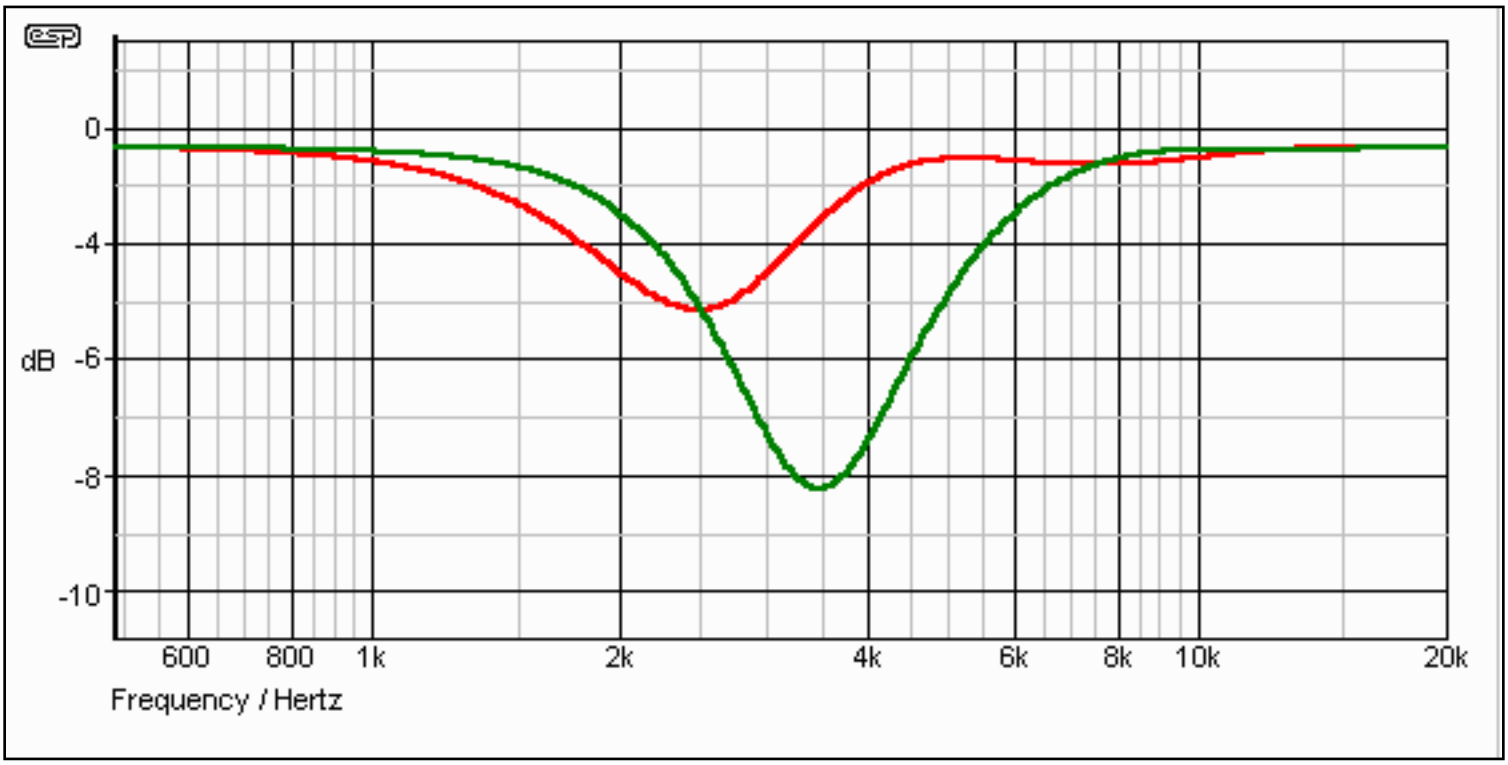

Figure 2.2 - Frequency Response With 35mm Acoustic Centre Offset

As you can see, both graphs show a distinct dip in response (the red graph is the out of phase connection). Acoustic summing will give a result that is slightly better than what you see here, but it will still be audible. The optimum fix is a digital delay that will hold the tweeter signal back by 100us, but this is an expensive option. The next diagram (Figure 3) shows the response using an all-pass filter (phase shift network) that has been optimised to get the best response possible from the combination of drivers and

time delay.

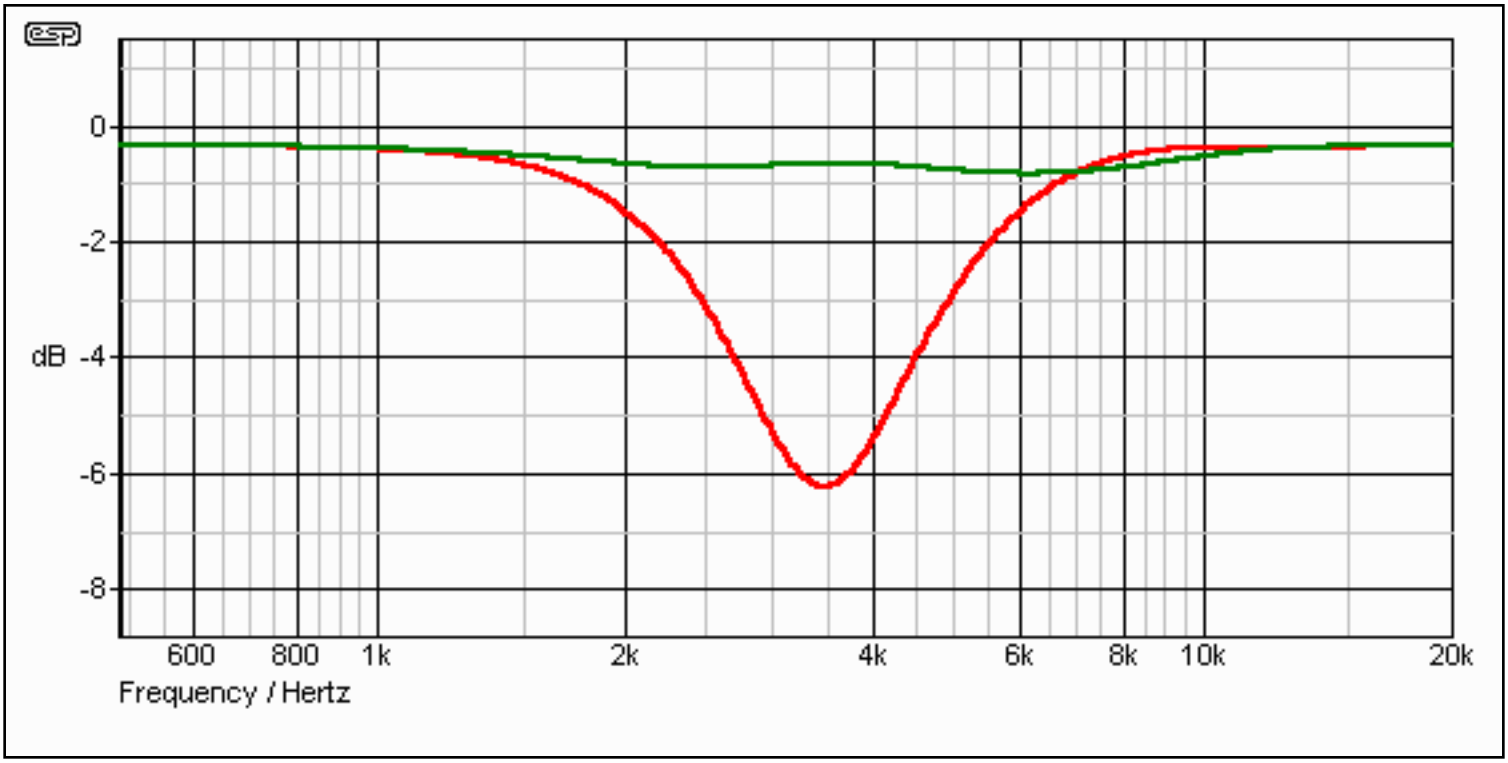

Figure 2.3 - Frequency Response With Phase Compensation

The maximum deviation of the phase corrected version (shown in green) is now 0.51dB, at 6kHz. It is actually possible to improve on this slightly, but in practice this requires accurate measuring equipment. Attempting to perform an adjustment of this nature without measurements will simply lead to confusion and great bafflement, since you have no flat reference for comparison. The setting that sounds the best (to you) may be the result of personal preference or acclimatisation to the sound, and it is very possible that it will not be correct.

In addition to the phase adjustment, it is important that polarity inversion is available. Although the above example uses normal polarity for best results, this will not always be the case. If the polarity is incorrect, no amount of phase adjustment will ever make the situation better, but it can easily make it a lot worse. For example, the response shown in Figure 2.3 is totally changed (and very much for the worse) if the phase is inverted.

2.2 - Phase Shift Networks

The standard and traditional all pass filter (phase shift network) is shown in Figure 3.1 - note that there are two variants, and their behaviour is completely different when phase aligning a loudspeaker. 3.1.a shows a non-inverting configuration, and 3.1.b is inverting.

This is something of a misnomer, since both circuits will have an output whose phase is frequency dependent, but version 3.1.a leaves low frequencies alone and inverts high frequencies, while 3.1.b inverts low frequencies. At the mid frequency of the network, the phase is rotated by 90°, but note that this is not necessarily aligned with the crossover frequency.

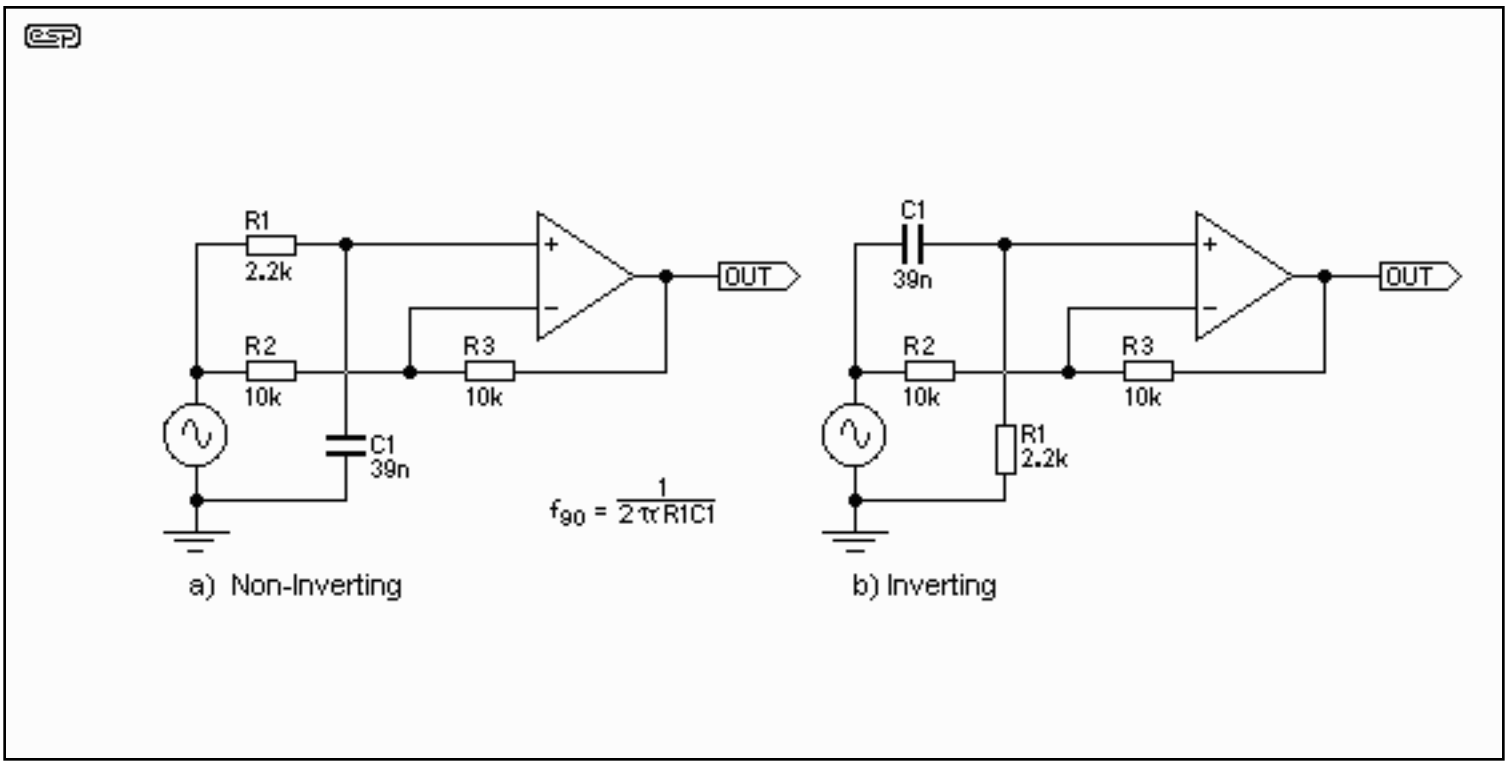

Figure 2.4 - Inverting and Non-Inverting Phase Shift Networks

The networks themselves are virtually identical, with only the position of the resistor and capacitor (R1 and C1) changed. This effectively reverses the frequency at which there is no phase shift - in this case we would arbitrarily select around 10Hz as the 'reference' frequency. At such a low frequency, the capacitor has virtually no effect with either network, and the circuits can be considered to be (almost) conventional inverting and non-inverting opamp circuits.

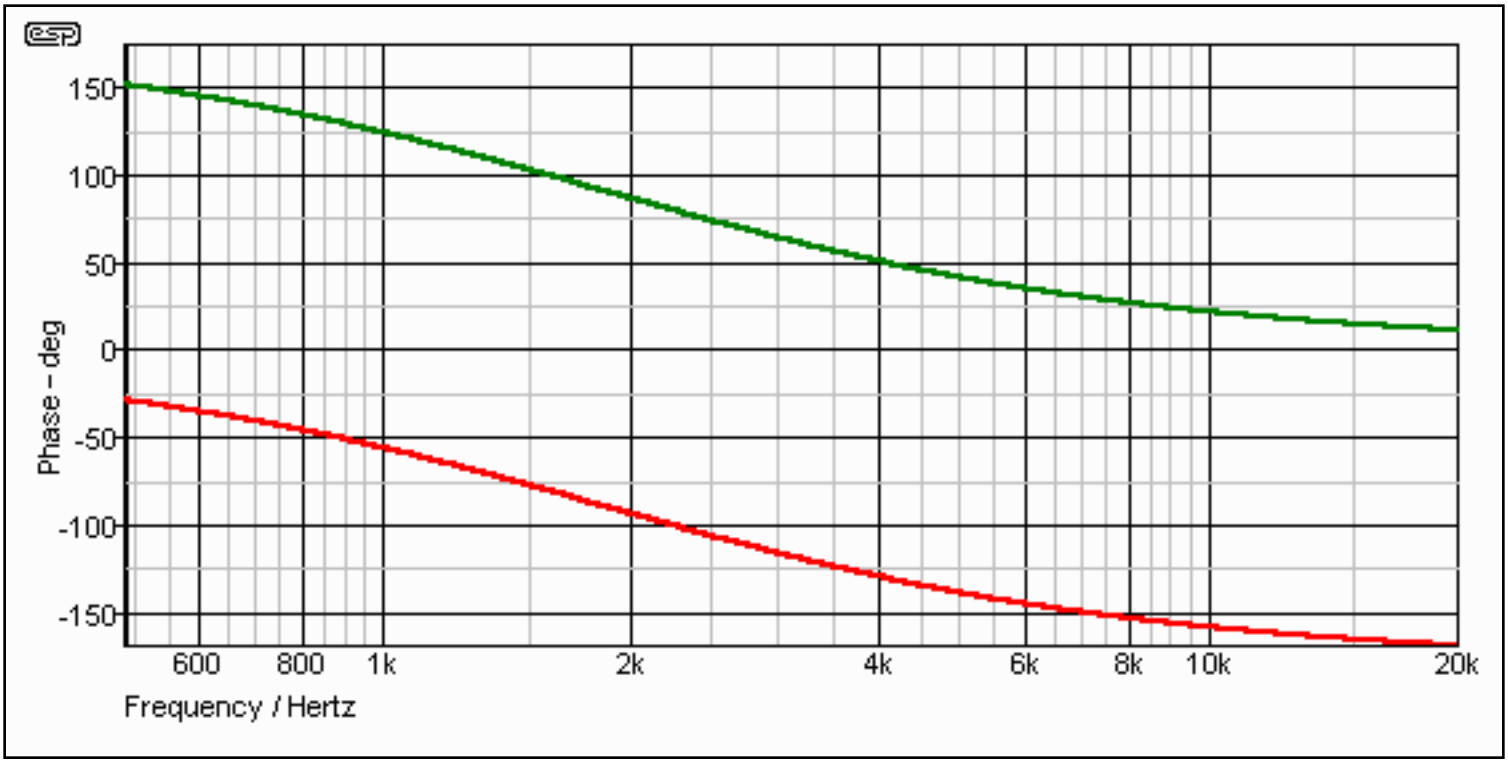

Figure 2.5 - Inverting and Non-Inverting Phase Shift Response

The networks as shown are exactly the same as those used for the alignments shown above. The centre frequency for optimum alignment is not 3kHz as one might expect, but for the example shown is 1,856Hz. Phase shift at 3kHz is 116° or 64°, depending on the phase polarity selected. 116° is the phase shift that gave the best result.

2.3 - Results Verification

If everything has worked as intended, we should get a good correlation between the applied phase shift, time delay and wavelength. Since we know that the time delay used was 100us and frequency was 3.0kHz, we can calculate the effective wavelength that corresponds to the phase shift ...

Wavelength	115mm
Time Delay	100us
Distance Offset	35mm
Phase Shift	116°
Effective distance compensation	(115mm / 360°) * 116° = 37mm

Well, that seems to be very close indeed. Since the non-inverting phase shift network

was used, it has 116° of shift at 3kHz (after careful adjustment), hence the calculation above for the "effective distance compensation". Now, looking at the graphs, it is obvious that they are not perfect, but the end result is a lot better than one could expect without any compensation at all.

Sidenote
There is a relatively simple way to introduce a time delay at any frequency. Coaxial cable has a velocity factor of around 0.7 (typical) - that means that the signal travels at 0.7 of the velocity in a vacuum. Unfortunately, 100us is rather a long time, so given that normal speed of a signal is 3×10^8m/s, for a velocity factor of 0.7 (for example), we would need $3 \times 10^8 * 0.7 = 210$Mm (Mega-metres!) for a one second delay.

Therefore, 210 metres will give a delay of 1us, so you would need 21km of coax to obtain the required delay of 100us. For what that would cost, one could purchase any number of digital delays. In case you were wondering, the idea is not completely silly. High-end oscilloscope manufacturers used to include a coax delay line to delay the signal for the few nano-seconds that it would take for the trigger circuits to operate, so that one saw the waveform without a 'glitch' at the beginning of the trace. This typically only required a few metres of cable (perhaps 10 metres at the most).

Lest one think that knowledge of such technology is restricted to old buggers like me, a web search will reveal that there are still a great many manufacturers of coax delay lines, and they are far from dead. They just happen to be useless for this application.

3.0 - Conclusion

While this discussion has dealt only with 24dB/octave Linkwitz-Riley alignment crossovers, the principles are recommended by many to be applied with other orders as well. First order (6dB/octave) crossovers are likely to benefit the least, because the time delay created by a phase shift is too narrow, and is completely incapable of creating an offset that is broad enough to be useful. This is illustrated below, where the same time delay (100us) was used, and modification of the phase shift network was only able to achieve the response shown.

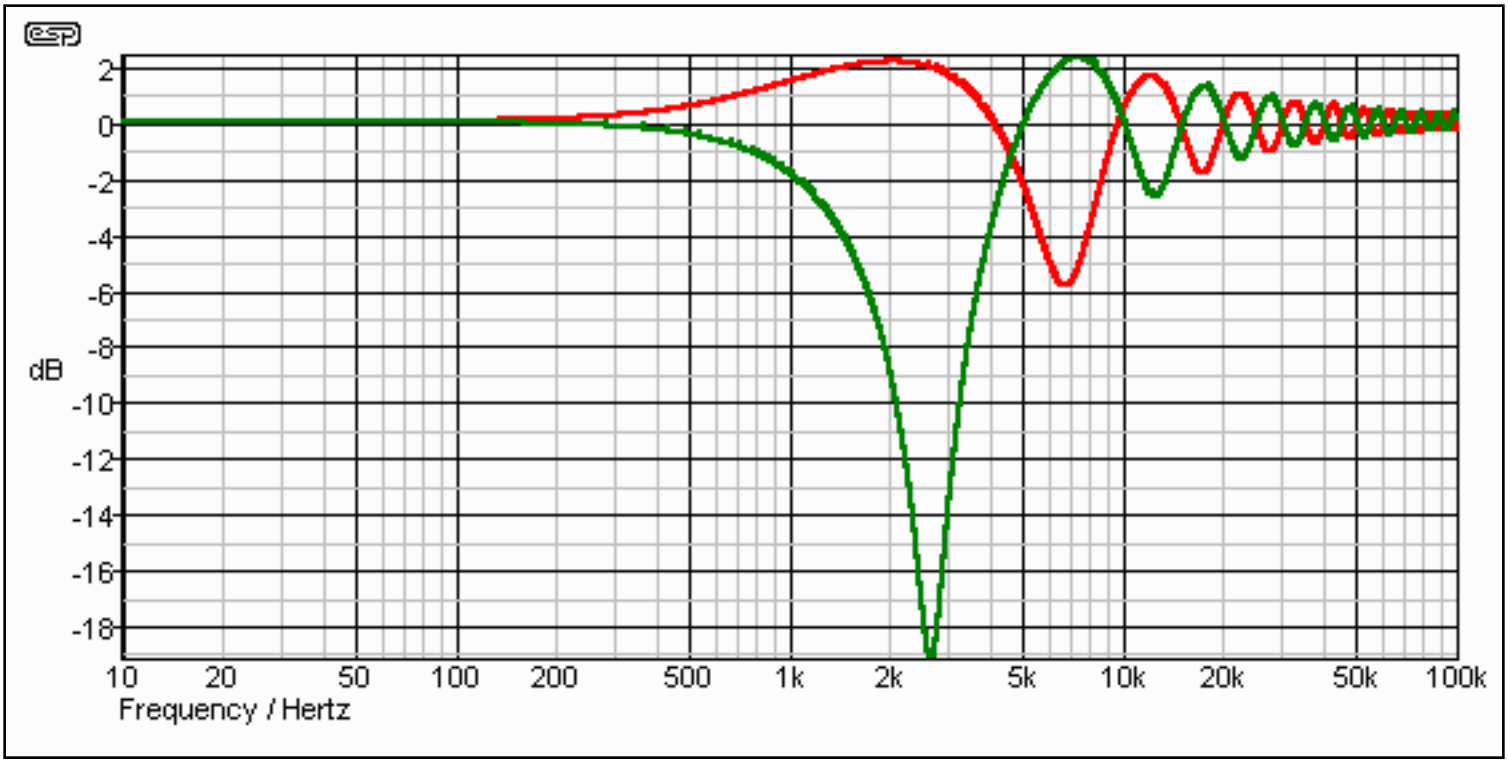

Figure 3.1 - Applying Phase Correction to a 1st Order Crossover

Note that the uncorrected response is a lot worse than the corrected response, but even there, the ripple is over 7dB in peak variation. The *best* one could say for the response is that it is appalling, both before and after 'correction'. There are terms that describe it far more accurately, but they will not be used here

It is fairly obvious that since the range over which an all pass filter can be used is quite narrow, it becomes more effective as higher order filters are used. While it has been shown that the effects are reasonably good with 24dB/octave crossovers and useless with 6dB/octave, it follows that 12dB and 18dB crossovers will fall in the middle, with 12dB types being considerably worse than 18dB networks.

It is worth noting that a phase reversal of the all pass filter changes very little. The first major peak is converted into a dip, but the overall ripple remains the same, at 7dB. As always, these tests were done with summed electrical signals, so the acoustic effects will not be as severe ... but! They will still be there, and *will* be audible.

The next chart shows the response of a corrected and uncorrected 12dB/octave filter. This filter is the same frequency as before (3kHz), has the same 100us delay, and is a Linkwitz-Riley aligned type. A phase inversion is mandatory for 2nd order filters and there is no point showing the result without it. (Hint - a 10dB dip at 3kHz is not a pretty sight.)

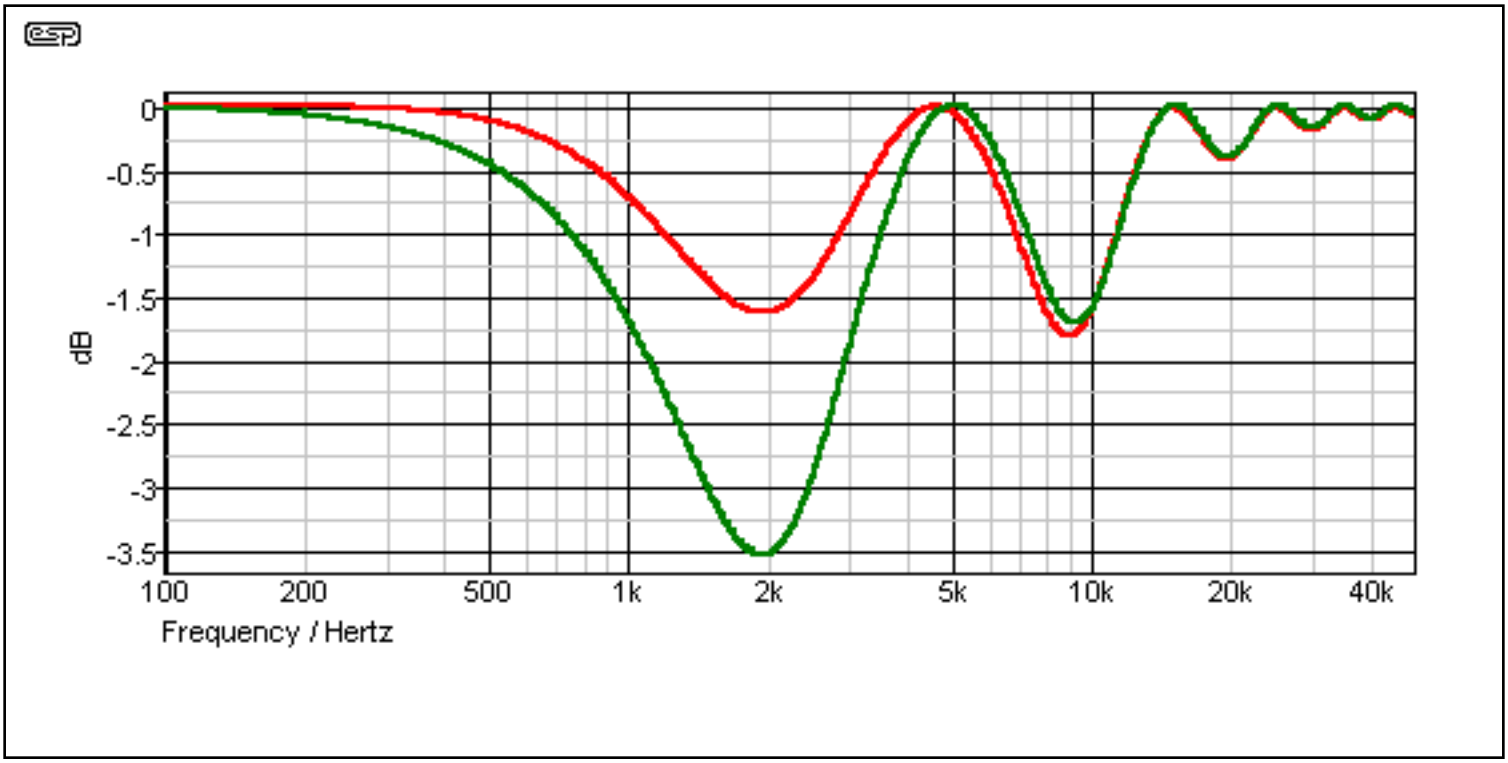

Figure 3.2 - Applying Phase Correction to a 2nd Order Crossover

The result is not completely dreadful, but it is certainly 'sub-optimal' (a kinder and gentler way of saying what I really think). Again, electrical summing is the worst case and the acoustic response will not be quite as bad. A phase shift network will probably rescue an otherwise unusable design in this case.

So, is an all pass filter a panacea for misalignment problems? Quite obviously not, since even at 24dB/octave the ripple is quite visible, and will be quite audible as well to anyone who knows what to listen for. However, it is still a lot better (at least in the amplitude domain) than nothing at all. Stepped baffles used to time align the drivers may look quite high-tech, but the step creates what I refer to as a 'diffraction engine' - a set of internal and external angles that will create interference patterns and response anomalies that are difficult to predict, but will certainly not improve matters.

What of sloping baffles? While there are no untoward diffraction effects (other than those found in any relatively conventional enclosure design), one is forced to listen to both drivers off-axis at all times. While the deviations may be small compared to on-axis response, they are nonetheless audible, especially where the midbass is working at the limits of its frequency range. For those who claim that all baffles with more than one driver should (*must*) be sloping to get time alignment, consider the difference in path length from the top and bottom of the midbass to the listener, and then compare that to wavelengths. Exactly the same effects are at work as with separate drivers, and this is the main reason that off-axis response of large diameter drivers is so poor.

One parameter that is potentially very important is group delay. The uncorrected 6dB filter shows a group delay that peaks at 0.8ms (800us), so in one respect we can be thankful for the fact that there will be a deep notch at that frequency, so the (very) delayed signal will not be audible. The concept of group delay is best explained by a fairly common description on the Net. If the treble were to be reproduced 5 minutes (or even 5 seconds) after the bass and mid, this would be noticed by even the most non-critical listener. Fortunately, this is not common even with the cheapest of speaker systems, but it illustrates the point. In reality, group delay (the delay introduced to any frequency relative to any other frequency), is normally very low, but can still be audible, and the audibility is frequency dependent. In the case of the midbass to tweeter crossover, a delay of 100us would be fairly typical, and is less than 1 cycle of the signal at typical crossover frequencies (a 'periodic time' of 100us represents a frequency of 10kHz). Although this delay in and of itself is inaudible, the phase cancellation effects are very audible indeed.

This is not going to be covered further here, not only because it will confuse the issue and make the processes described seem more complex, but also because I do not have enough data on the audibility of group delay to make an informed comment. This will change, and a follow-up can be expected to explain this further.

For those who might wish to get a little background into group delay, see the discussion at TrueAudio.

Please note that the process described here had an error (corrected 12 Jan 2006), and the values for Qms (and therefore Qts) values were wrong in the example. The error has been corrected, and the figures should now be as accurate as it is possible to get them. I apologise for any inconvenience this may cause (or may have caused).

The problem was not with the method as described, but in the accuracy (or lack thereof) of the measurements taken from the speaker model used (I could blame the simulator I used at the time, but that would be a cop-out - even though it is partially true).

The spreadsheet has also been changed (enhanced), and it is recommended that the latest version be downloaded to get accurate results. Interestingly, of four different methods I have been able to locate thus far, they all give (slightly) different results, however, measurement accuracy is the biggest issue facing your endeavours.

Measuring Thiele / Small Loudspeaker Parameters

There are several different ways to measure the Thiele/Small parameters of a loudspeaker driver. The method described here provides a way for the beginner and DIY enthusiast to measure the parameters without any expensive or specialised equipment.

Definitions:

Re	Electrical resistance of voice coil
Fs	Resonant frequency of loudspeaker moving mass (in free air)
Qes	Electrical Q of loudspeaker
Qms	Mechanical Q of loudspeaker
Qts	Total Q of loudspeaker
Vas	Equivalent air volume of moving mass suspension

Measuring Re, Fs, Qes, Qms and Qts

To measure these parameters using the method outlined below, you'll need to have the following items:

- A power amplifier, rated at 1-10 Watts (RMS) or thereabouts
- Audio frequency oscillator (PC based is fine)
- Digital multimeter (with frequency measurement), or PC based instrument
- An accurate test resistor (any value, although I suggest 10 ohms) A ½W component will be quite sufficient.

- Alligator clip leads - you will need 4 sets of leads (leads may be soldered instead if desired)

Figure 1 shows a typical impedance curve for a loudspeaker (see Figure 5 for the equivalent circuit of this speaker, which was simulated for this article). Resonance causes a large increase in impedance, and at some higher frequency, the inductance (or semi-inductance) of the voice coil causes the impedance to rise again. The region for the initial measurements must be within the "linear" region of the impedance curve. In the example below, resonance is at 27Hz, and the linear region ranges from about 100Hz to 400Hz.

At resonance, the speaker impedance is pure resistance. As the frequency increases towards resonance, the impedance characteristic is inductive. Beyond resonance as impedance falls, the impedance characteristic is capacitive. Within the 'linear' region, the impedance is again (almost) resistive, but at slightly below the speaker's nominal impedance (nominal impedance is usually taken as an average value over the usable frequency range). At the frequency where the inductance of the voice coil becomes significant, impedance rises, and is progressively more inductive as the frequency rises. It is common to add a compensation network to maintain an overall resistive characteristic at these higher frequencies, so that the performance of the (passive) crossover network is not compromised. This is not necessary with an active crossover.

Although a 'pure' inductance is shown in the equivalent circuit, this component is often referred to as 'semi-inductance'. Because of losses (primarily eddy current losses within the pole pieces), the impedance typically rises at around 3-4dB/ octave, rather than the expected (and simulated) 6dB/ octave. This has little or no effect on resonance parameters, and can usually be ignored for these measurements.

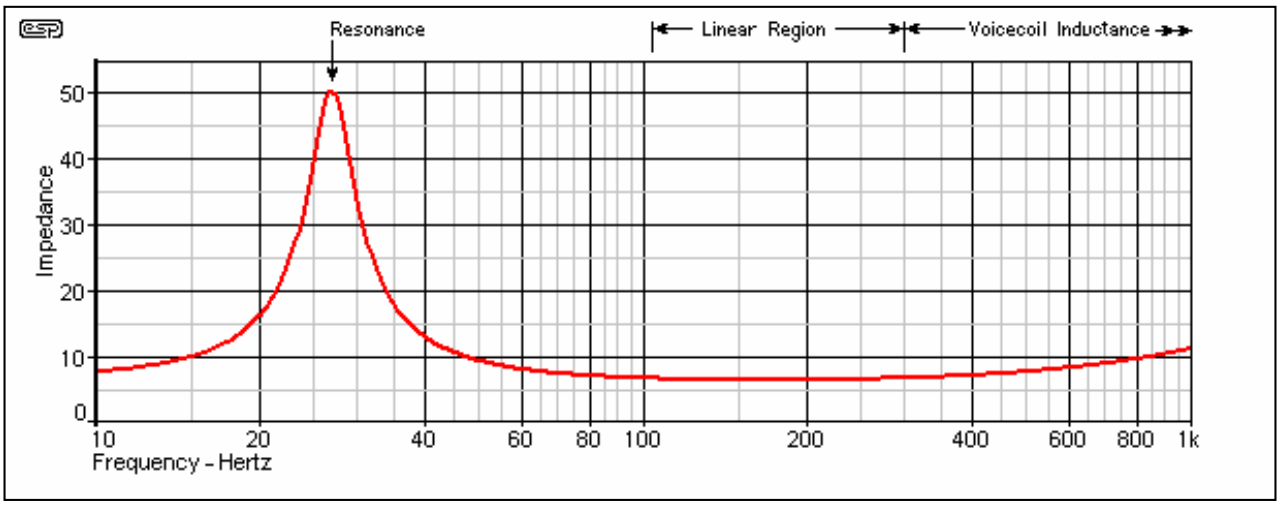

Figure 1 - Loudspeaker Impedance Curve

The multimeter should be capable of measuring frequency, as well as AC voltage and resistance. If it cannot, a frequency counter is highly recommended, since the frequency measurements are critical. The amplifier must be capable of reproducing from 10 Hz to 2 kHz with no variation in output voltage. It is imperative that it is insensitive to any load above 4 ohms. The audio oscillator must also produce a signal with relatively low distortion, and the output voltage must not vary as the frequency is adjusted. If a PC signal generator is used, it will usually display the frequency fairly accurately, but you still need to verify that output level is constant with frequency. Many PC instruments are incapable of fractional frequencies, which may limit the accuracy of the final result.

The need for accuracy cannot be stressed too highly if accurate parameters are expected. It should also be understood that there are many variables and many opportunities for things to go awry - during measurement, construction and normal operation. Loudspeakers are variable beasties at best, and 'perfect' results will never be obtained in practice. The room will usually cause more and greater errors than a small measurement error here.

Measure the resistance across the speaker terminals to obtain *Re*

Measure the exact resistance of the 10 ohm source resistor, *Rs*

The loudspeaker driver should be suspended in free space, with no obstructions or interfering surfaces nearby. Any boundary closer than around 600mm (about 2ft) will affect the accuracy of the measurements

Connect the circuit as shown in Figure 2, and set the oscillator to approximately 100 to 200 Hz (or around 2-3 octaves above resonance) - it must be within the 'linear' range as shown on the graph above.

Set the output of the amplifier to between 0.5V and 1.0V (this is *Vs*). Check that the speaker is nowhere near resonance, by changing the oscillator frequency by 50Hz or so in either direction, and measure the voltage across the resistor. It should not change by any appreciable amount.

You may need to try different voltages, depending on the accuracy of your readings (or calculations). Do not be tempted to use a voltage any higher than around 1V RMS , as the speaker may be driven outside its linear range, which ruins the validity of the measurements. The parameters being measured are 'small signal', and it essential that a small signal is actually used. With an 8 Ohm driver, 10 Ohm resistor and 1V signal, you will typically have a nominal current of around 55mA.

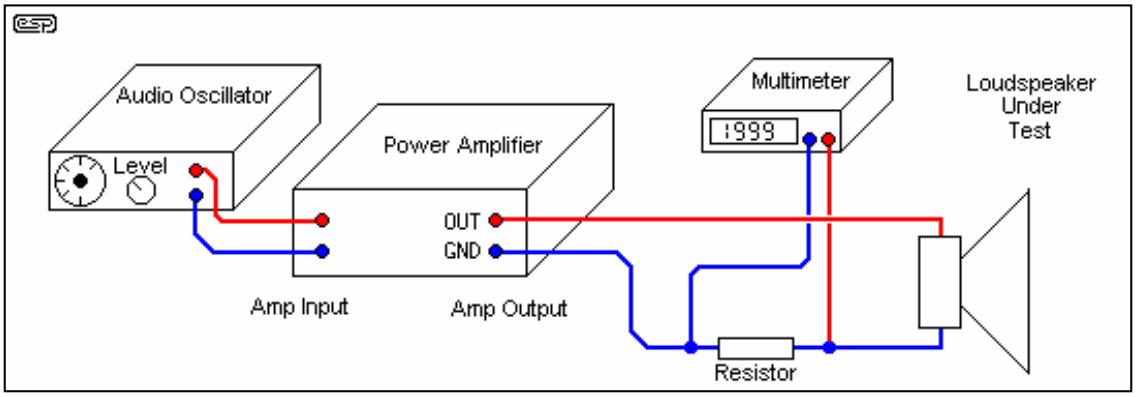

Figure 2 - Measuring Speaker Parameters

The traditional way to measure Q is to measure the bandwidth between the -3dB frequencies, then divide the resonant frequency by the bandwidth. For example, if resonance is at 29.6Hz and -3dB frequencies are at 25Hz and 35Hz, then Q is 2.96. This would be Qms in the calculations. This method may be suitable for low-Q drivers, but you can easily make a tiny error (causing a large final calculation error) with high-Q drivers.

Most of the methods described elsewhere rely on a more complex formula that uses -6dB or even -9dB as the reference point to determine Q. This makes the measurement accuracy slightly less critical. The method below describes the -6dB method, which gives a reasonable compromise between ease of measurement and accuracy.

First, measure the resonant frequency. Adjust the frequency until the voltage across the resistor reaches a null (minimum level). Without changing anything, carefully measure the frequency and voltage across the resistor ...

Frequency	*Fs*
Voltage across the resistor	*Vm*

Calculate the following ...

Speaker current	*Im = Vm / Rs*
Resonance impedance	*Rm = (Vs - Vm) / Im*
r0 (reference value)	*r0 = Is / Im*

-6dB current	*Ir = √(Im * Is)*
-6dB voltage	*Vr = Ir * Rs*

Complete the measurements for *Fl* and *Fh*, for which the voltage across the source resistor is equal to *Vr*, and as a sanity check (to ensure that your calculations and measurements are accurate), calculate the resonant frequency based on these last two measurements. Note that these measurements are critical, and even a small error will cause large deviations in the driver parameters.

Check that ...	*√(Fl * Fh) = Fs*

If the above checks out (within 1Hz or less), then *Qes, Qms* and *Qts* can be calculated as follows ...

Mechanical Q	*Qms = Fs * √r0 / (Fh - Fl)*
Electrical Q	*Qes = (Qms / (r0 - 1)) * (Re / (Rs + Re))*
Total Q	*Qts = Qms * Qes / (Qms + Qes)*

You can use the spreadsheet to perform the calculations automatically for you: **ls-param.zip**

Measuring Vas (equivalent air compliance)

To measure Vas, use a good solid enclosure of known volume that is approximately a cube of the nominal speaker size. For example, a 300mm driver (12") needs a box of about 28 litres (1 cu ft). For reference, a cubic foot is 28.3168 litres, and one litre is contained by a cube of 100mm (10cm) to each side.

HINT: If you make all measurements in centimetres, the result will be in millilitres (cubic centimetres, or cc). This makes it very easy to convert to litres ... simply divide by 1,000. If you work in millimetres (mm), the result is less intuitive, although you can still get to litres by dividing by 1,000,000. (For those who insist on using outmoded measurement systems, I can provide a spreadsheet that uses cubits as the base linear measurement, and firkins for volume. I will part with this upon receipt of a kilderkin of Australian $1 notes or its equivalent <grin>).

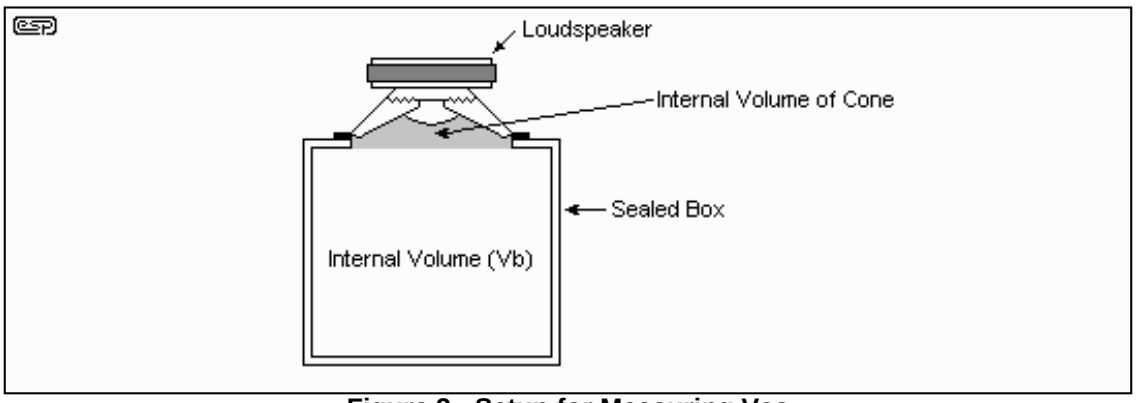

Figure 3 - Setup for Measuring Vas

Determine the total volume, including the speaker cut-out and that trapped by the cone with the speaker mounted on the outside of the box for easy access. Measure the resonant frequency in this situation, and use the free air space resonant frequency determined as shown above. Determining the volume trapped by the speaker cone is slightly tricky.

Use one of the following methods ...

1. Place the driver in a plastic bag, ensuring it is completely sealed. The bag should be loose enough so that it can be pushed easily into the cone area. Place the wrapped speaker on a flat surface, with the cone facing upwards. The cone may now safely be filled with grain (such as rice, wheat, etc), and the grain carefully poured out into a measuring jug. The resulting measurement will be a little greater than the actual volume because the cone will be depressed by the mass of the grain. The area of the speaker cutout in the cabinet must still be added. Don't omit the plastic bag, as fine dust may penetrate the speaker without it.

2. Take a series of measurements. The internal cone area is measured, then divided into sections whose volume may be calculated. For most speakers we will have two basic shapes to deal with, and although this method is not 100% accurate, it will probably give the best result in the majority of cases.

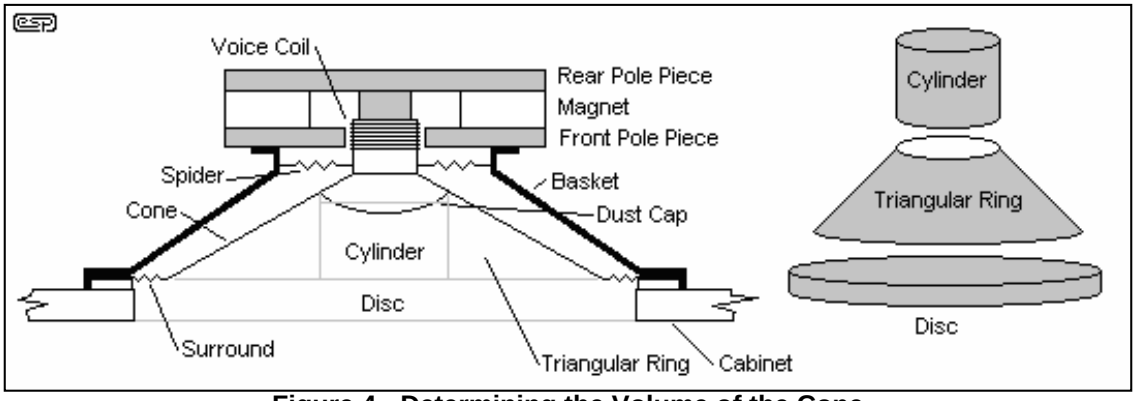

Figure 4 - Determining the Volume of the Cone

There is a flat cylinder (disc) that is formed by the outer area of the basket and the cutout in the enclosure. The triangular ring is formed by the cone itself, as shown above. Finally, the cylinder occupies the area over the dustcap. The depth of the cylinder should be an approximate average of the distance from the mounting surface and the dustcap.

The volume of cylinder and disc is given by the conventional formula ...

$V_{cyl} = \pi * r^2 * h$ (where *r* is the radius and *h* is height), and ...

$V_{disc} = \pi * r^2 * h$

The triangular ring's volume is given by ...

$V_{ring} = ((\pi * r^2 * h) / 3) - V_{cyl}$

The total speaker volume is simply the sum of the 3 volumes calculated above. Box volume is calculated as one normally would, taking great care to ensure that the measurements are accurate. The box may be braced, but must have no fibreglass or other sound deadening material inside. Make sure that the volume occupied by any bracing is accounted for in your calculations. Even a simple box will be sufficiently rigid at the frequencies of interest, so a completely acoustically dead cabinet is not required (although it won't hurt). Do **not** use any speaker cabinet filling material for this test.

$Vas = Vb((Fb / Fs)^2 - 1)$

where *Vb* is the volume trapped by the speaker and box, and *Fb* is the resonance frequency of speaker and box combined. *Fs* is the free air resonance measured previously.

An Example Calculation

A dummy test loudspeaker was used to demonstrate the process, and I have used a simulation of this speaker in the calculations shown. The equivalent circuit is shown in Figure 5. This circuit was also used to create the impedance graph shown in Figure 1.

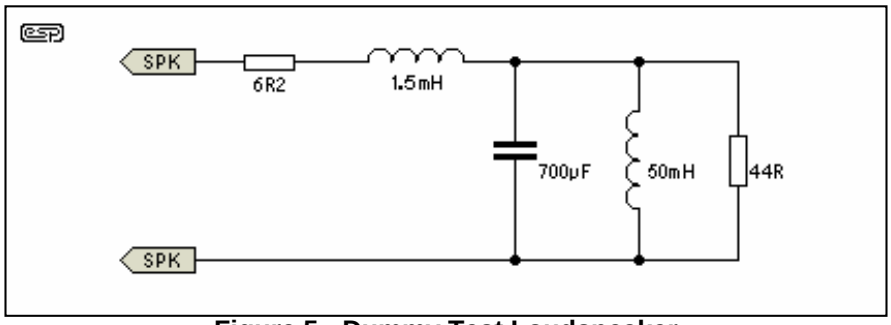

Figure 5 - Dummy Test Loudspeaker

The following screen shot shows the values for the speaker, and the only contrived (i.e. invented) value is for the resonance in the sealed box. It was necessary to invent a number here, as it is not possible to simulate it. The final figure shown is fairly typical of many such drivers, so is not too far from the truth either.

1.0 Introduction

In recent years the satellite sub woofer type of loudspeaker system has become popular, this largely due to the advent of surround sound home theatre. For this and also for music the sat+sub system has many things to recommend it, the use of one subwoofer is made possible because the range bellow 100Hz is, as indicated by most testing, non directional, thus allowing the subwoofer to be put in the best place for bass, and allowing the various other smaller speakers to be arranged in a way most suited to imaging and

surround effect. Another benefit is that the higher cut off frequency of the satellites potentially keeps the non linear distortion caused by large low bass cone excursions at a low level.

The low cost and compact size is however bought at a cost, this is that the sound pressure generated by such a system is limited by the use of a small driver down to a typical 80Hz crossover frequency. This is exacerbated by the current fashion to denigrate the reflex enclosure, with people advised to block up those despised ports, and be transported to the sunlit uplands of sonic bliss thereby.

It is generally true that the transient response of vented enclosures is not as good as that from a (properly designed) sealed box, but we live in a world of compromise. There is little point having a system with perfect transient response if the distortion at realistic listening levels is intolerable. It is also pointless to try to convince someone who has a small listening area that they need large 3-way systems - especially if there is no physical room for such enclosures. So, in this area of compromise, there has to be a solution that will provide a reasonable SPL with minimal excursion created distortion.

While sealed enclosures certainly have their place in the scheme of things, any attempt to use them in a 'full range' 2-way system will almost certainly cause excessive distortion at even a moderate SPL, whereas a solution is available that lowers distortion, raises the SPL limit and if carefully done will give very good performance.

Interestingly, any information about the alignment discussed in this article is very scarce on the Net, to the extent that it is almost non-existent. While the author has recommended the method described for some time (mainly in forum sites), it is an alignment that the editor has also contemplated, but (until now) did not have the information to perform a theoretical design - any attempts had to be empirical. That this is time consuming in the extreme is obvious, and it is probable that the Quasi-Butterworth, 5th order (QB5) alignment will see an increase in popularity in the future.

What follows is a discussion of the issues and methods for dealing with the most vexing problems, but first some discussion about the linear excursion limit is in order.

2.0 Description

Over part of its cone excursion the loudspeaker driver is to a good approximation a linear transducer, if its B*L (magnetic field strength * conductor length) product is constant, then the force generated by the voice coil is linearly proportional to the current

in the voice coil, i.e. ...

$$F = (B * L) * I$$

Olsen, in his 1962 paper [1], identified two non linear elements that produce harmonic distortion as a function of cone displacement. Typically as the voice coil moves out of the magnetic gap, the B*L product is no longer constant but starts to fall as the excursion increases, this can be described mathematically as ...

$$F(x) = a * x + bx^2 \text{ and } F(x) = a * x + bx^3$$

Where, **F(x)** is an expression relevant for force when B*L is falling, **a** & **b** are constants relevant to a particular driver, and **x** is the displacement. The first of these expressions is relevant for the voice coil moving from its rest position asymmetrically, and the second when the motion is symmetrical about the centre position.

When excited by a sine wave the Fourier transform of these yields ...

$$x = A * \cos \omega t + B * \cos 2\omega t \text{ and } x = A * \cos \omega t + B * \cos 3\omega t$$

Where ω represents the angular frequency (equal to $2\pi f$), **x** is the amplitude, ω**t** is the exciting frequency and **A** ,**B** are proportional constants, dependant upon signal level.

The second terms, **B * cos 2**ω**t** and **B * cos 3**ω**t** represent the second and third harmonics respectively.

For small displacements when BL is constant, the second term is vanishingly small, and the distortion produced comes from non linearities in the suspension and surround, and from air trapped in the magnetic gap. The 2nd harmonic component is largely out of our control since its level is largely due to the design and construction of the driver.

The third harmonic is in our control however because it is directly related to the amount of signal we put in. This where the linear excursion comes in....

The peak linear excursion limit is derived, unless it is specified by the manufacturer, by using the rule of thumb that it is the voice coil length, minus the magnetic gap height over two, this is true for the usual overhung voice coil. Gander, [2] measured a wide selection of drivers and came up with the findings that calculating the linear excursion limit in this way is a very reliable indicator of the driver producing 3% third harmonic

distortion, when driven to this limit. In what follows this is taken as the maximum peak distortion that is acceptable.

As an example of what this means in practical terms, let us take a typical good quality satellite mid/woofer, the Vifa P17WJ, and put it in a sealed box.

Nominal impedance [ohm]	8	Air gap height [mm]	6
Voice coil resistance [ohm]	5.8	Voice coil inductance [mH]	0.55
Nominal power [W]	40	Eff. diaphragm Area [cm²]	136
Short term max power [W]	350	Moving mass [g]	14
Long term max power [W]	150	Magnet weight [g]	415
Operating power [W]	6.3	Force factor [Bl]	6.5
Sensitivity [dB]	88	VAS [litres]	34.7
Frequency range [Hz]	37-5000	Qms	1.55
Free air resonance [Hz]	37	Qes	0.45
Voice coil diameter [mm]	32	Qts	0.35
Voice coil height [mm]	14		

P17WJ-00-08 Parameters

In a box of 11.5 litres it will have a Q of 0.707 and an fs around 78Hz by the manufacturers specifications. it has a linear cone excursion of around 4mm peak. Using Small's expression for the acoustic power we can expect in an average room [3]

$$\mathbf{Pa = kp * Vd^2 * f3^4}$$

Where **kp** is the power output constant, it has a value of around 0.8 for a sealed box

Vd is the volume displacement (cone area * peak excursion) and **f3** is the system's lower -3dB frequency. This gives...

$$\mathbf{kp = 0.8 * (0.0136 * 0.004)^2 * 78^4} = 0.088 \text{ Watts}$$

Converting this to decibels we have...

107.5 - 10 * log10 (1 / 0.088)= 96.9dB

This is the peak sound level we can reproduce before exceeding the excursion limit. Taking into account that "normal" program is said to have a 20dB dynamic range then our average level is around 77dB. This falls far short of the standard 90dB with 20dB headroom requirement for a hi fi system. Although it can play a lot louder, this will not be without producing large amounts of harsh sounding non linear distortion - the amount of distortion increases very rapidly beyond our excursion limit.

For instance the 110dB peak output causes a 4mm excursion at 189Hz. At the 78Hz region, the driver needs an excursion of 16mm.

From the above it seems that the position is hopeless, crossing small satellites of this sort over to a single subwoofer causes large amounts of distortion.

There are of course several alternatives, these include three way satellites, stereo subwoofers crossing over at a higher frequency and so on, but all of these lack the basic simplicity and low cost of the two way satellite plus single subwoofer system.

Luckily there is a solution, this is in the form of the QB5 reflex alignment.

I know that immediately I say that word 'reflex', many people will throw their hands up in horror, make the sign of the cross, or other gestures that are best not considered. Swimming against the tide of fashionable anti-reflex sentiment is difficult, but I nevertheless present the following for your consideration ...

2.1 The Basic Principles

Two people named Kreutz and Panzer derived the QB5 reflex alignments, and published their work in 1993, [4] the class II group of these have the characteristic that they optimise power handling by means of reducing the cone excursion needed for a given acoustic power output, and these are the most useful for our purpose.

In essence, what we will do is create a box that is specifically designed to have a peaked response at the low end. This means that the box tuning (rather than the loudspeaker cone) is producing the larger proportion of the LF energy, so less power is needed to achieve a given SPL. In order to prevent the system sounding like a boom-

box, a 2nd order filter (whose Q is also obtained from the table) is placed before the power amp, tuned to the frequency obtained from the charts below. The system as a whole will now have a vastly higher power output at the low frequency end, without the problem of excursion limiting and subsequent distortion. On the down side (and like all things, there are compromises), the box will be larger than a conventionally tuned system, but this would be the case regardless if a larger woofer were to be used to try to maximise the excursion limited SPL.

The details of these derivations are as they say 'beyond the scope of this article', and for those interested the paper cited in the references is available from the AES. Suffice to say however, that the benefits of filter assisted reflex boxes have been known and exploited for many years, but the derivation of these particular alignments was not achieved formally until Panzer came up with a solution to some very difficult mathematics. Luckily for us this gave us three alignment tables, these are reproduced below.

The three tables stem from the value of a parameter used in the solutions of the equation set. In practical terms, Group I is the optimum power handling vs. bass extension for drivers in the Qt range specified. The Group II alignments are for maximum power handling, again within the Qt range covered. Group III are included for completeness, as they represent the edge of usefulness and can be largely ignored.

2.5 Examples and Charts

Plugging our Vifa P17WJ driver into the relevant class **II** alignment, i.e. that for a Qt of 0.35, yields (after calculation) the following ...

Box volume	21.4 litres
f3	61.5Hz
Box tuning frequency	55.5 Hz
Fa (Aux. filter 12dB/Octave high pass)	60.8Hz
Qa	0.622
kp	34.74

Note that in the above the power handling constant **kp** has gone up from 0.8 to an impressive 34.74, the practical effect of this is shown below...

$Pa = 34.74 * (0.0136 * 0.004)^2 * 61.5^4 = 1.47$ Watts
dB SPL = 10 * log10(1.47) + 107.5 = 109.17dB

Our peak output before we reach our excursion limit has gone up by 12.3dB even with a lower f3, if we use the high pass filter from our subwoofer amplifier this should be set at the 61Hz frequency as a minimum, setting it higher results in an even greater increase in power handling.

Two of these speakers in a room can easily meet the 110dB SPL peak level that is the standard for domestic hi fi systems without exceeding the 4mm peak cone excursion limit, this results in a significant reduction in non linear distortion. One must be careful not to exceed the long term power handling of the drivers - since there will be little loudspeaker distortion at even high levels, there will be no warning that the average electrical power is too high, so some common sense is required to prevent voicecoil damage.

Another fully worked example (similar speaker, but different parameters) will help understanding ...

P17WG-00-08 Parameters

The above data were obtained from WinISD, and some parameters are missing, or may be in error. However, this was used for the simulations that follow, and the general idea is the same for any speaker.

Driver	Vifa P17WG-00-08		
Qt	0.40		
fs	35 Hz		
Vas / Vb	0.960	Vb = 49.4 / 0.96	Vb = 51.45 litres
f3 / fs	1.303	f3 = 35 * 1.303	f3 = 45.6 Hz
fb / fs	1.228	fb = 35 * 1.228	fb = 42.98 Hz
1 / Qa	1.576	Qa = 1 / 1.576	Qa = 0.635
fa / fs	1.264	fa = 35 * 1.264	fa = 44.24 Hz

The box in this case is a little over the normal volume for a critically aligned vented enclosure, and will have a response as shown below. The normal reaction to this would be *"Yuck!"* because of the large peak of 2.45dB occurring just before rolloff. This is where the electrical filter comes into play, and this filter should have a frequency of

44.24 Hz (**fa**) and a Q of 0.635 (**Qa**) to match this alignment.

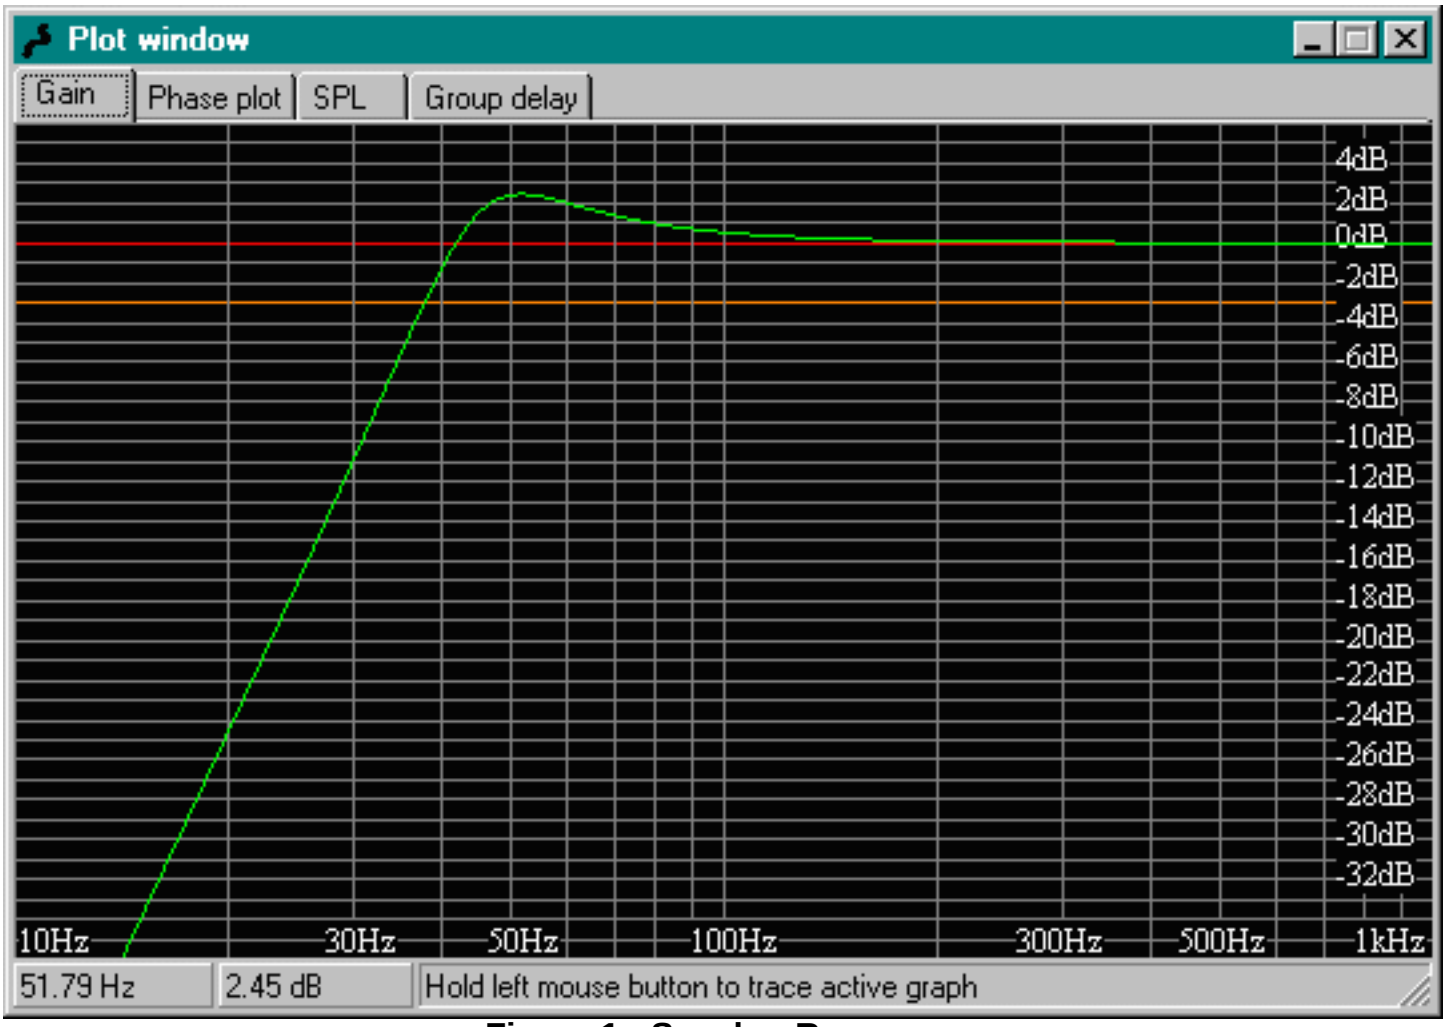

Figure 1 - Speaker Response

The above graph is the output from WinISD, with the box size and tuning frequencies adjusted according to the calculations above. The actual f3 point of the speaker is 37.8Hz, but this will be raised by the electrical filter to the figure of 45.6Hz as obtained from the table. The simplest filter to use for this is the equal component value Sallen-Key, and the schematic for this is shown below. As noted above, the exact Q will not make a great deal of difference - it may look bad, but will be completely overshadowed by room nodes. For the time being, we'll look at the system response with the correct Q, especially since it is quite easy to do.

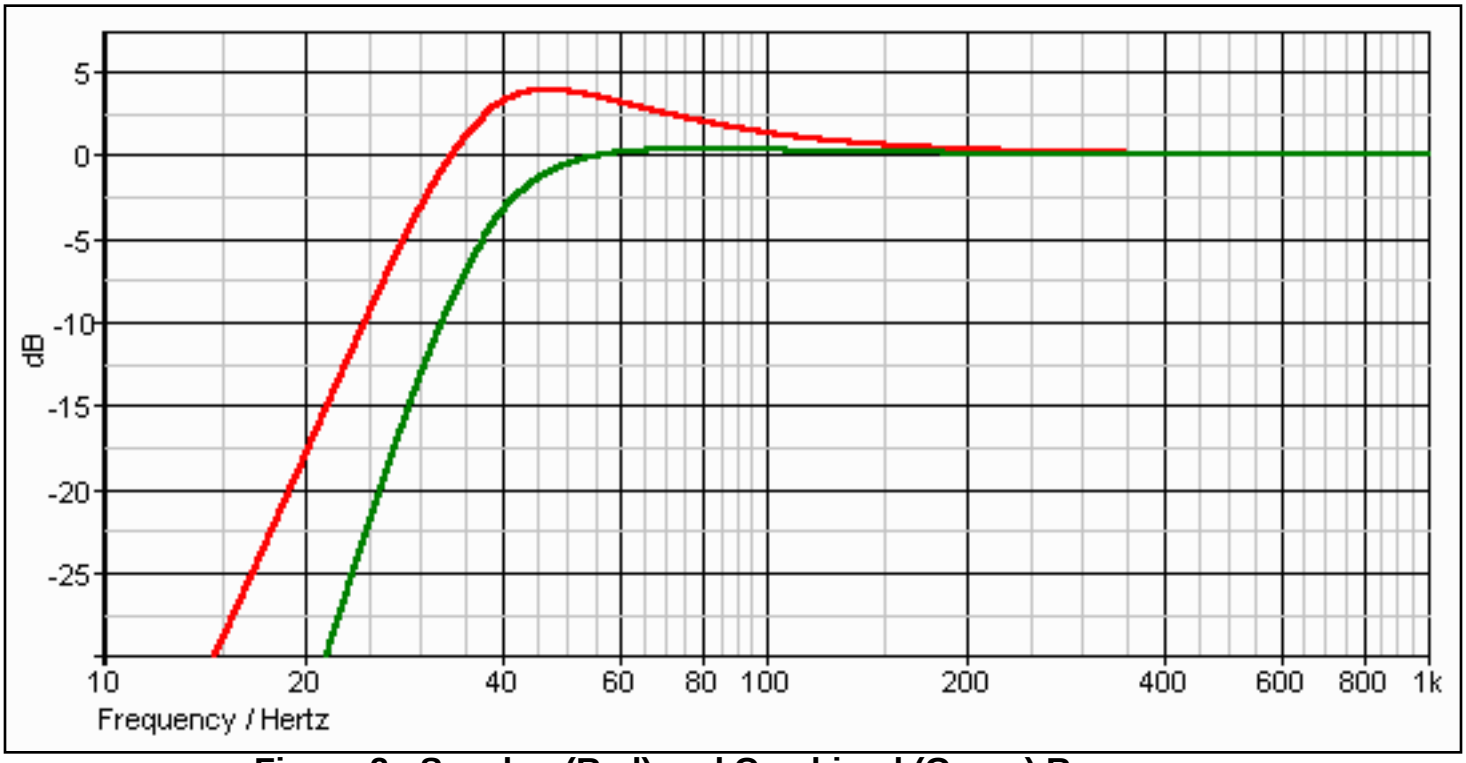

Figure 2 - Speaker (Red) and Combined (Green) Response

I used the Simetrix simulator to produce the above, and although it is not a perfect match for the loudspeaker response in Fig. 1, the result is very close. The red trace is the uncorrected simulated loudspeaker response, while the green trace shows the result after correction with the auxiliary filter. The simplest way to make the auxiliary filter is to use the 'equal component value Sallen-Key' filter topology. This allows independent selection of frequency and Q, but the gain of the circuit will change. The gain obtained from a low Q filter is small, and is unlikely to cause any problems in typical systems.

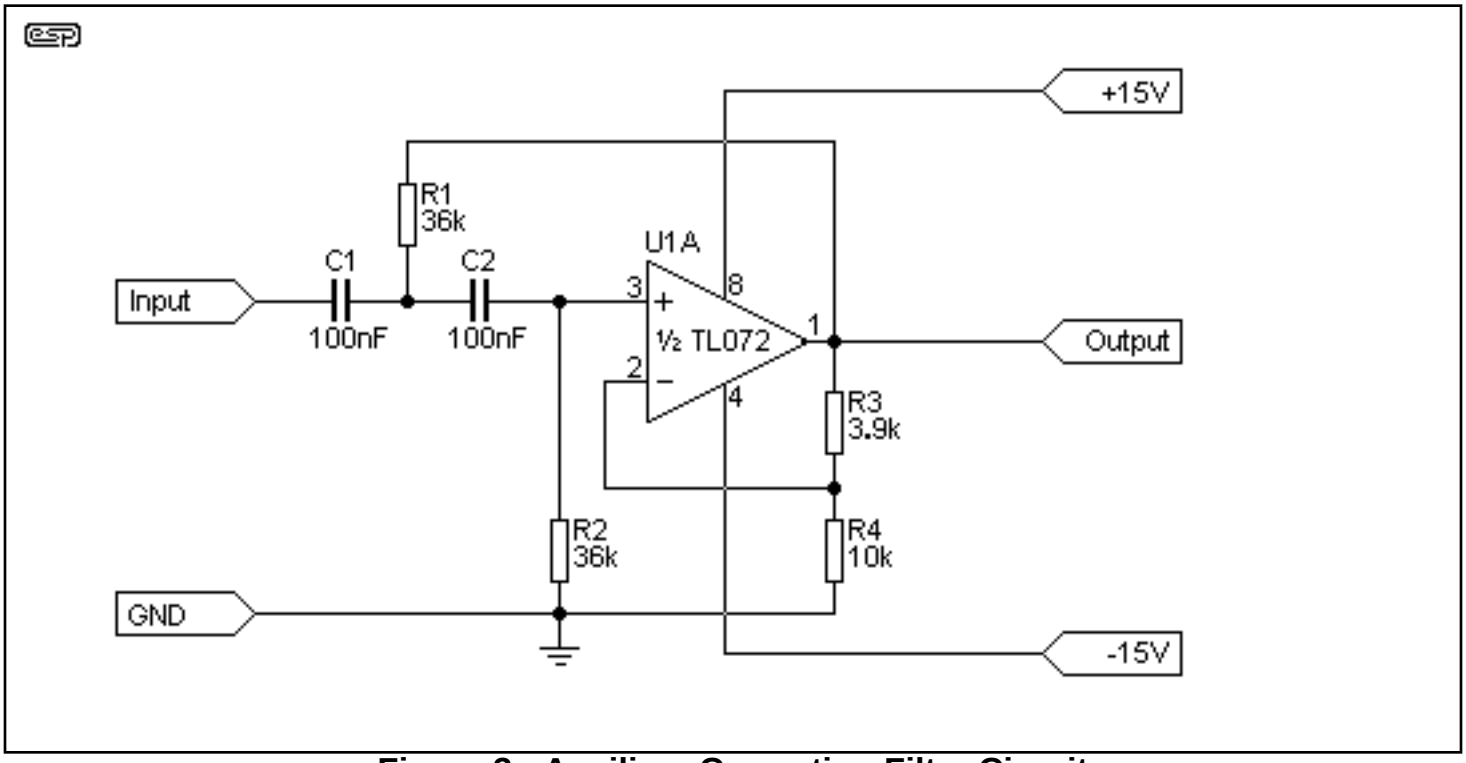

Figure 3 - Auxiliary Correction Filter Circuit

Referring to the schematic above, you can see that R1=R2 and C1=C2. The second half of the opamp would be used for the other channel. Note that this circuit must be fed from a low impedance source (typically less than 1k). The values needed are given by ...

f = 1 / (2 * π * R * C)

This is not affected by the gain setting (which alters the Q), so it is a flexible solution with no bad habits. For the filter response we calculated above, first we shall select a convenient value for C - say 100nF. The value for R is obtained by ...

R = 1 / (2 * π * C * f)= 1 / 2 * π* 100E-9 * 44.24 = 35.98kΩ

It has to be said that the calculated resistance value is not going to be easy to get, but a 50k dual-gang pot will allow you to set the frequency wherever you like. Alternatively, you could use a 33k and a 2.7k in series, or even just 33k with a still insignificant error. Now that the frequency is decided, we need to calculate the Q. This is not even a little bit painful, since the tables actually give the figure for damping (1/Qa), which simplifies things even more.

Q = 1 / (3 - K)or **R3 = (2 - d) * R4**

where **K** is the circuit gain (determined by the ratio of R3:R4), and **d** = 1/Q. For minimum DC offset, the parallel combination of R3 and R4 should equal R1, but this is of no consequence if the power amplifier has a capacitor input as offset will be very low. A value of 10k will be quite acceptable for our purposes. From the table, we determined that d (1/Qa) is 1.576, so substituting ...

R3 = (2 - 1.576) * 10k= 0.424 * 10k = 4.24k

Alas, we have another non-standard value, but a 3.9k resistor in series with 330Ω gives 4.23k which will be quite acceptable. In fact, you could just use the 3.9k resistor, since the error is very small indeed, and will be completely un-noticed in practice. The values calculated and shown on the schematic were used in the simulation, and as is obvious, the error is small.

Using the same formula as before, we can calculate the acoustic power increase over a sealed box. 5mm linear excursion is assumed, from the specifications for the P17WG ...

$Pa = kp * Vd^2 * f3^4$

$Pa = 0.8 * (0.0136 * 0.005)^2 * 62^4$= 34mW

and for the QB5 alignment we calculated ...

$Pa = 15.176 * (0.0136 * 0.005)^2 * 40^4$= 179mW

Not quite as impressive as the previous example, but note that we have a -3dB frequency of 40Hz instead of 62Hz, and still have a 7.2dB increase in effective acoustic power output. Converting to dB SPL, we get ...

dB SPL = 10 * log10(0.179) + 107.5= 100.03 dB

The is a substantial improvement over the 92.8dB SPL obtainable from a sealed box, plus we have over ½ octave more low frequency extension. As before, if we were to raise the crossover frequency, there will be an equivalent increase in level before the excursion limit is reached. As it stands, the arrangement just calculated would outperform the majority of systems using conventional vented boxes and the same driver. The enclosure is only marginally larger than a 'critically aligned' system, but has an f3 of 40Hz rather than 34Hz. Another plus is that there is a filter that will help reduce subsonic excursions that produce no useful output, but can introduce considerable

distortion because the cone is unloaded below the cutoff frequency.

As previously mentioned, the 2nd order high pass output from your sub amplifier can be used as the filter. While it is true that this is usually a Butterworth type, with a Q of around 0.7, overall this does not make much difference at this low crossover frequency, as room modes and cancellation/reinforcement from walls predominate over any exact crossover characteristic. Be aware that many 'plate' sub amps have a fixed high-pass filter, and only the low-pass section is variable. Such units will almost certainly need the filter circuit described.

If the high-pass section of the crossover is variable this is also useful, as this allows an optimum setting for a smooth response to be found more easily. It also increases power handling even more. Referring to the original driver (the P17WJ), if kp remains the same and f3 is increased to 80Hz, the excursion limited peak output goes up to 113.7dB - this represents an increase of 16.8dB in peak output over a sealed box before excursion limit is reached. One can use a peak input of 263 Watts in the case of the P17WJ, which has an unspecified 'short term' maximum power input rating of 350 Watts.

The method outlined here allows the maximum performance to be extracted from the single subwoofer plus two way satellite configuration, and in terms of 'bang for your buck' is hard to beat.

It does however use the now demonised reflex enclosure, but it must be emphasised that any negative effects from a port are more than compensated for by the very significant reduction in non linear distortion this technique confers.

In addition, it could be argued that the electrical filter brings the box back into alignment, and not only relieves the loudspeaker of undue stress and distortion, but by removing the low frequency component from the amplifier, the power actually needed could be reduced by perhaps 3dB or more. While this may not sound like much, it is the difference between a 100W amp and a 50W amp, so the savings all round could be very significant.

1 - Introduction

Conundrum *(noun): A paradoxical, insoluble, or difficult problem. A dilemma.* Well, that just about sums it up for subwoofers, doesn't it? Of all the add-ons that can be applied to a system, the sub often gets the short straw - they are routinely shoved into a corner, or behind the couch, or even made into coffee tables. The problem is that none of these treatments will work properly unless you have some idea of the physics behind it. The vast number of compromises needed only makes things harder.

The use of subwoofers in any audio system that is intended mainly for music is often the cause of much soul-searching, not to mention web searching, trying to find out what will

work and what won't. Home theatre is easier, since the primary requirement is for satisfyingly deep rumbles at the appropriate times, and to give the sense of "depth" to the soundtrack, and accuracy is not required to the same degree. Yes, I know that many consider film soundtracks to warrant accuracy too, but most listeners/ viewers don't care that much.

In the case of a home theatre system, there is usually no concept of "speed", since the sounds do not usually have the tight connection found in music, and a few milliseconds here or there is of little consequence. Not so if the system will be used for music as well, since now there are distinct notes that should be reproduced with as little time delay as possible. If this is not the case, the bass becomes blurred and indistinct, and has no proper connection to the music overlaying the lowest notes.

People often describe a bass reproducer as "slow" or "fast", but in fact neither term is applicable. A 40Hz bass fundamental cannot be fast or slow - it is simply a 40Hz (transient) tone, and our hearing is depressingly bad at even hearing such frequencies until they have been present for several cycles.

So, do the terms actually mean anything, or is this more fluff and bluster from the marketing departments of the larger manufacturers?

---

2 - Timing is Everything

When used in any advertising, you have basically fluff and bluster, and little else. Bass *cannot* be slow or fast, but it *can* be reproduced and heard when you are supposed to hear it, or it can be out of time with the rest of the music. The timing in *itself* is usually not the problem, but there are many things afoot that make a huge difference. These (not surprisingly) are the subject of this article.

Consider the setup shown in Figure 1. The sub is off to one side, with the listener placed directly in front of the main speakers. With spacings as shown, the distance from the main speakers to the listener is 2.23 metres to each box. Subwoofer to listener is 3.6 metres, a path length difference of 1.37 metres. This is not an uncommon setup, and as is often the case, the WAF (Wife Acceptance Factor) must be considered in the final placement. It is also non-sensible to have a subwoofer in the middle of the floor for people to trip over

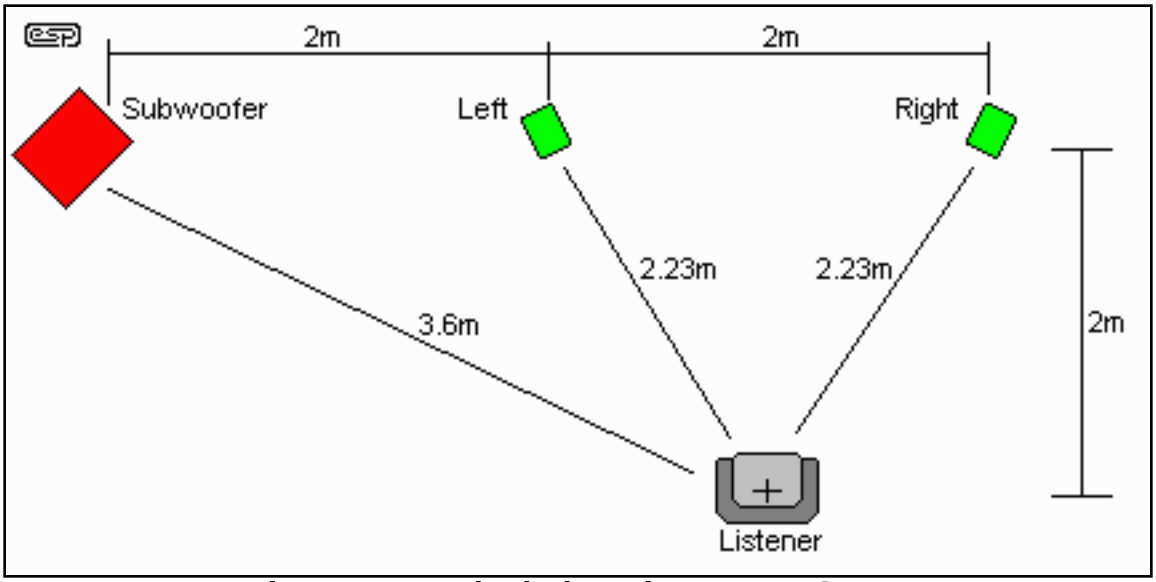

Figure 1 - Typical Listening Room Setup

At higher frequencies, a path difference of 1.4 metres (near enough) would be completely unacceptable, but it can also be unacceptable for bass, too. It depends on the crossover frequency. The following table shows the important frequencies and wavelengths at various frequencies.

Frequency	1/4 Wave (-3dB)	1/2 Wave (cancels!)	3/4 Wave (-3dB)	Wavelength
120Hz	0.718	1.44	2.16	2.875
100Hz	0.8625	1.725	2.875	3.45
80Hz	1.078	2.156	3.23	4.3125
60Hz	1.4375	2.875	4.3125	5.75
40Hz	2.156	4.31	6.47	8.625

Table 1 - Frequency Vs. Wavelength (in metres)

For the purposes of this exercise, I have no choice but to assume a perfect (anechoic) listening space, devoid of reflections and standing waves. Unfortunately, these always exist, and rarely improve matters, but may mask some of the effects that will be described. No matter, since the basic principles stand and should be considered - the effects of standing waves (in particular) are a separate topic altogether.

Over the entire crossover range, if the difference between the listener and main speakers vs. the distance from listener to sub is 1/2 wavelength, then the sub's output will partially cancel the output from the main speakers. A phase switch is often included to fix this, and this is the most obvious of all problems. In the case shown in Figure 1, 120Hz is a crossover frequency to be avoided at all costs, since there is almost a

complete cancellation due to relative path lengths. Remember that the crossover range should be considered to be a full octave with typical crossovers, and much higher slopes are needed to minimise this. 12dB/Octave is an absolute minimum requirement, and 24dB/Octave should be considered the standard.

But, why can't we just operate the phase switch and make it right again? Well, we can, but then there are other problems. What of the path length between the sub and the speakers themselves, and what of the frequencies either side of crossover? Since these are all different, there will be interactions at the main speakers, at the sub, and at various places throughout the room. Note that in an ideal case, 1/4 or 3/4 wavelengths will cause a dip of 3dB, since they have a 90° and 270° degree phase angle respectively. If at all possible, the relative path lengths should be no more than 1/4 wavelength for at least 1/2 octave above crossover - this effectively rules out the layout shown in Figure 1, but in reality it *will* work provided the crossover frequency is no higher than 60Hz or so.

Every multiple of 1/2 wavelength throughout the room will cause a dip in response, which may be partial or total (no signal at all), and this will be effective to a greater or lesser degree for the whole range of frequencies across the crossover region. With a setup such as this, the crossover frequency should be no higher than 60Hz, or the subwoofer must be moved to a more central location, closer to the main speakers.

At any crossover frequency higher than around 60Hz, standing waves, which are influenced by the size of the room, the wall, floor and ceiling materials, (large) soft furnishings, etc., will confuse an already confused bass image, and may well give rise to the impression that it is 'slow'. Bass signals around the crossover frequency will be of variable amplitude, and may change from one note to the next. Despite claims to the contrary in some areas, you will also probably find that you *can* tell where the bass is coming from as well - there will be enough higher frequency energy from a 120Hz crossover to enable you to localise the bass as being well off-centre.

---

3 - Optimum Crossover Frequency

Generally, a sub should be crossed over at the lowest practicable frequency. Based on the information in Table 1, you may need to re-think the idea of just shoving it behind a lounge chair, based on the crossover frequency and the relative distances from main speakers (*both* of them!) to the listener and the sub itself.

An ideal solution would be to use two subs, each located near to the speakers.

Unfortunately, cost, size and even the ability to place them optimally often (usually) rules out this approach. The next best thing is to try to arrange it so that the path length between the sound sources and the listener are within at least 1/4 wavelength at the crossover frequency. Unfortunately, this will often mean a location that is already occupied by other furnishings, the TV or even the cat

The limitations on crossover frequency are alleviated somewhat by positioning, but the optimum position for the sub to minimise phase and timing issues may well turn out to the worst possible location for standing waves and good bass at the listening position. As shown in Figure 2, by re-positioning the sub so that it is between the two main speakers will allow a crossover frequency that is much higher than the previous example, but the room shape and size may make this position unacceptable for standing waves.

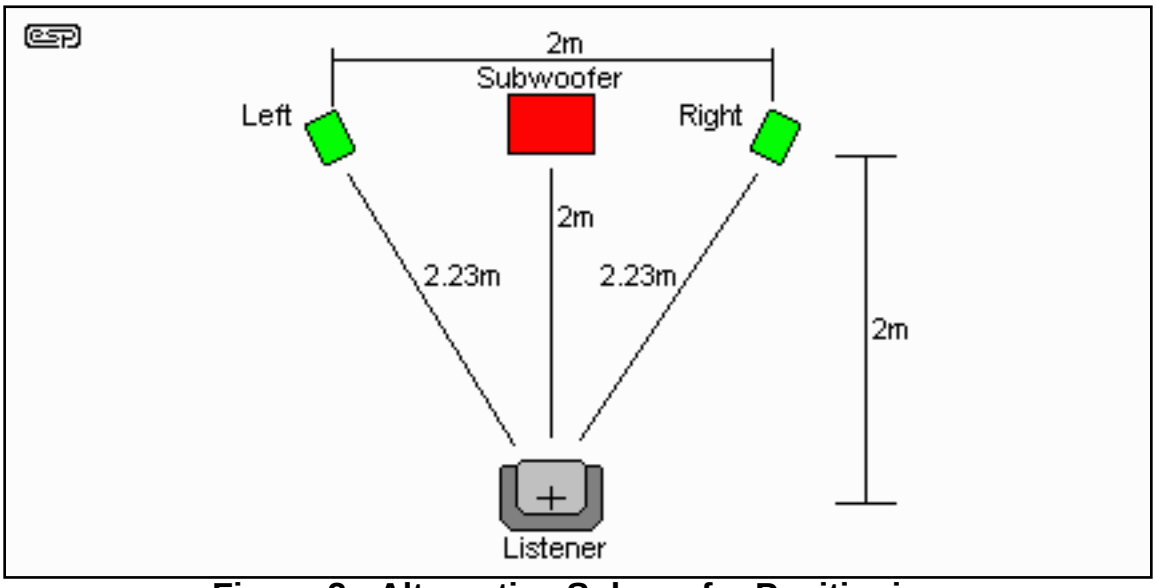

Figure 2 - Alternative Subwoofer Positioning

If this works well for bass at the listening positioning, then based on timing errors, the maximum phase shift is negligible, and well under 90° (path length difference is reduced to 230mm) even with a 100Hz crossover frequency. If this cannot be achieved, then the alternatives are few.

Adjustable phase controls usually do more harm than good, since the final phase relationships are something of a lottery. You might win, but the odds are stacked against you. Digital delay will work too, but it cannot correct off-centre positioning where the distances from each box to the listener and between each other are all different. One of the few tools at your disposal (for a sensible price at least) is an equaliser (for example the Sub-Woofer Equaliser shown in the projects section. It is not a panacea, but can help if things aren't quite right, and can correct many problems that cannot be fixed any

other way. The other thing (of course) is to optimise the crossover frequency, getting it as low as you can - the limiting factor is often the main speakers (especially if smaller bookshelf types), but most speakers will get down to 70Hz, and many a lot deeper.

There is always an inevitable tradeoff between the minimum frequency of the main speakers and the likelihood of intermodulation distortion caused by excessive cone excursions - this is relieved somewhat by using a 3-way main system, but this is not always practical. Additional phase anomalies are introduced as any loudspeaker approaches resonance, again, there is little you can do about it, but careful placement is a better solution than variable phase controls in most cases.

---

4 - Cone Area Vs. Displacement

A common misconception is that cone area can be reduced if displacement (Xmax) is increased. While it is true up to a point, it is only possible to increase Xmax up to a few millimetres of linear travel without a severe sacrifice in loudspeaker driver efficiency. Consider the two options shown in Figure 3 - the voicecoil may be overhung or underhung, but one either loses efficiency by having only a part of the coil in the gap, or by having much of the magnetic field bypassing the voicecoil altogether. Low efficiency (less than 90dB/m/W) requires more amplifier power and more heat. Remember that each 3dB fall in efficiency requires double the amplifier power for the same SPL.

Also, many manufacturers rate efficiency at 2.83V instead of 1W. At 8 ohms, the figures are the same, but for a 4 ohm driver, the efficiency is artificially inflated by 3dB, and you will need twice as much power as you may have thought.

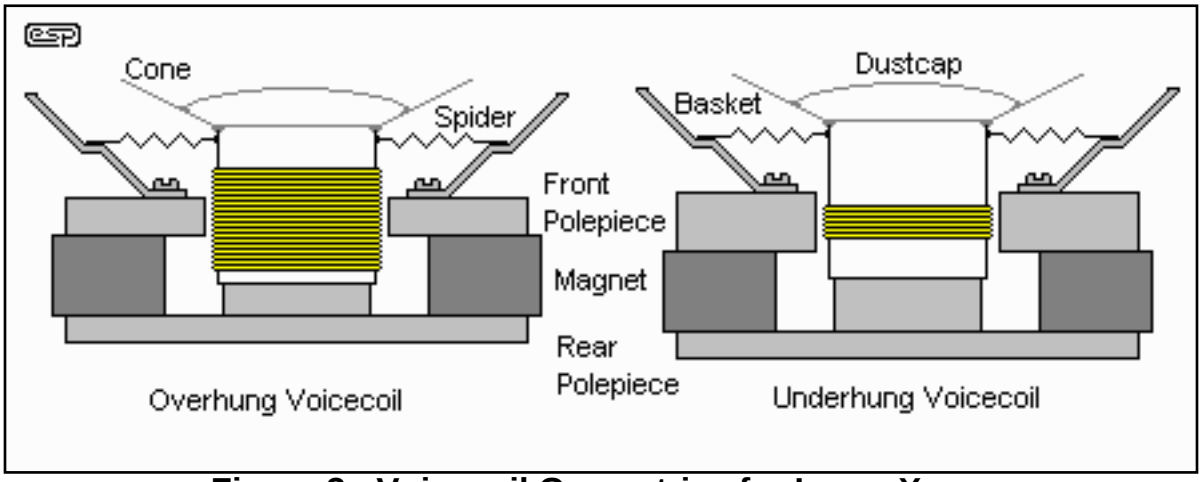

Figure 3 - Voicecoil Geometries for Large Xmax

In each case, *linear* Xmax is defined as the distance the voicecoil can travel, while

remaining within the magnetic field. Xmax is often stated as the maximum cone travel before the suspension prevents further movement (or the coil former hits the rear polepiece, which will damage the former). IMO this is very misleading, and while the cone may well be capable of travel to the distances (Xmax) claimed, the distortion becomes unacceptably high. Distortion can easily exceed 20% in many cases.

This is only a part of the problem however. For the sake of easy explanation, imagine a cone 25mm in diameter, but with a linear Xmax of 350mm. It would reproduce little or no bass at all, despite its massive excursion. At the other end of the scale, a 350mm diameter loudspeaker cone with an Xmax of 25mm will be an efficient reproducer of very low frequencies. The problem with generating bass using excursion to 'replace' diameter is the radiation impedance of the cone area. Cone loudspeakers are inefficient at the best of times, not (only) because the coil and magnetic circuits are not always optimised, but because there is a huge mismatch between the impedance of the cone and that of the air which must carry the soundwaves. This is but one of many compromises that must be made in any loudspeaker driver design.

An ideal bass radiator has a cone that is large, very light (or at least a lot lighter than most of the current crop of subwoofers), is still strong, and has a low resonant frequency. Unfortunately, this is very difficult to achieve unless the suspension is made very "floppy" indeed, and this will cause problems since it is not possible for such a suspension to keep the voicecoil properly centred when the speaker is driven hard. A low resonant frequency with a light cone also means that the driver will be very sensitive to the enclosure size (large Vas), and will need a big box to work well. This all goes against the current trends (and the need for the sub to be "acceptably invisible" in the listening room).

Horn loudspeakers minimise the impedance mismatch between diaphragm and the air, by acting as an acoustical transformer. The horn flare provides a controlled expanding wavefront to transform relatively small diaphragm movement into a large air movement, and with careful design efficiencies of well over 100dB/W/m are easily achieved. Unfortunately, bass is again a problem, since the circumference of the mouth should be equal to the wavelength of the lowest frequency to be reproduced. At 20Hz, this means a circumference of over 17 metres, and for a square horn (less than ideal, but smaller than circular) that means 4.3 metres per side! That is very large indeed, and the length hasn't even been considered yet. To avoid impedance mismatch (which causes "ripples" - peaks and dips in the frequency response), a horn should have a minimum length of 1/4 wavelength , and preferably more. This is not a practical solution for most listening rooms.

Radiation impedance is a complex area of acoustics, and I'm not going to even try to explain the maths involved. Suffice to say that small cones (in small boxes) will be incapable of reproducing spectacular bass, regardless of the claimed Xmax of the driver. As an example (and please note that this is a very rough estimate only) the following table shows the expected minimum frequency of various sized drivers in a sealed enclosure having a small baffle, and radiating into ½ space.

Driver Diameter	Minimum Frequency (-3dB)
200mm (8")	40 Hz
250mm (10")	32 Hz
300mm (12")	27 Hz
380mm (15")	21 Hz
450mm (18")	18 Hz

Table 2 - Diameter Vs. Minimum Frequency (½ Space)

The above figures should be taken as a guide only, and are based on wave propagation (as opposed to pressure mode - see below). The figures are independent of Xmax! When the subwoofer is located at a room boundary (e.g. close to the wall and sitting on the floor) there is an increase of low frequency energy, and a driver will reproduce to a lower frequency than indicated, but with poorer frequency linearity. Corner location gives a further boost, but at the expense of further frequency non-linearities. Vented (or passive radiator) boxes perform differently, and it is not possible to cover all the permutations here.

It has been claimed (and it is true up to a point) that distortion of extreme bass is not a problem, since it is masked by the main system, and may be rendered inaudible. While this is fine in theory, remember that the distortion will be primarily 3rd and 5th harmonics. If a 50Hz signal has significant distortion because Xmax has been exceeded, then you *will* hear 150Hz and 250Hz harmonics. Further, these will allow precise location of the sub, since 250Hz is easily high enough to allow our ears to localise the sound source.

The same thing happens with vented subs - if vent noise becomes audible during low frequency programme transients, then you will again be able to pinpoint the sub's location quite easily. This detracts greatly from the listening experience. In all cases, a hi-fi system should be as transparent as possible, and do nothing to draw attention to itself. Only the programme material is important, and it is this - and this only - that you should be listening to.

5 - Soundwave Vs. Pressure Mode

One claim that is very popular is that you cannot reproduce bass in a small space. While this is certainly true of soundwave propagation, it is completely false if pressure mode is excited within the space. In most rooms, there is a transition point between soundwave propagation and pressure mode (sometimes referred to as 'Room Gain'). That low frequencies can be reproduced in small spaces is clearly shown by headphones and car subwoofer systems. Both of these rely on pressure mode, and the low frequency -3dB point is defined by 'leakage' because the space is not perfectly sealed. In a completely sealed environment, bass reproduction is attainable right down to DC - not that this is actually useful. Most subwoofers ultimately rely on pressure mode to obtain the lowest frequencies in typical rooms, and it is notable that vented systems in particular are unable to excite the pressure mode properly in many rooms.

One of the reasons for this could be that there is a vent that allows the pressure to equalise. In theory, this is meant to be a resonant system, where the back wave of the loudspeaker is inverted in phase and augments the main cone wavefront. That the principle works is demonstrated by many large systems in auditoria, theatres and even outdoor venues, but all of these are large spaces where sound*wave* propagation is dominant.

When room dimensions become small compared to wavelength, soundwave propagation will not work, and bass can only be reproduced by pressurising (and de-pressurising) the listening space ... pressure mode. In tests I have performed in my workshop, a vented subwoofer seemed to make a lot of noise, but completely failed to produce bass that could actually be felt. A similar driver in a sealed box causes the whole house to vibrate, something that I have not been able to achieve to the same (or even similar) levels using any vented subwoofer system.

To some extent, this section is comprised of musings on my part, and at this stage I have no measurements to back up my claims. The effects I have reported are (or at least seem to be) real, but there is no clear point of delineation - I don't know exactly where soundwave propagation ceases to be the dominant force, and where pressure mode takes over. This will be covered in more detail when I get the chance to do some measurements and research.

6 - Subwoofer Positioning

One of the easiest ways to position a sub is to place it in the listening position - in the chair. Play material that has significant low frequency material, and then crawl around the room, placing your head in the most desirable potential locations. Listen carefully to the bass - it should be smooth and extended, with a minimum of large peaks or dips. The optimum position for the sub is now the location where you heard the best response.

It is very likely that the position of best response is completely undesirable for other reasons, so be prepared to spend a fair bit of time moving around, and listening carefully. There are always compromises, but with care you can still find a location that is acceptable aesthetically, is not inconvenient (e.g. the middle of the lounge room doorway), and does not cause howls of protest from SWMBO (She Who Must Be Obeyed).

It is a given that the other members of your family will naturally assume that you have finally lost it completely during this exercise, but it *may* be possible to get their assistance - or at least a second opinion. Involvement in the process could make it a lot easier to explain why the china cabinet really should be moved - preferably to another room if you have a powerful subwoofer

---

7 - Conclusion

It is probable that this article has not helped a great deal, and may even add to the confusion. Apart from the more common sealed and vented subwoofers, there are also dipole subs (of various types and designs), horns (which are generally too small, but often work well despite this), and even whole walls of low frequency drivers. No one system type can be recommended for all applications, and most drivers will function at their best in only one box type. Sub drivers that are designed for small sealed boxes will usually not work well in a larger vented box, and vice versa.

This should be considered a work in progress, and more information will be added as soon as additional tests can be run, and more details obtained.

Welcome to ESP, the home of DIY audio articles, projects and shortform kits. Audio is a wonderful hobby, and with DIY there is a huge scope to get the very best performance for a lot less money than otherwise. DIY audio is fun and educational, and by building your own audio equipment, you get to learn electronics as well as build equipment that would cost a great deal more in the shops. ESP is committed to providing high quality projects that are known to work, printed circuit boards (PCBs) for the most popular projects, and to assist you if necessary to complete or debug your project. There is a very wide range of power amplifiers, preamps, guitar/ bass amplifiers, studio equipment, effects, and other projects to build, including loudspeakers, subwoofers, and many others. Purchase PCBs to gain access to even more information.

24 dB/Octave 2/3-Way Linkwitz-Riley Electronic Crossover

Rod Elliott - ESP
Last Updated 06 Sep 05

Please Note: PCBs are available for this project. Click the image for details.
Click here to see a photo of the board in 12dB/Octave format (See Project 81 for details of this modification).

Introduction

The Linkwitz-Riley filter featured here has (almost) perfect phase-coherency, with no peaks or dips at the crossover frequency. The design is adaptable to 2-way or 3-way operation, and all formulas are provided below (or use the ESP-LR component calculator program).

The photo shows the standard P09 circuit board, but wired for 12dB/octave operation as described in Project 81.

2-Way Linkwitz Riley Crossover

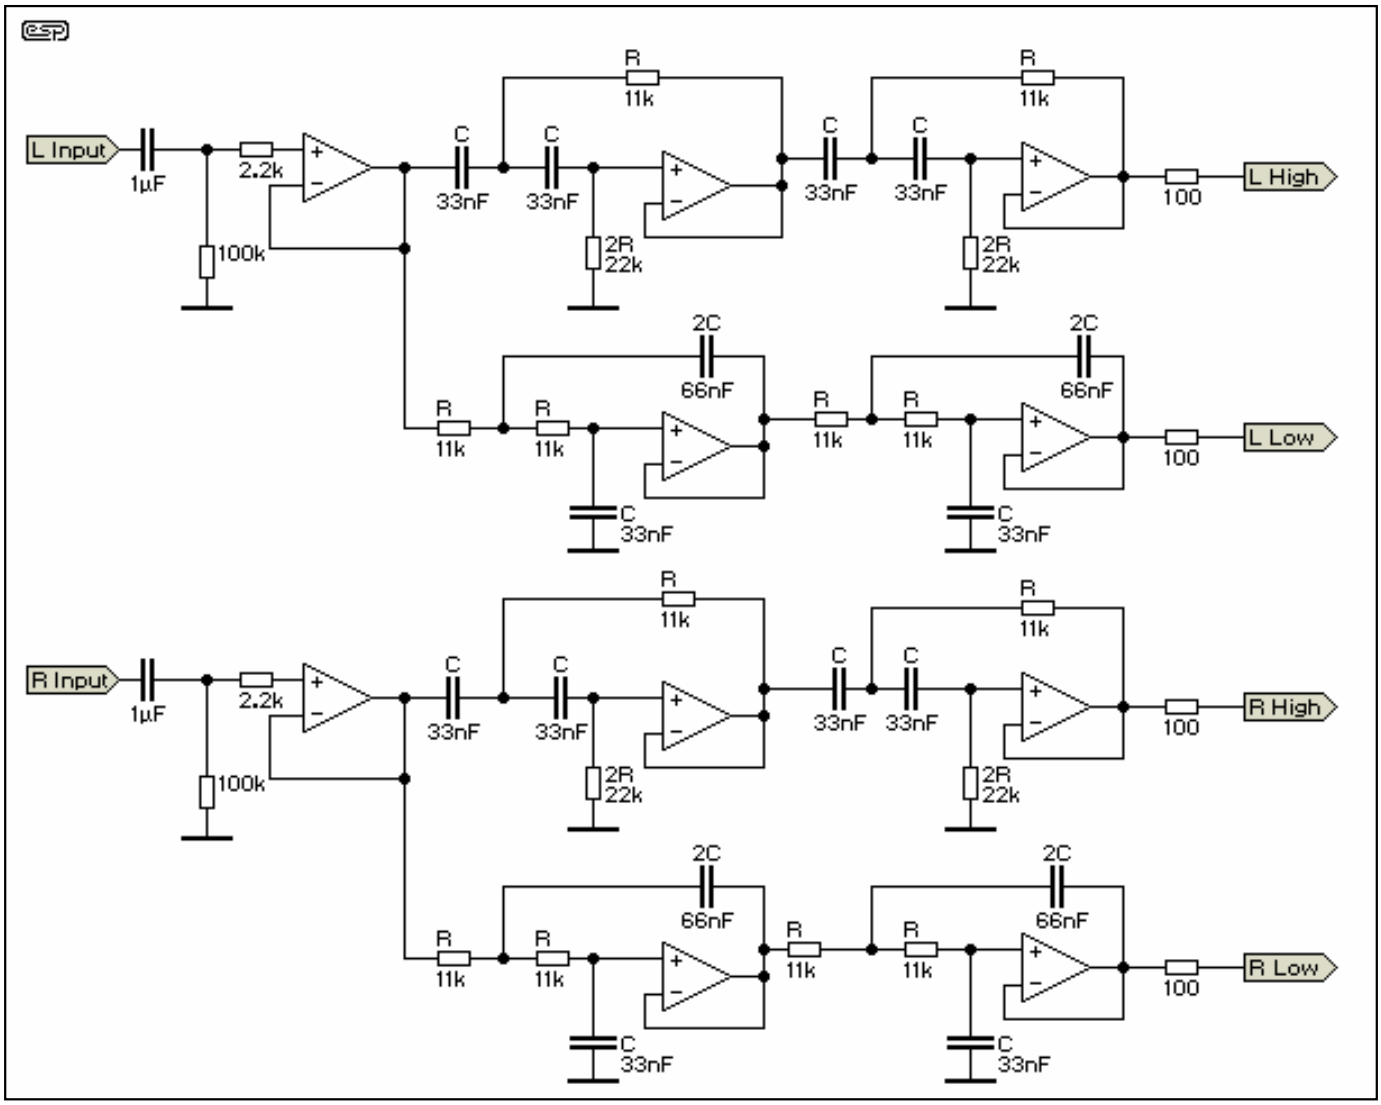

Figure 1A - Stereo Version of a 2-Way LR Crossover

Figure 1A shows a full stereo version, with two identical filter sections. With the component values shown, these have a crossover frequency of 310Hz (refer to the article on Bi-Amping to see the reason for my choice of frequency). This unit will provide a completely flat frequency response across the crossover frequency, with the signal from both filters remaining in phase at all times.

The 2-Way unit is separated into 3 sections per channel ...

- **Input Buffer** - ensures that all filters are driven from a low impedance source, to prevent frequency and phase shifts
- **High Pass** - as shown, frequency is approx. 310Hz
- **Low Pass** - as shown, frequency is approx. 310Hz

It is important with both versions that the filters are properly matched, both within the individual filters, and between channels. While small variations between channels will not be audible, if the high and low pass sections are not accurately matched, then phase and amplitude errors will result.

3-Way Linkwitz Riley Crossover

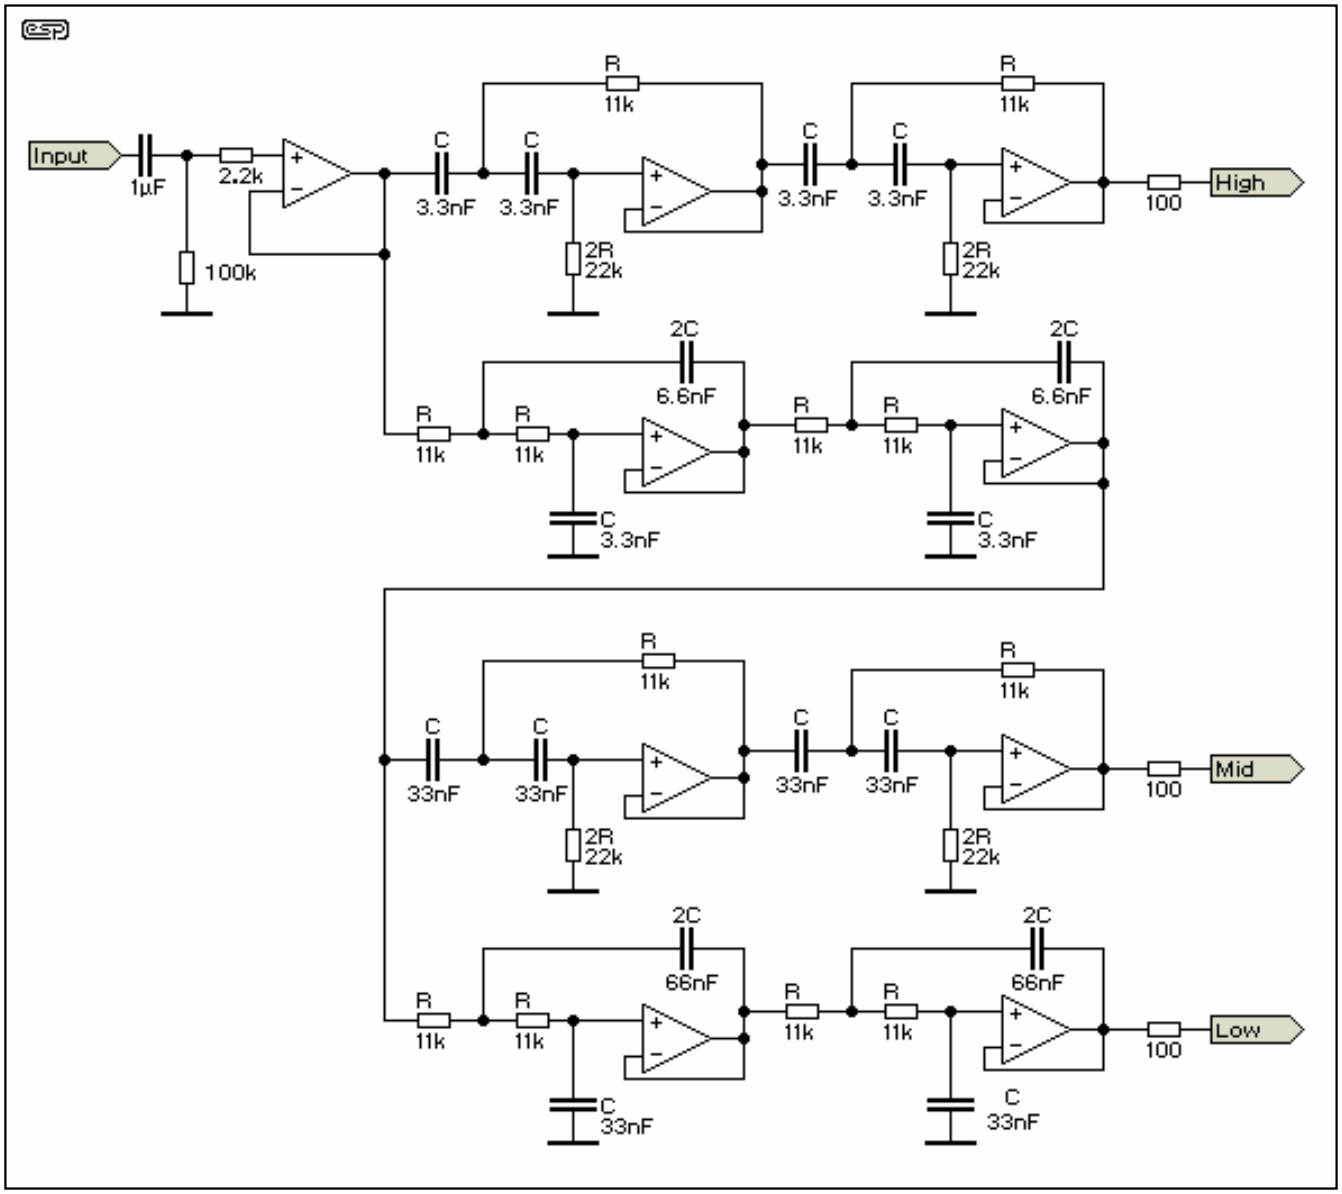

Figure 1B - 3-Way Mono LR Crossover (2 Needed for Stereo)

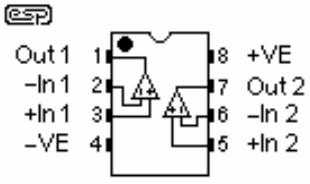
Figure 1B shows the way to connect a 3-Way crossover. This unit will produce excellent results, with good phase coherency and a flat response across the entire frequency band.

I know the circuits look complicated, but each is basically repetition of a common circuit "block" - the filter section. Since the opamps are all used as unity gain buffers, the use of premium devices is not really essential, so the TL072 type would be quite servicable in this role. Needless to say, if you want to use better devices (even discrete opamps) you can easily do so. Make sure that any device used is stable for unity gain - this is not always the case with some devices, especially when external compensation is used. In this case, use the manufacturer's recommended value of stability cap for unity gain operation.



Power supply connections (and bypass capacitors) have not been shown, but the diagram shows the standard connections for a dual opamp. The IC is viewed from the top. The +/-15V power supply described (see Project 05 - Power Supply For Preamps) is suitable for this crossover as well. For dual opamps, power is connected to Pin 4 (-ve) and Pin 8 (+ve).

NOTE: Only one channel is shown for the 3-Way - for a stereo setup, two identical filter circuits are required.

As can be seen, the 3-Way unit is separated into 4 sections ...

- **Input Buffer** - ensures that all filters are driven from a low impedance source, to prevent frequency and phase shifts
- **High Pass** - as shown, frequency is approx. 3100Hz
- **Band Pass** - as shown, frequencies used are high pass at 3100Hz and low pass at 310Hz
- **Low Pass** - as shown, frequency is approx. 310Hz

In 3-Way mode, the bandpass section must have a highpass section whose frequency is exactly equal to that of the main lowpass filter, and a lowpass section whose frequency is equal to the main highpass filter. (No, this isn't confusing, it just looks that way.) See the chart above for clarification if this doesn't seem to make sense.

If it helps, I have added a block diagram that may make things clearer. This is shown below, and has all the sections for a 3-way crossover network. Again, this is mono, so two complete blocks are used for a stereo system.

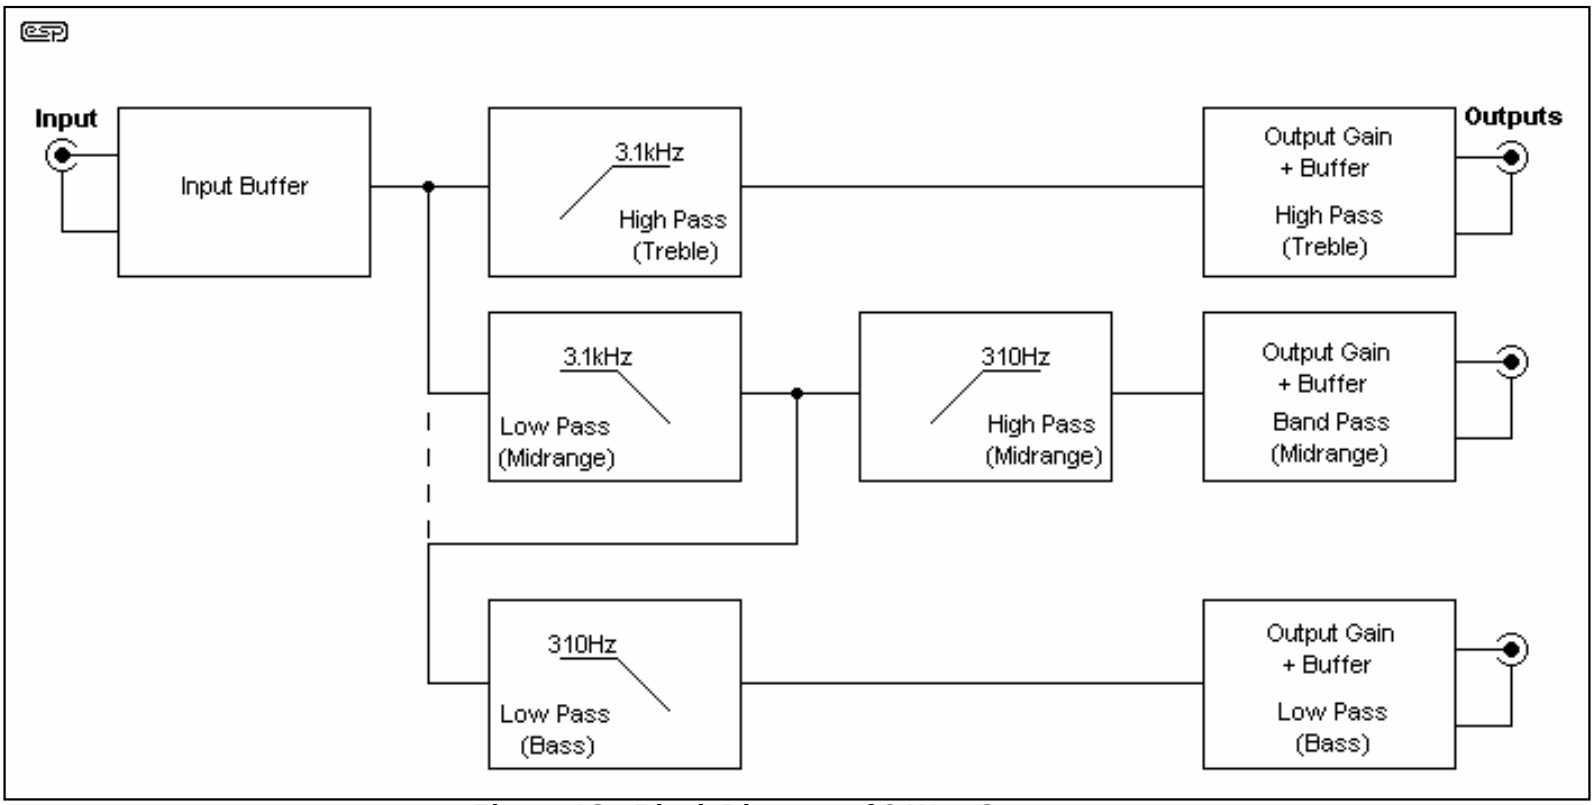


Figure 1C - Block Diagram of 3-Way Crossover

Frequencies shown are for reference only, and are the same as described above. Naturally, these may need to be changed to suit your application.

The frequency responses of each section are shown below, note that the crossover frequency is at the -6dB point, and not at the traditional -3dB frequency. This is an important difference between a Butterworth and Linkwitz-Riley filter, and allows the signals to be in phase across the audio band, regardless of which

filter section they are being passed by. The summed output of this filter is flat, there are no peaks or dips, and no phase reversals are produced (unlike Butterworth filters).

A simple test with any electronic crossover is to connect a 10k resistor to each output, and join the other ends together. Run a frequency sweep from an audio oscillator into the input, and observe the output level at the output of the resistor summing network. Most crossovers exhibit a 3dB increase at the xover frequency, and drop back to the reference level about an octave or so each side. This is a less than ideal situation, since in most cases a similar effect will occur from the speaker's summed acoustical output - assuming that the drivers are "time aligned" so the output of each is in phase (acoustically speaking) at the crossover frequency. If time alignment is not done, and the physical distance difference between speaker voice coils is large (more than 0.1 wavelength of the frequency concerned), then other acoustical differences caused by phase will tend to overshadow any anomaly in the crossover network.

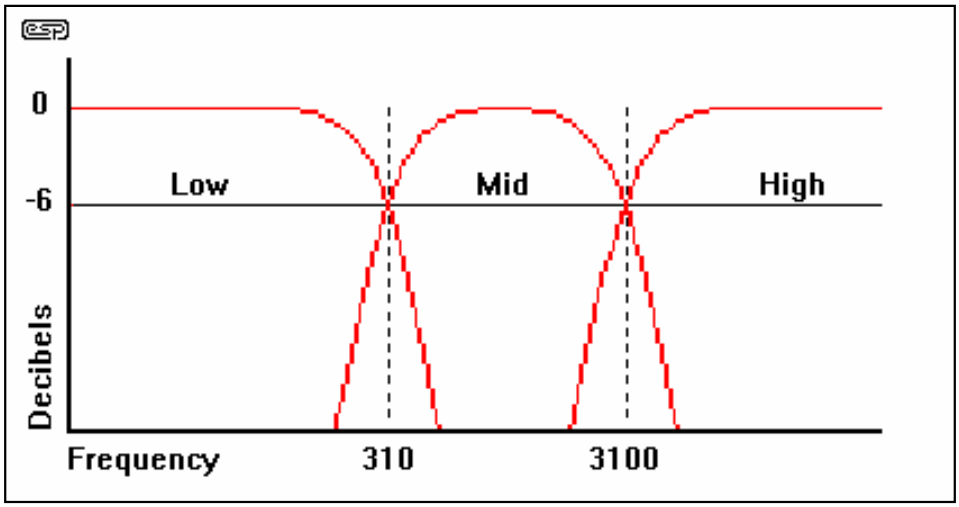

Figure 2 - Frequency Response of 3-Way Linkwitz-Riley Crossover Network

When the original graphs were produced, frequency response ranged from 10Hz to 50kHz, and the influence of the 1uF capacitor in the input is negligible (the -3dB point is 1.59Hz). Insertion loss is 0dB, since there is no gain or loss introduced by the filters in their pass-band.

Output Buffers (and ....)

If you are going to use the crossover, you will need some way of equalising the levels from each output to match the power amp sensitivity and speaker efficiency. I have had several requests for this, so the circuit for a suitable buffer is shown in Figure 3. There is nothing special about it, but it is designed to give a gain of 2 to allow maximum flexibility, and ensures that the impedance of the pots does not cause any high frequency loss with long nterconnects.

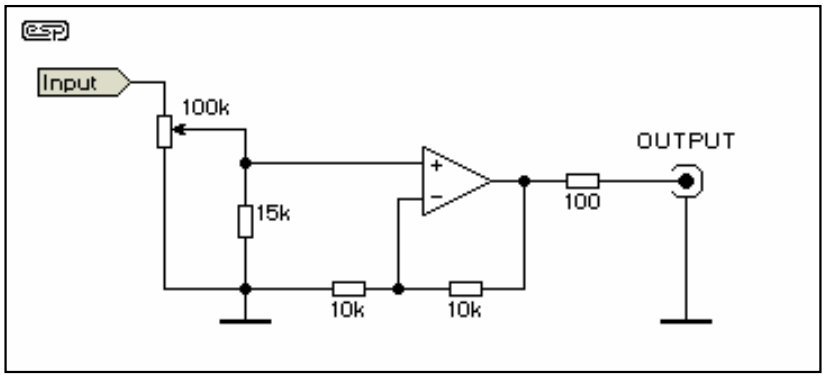

Figure 3 - Buffer Stage. One Per Output Needed

These buffers should use high quality opamps, and can be mounted on a separate board if desired. Construction is not critical, but proper bypassing must be used to ensure stability.

Several people (including me) have found that the crossover unit has a short 'chirp' or 'snap' (depending on the opamp characteristics) as power is removed, and this may be accompanied by some DC swing. If you use the new version of the P05 preamp power supply, the auxiliary output can be used to activate a 6-pole relay (or as many smaller relays as needed) to short all outputs to earth when there is no power. The normally closed contacts simply short the outputs to ground, and when power is applied the short is removed. P05 (Rev-A) boards use a loss of AC detector that will mute the crossover almost immediately when power is turned off.

Because all common opamps have short circuit protection, this will not cause any damage, and current is limited further by the 100 ohm output resistors.

My thanks to Chris Hoppe for initially alerting me to this problem.

Variable Frequency Crossover

As you can see from the main circuit diagram, a 4th order Linkwitz-Riley would be difficult to make into a variable network, due to the large number of resistors which need to change. Use of multi-ganged potentiometers is discouraged, because of the matching requirements. Sufficiently accurate 8-gang pots are unlikely to be readily available!

One possibility is to build modules, containing the tuning components. These may be plugged into suitable sockets on a printed circuit board, which otherwise contains the rest of the circuitry. The modules could be made quite small. A possibility for this option is shown in Figure 3, showing the connections which need to be made for each unit. It would not be possible to make these "hot-pluggable" (i.e. with power on), since the opamps will be deprived of their biasing resistors, and will swing to the +ve or -ve rail. Power amplifiers and speakers are not expected to enjoy the experience!

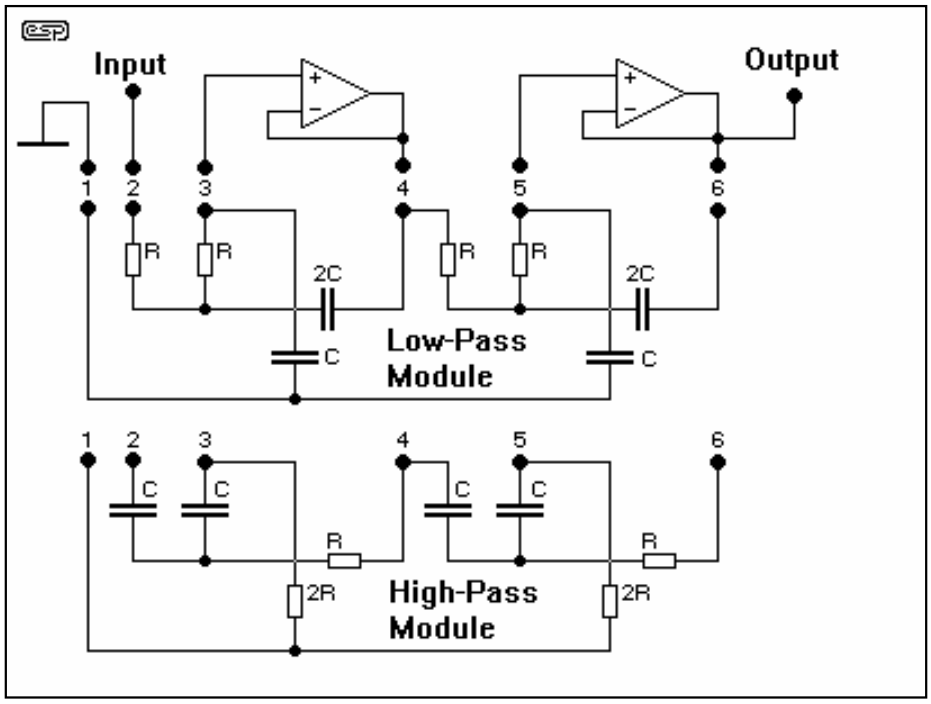

Figure 4 - Modular Connections for L-R Crossover

With this arrangement, the main PCB will simply contain a whole bunch of opamps (and their power supply bypass components), and some suitable sockets for the tuning modules. Each plug/socket combination needs 6 pins (as shown), with one for the earth (ground) connection, and the others for connection to the opamps. The plugs and sockets should be of high quality (preferably gold plated) to ensure reliability. The standard 0.1" pitch PCB pins (often used for IDC connectors) would make a good choice - they are quite cheap and reliable. Sockets are also available, but you might have to search for them - I have not seen them in any of the local retail electronics shops in Australia.

It might be an idea to use a 10M Ohm resistor (which will have virtually no effect on the tuning resistance) from the opamp's +ve input terminal to earth, just to ensure that bias cannot be lost. This will cause some offset, but it will be a lot less than 15V.

Tuning Formula If you absolutely insist on performing the calculations yourself, the formulae are ...

(1) $R = 1 / (2 * \pi * 1.414 * f * C)$
(2) $C = 1 / (2 * \pi * 1.414 * f * R)$
(3) $f = 1 / (2 * \pi * 1.414 * R * C)$

Where R = resistance in Ohms, π = 3.14159, 1.414 is $\sqrt{2}$, f = frequency in Hertz and C = capacitance in Farads

(1) This assumes that you have selected the capacitance first, which is the most sensible, since they are available in fewer different values in each decade than resistors. Capacitors follow the "E12" series, which has 12 values per decade, so:

1.0, 1.2, 1.5, 1.8, 2.2, 2.7, 3.3, 3.9, 4.7, 5.6, 6.8, 8.2, 10

These are multiplied by 10, 100 (etc), to obtain all the values from 1nF - 10nF, 10nF - 100nF, and 100nF -

1uF. Values above 1uF and below 100pF are generally not as readily available in all values, and should be avoided for this design, since very large or very small values will create impedances which are too difficult to handle. Very low values of capacitance mean that even small amounts of stray capacitance on PCB tracks or in wiring will create errors. Large values of capacitance will imply low impedances, which opamps may not be able to drive without excessive distortion or clipping.

(2) Is the least useful, since the range of capacitor values is only half that of 1% resistors. Really strange values can be assured, which will require parallel combinations of smaller caps - messy.

(3) Is useful to check that the components selected will give you the frequency that you first thought of, or something reasonably close after standard component values have been substituted for the theoetical values you will get with the calculation.

The calculator program is far easier and more fun, too. (Of course I like it - I wrote it!)

Capacitor values need to be accurate - the standard offering is +/-10%, which is not really good enough. If you have (or can get access to) a capacitance meter, simply buy more than you need (they are inexpensive), and select the values to be within 2% or better if possible. My experience is that the tolerance of most MKT and MKP caps is actually better than that quoted, but you do need to check!

The easiest way to get the "2C" value is to use two capacitors in parallel, each of value "C".

Resistor values also need to be accurate, and 1% metal film resistors are perfectly acceptable. These are generally available in the E24 series (24 values per decade), allowing a much wider choice of values. Both the E12 and E24 series values are available in the Component Calculator (Help-Preferred Values) for reference. In some shops (oh, really?) you might even be able to get resistors in the E48 or E96 range - these offer an almost limitless range of possibilities (48 or 96 values per decade - awsome!), just don't count on it.

General Notes ...

- As noted above, some opamps create a transient signal upon application or removal of power. Because this will create a loud sound, many builders may want to incorporate a delayed action switch, to ensure that the outputs of the circuit are not connected to the load until the operating conditions have stabilised. One simple solution is described above, and will work perfectly. Alternatively, the circuit described in Project 33 (Loudspeaker Protection and Muting Circuit) can be adapted quite readily to accomplish this.

  The transients are unlikely to cause damage to any amplifier or loudspeaker, but do not sound very nice. For a system that you build yourself, there is a great satisfaction in having it perform flawlessly, so it is probably worth the effort. If you have a separate power amplifier switch, there is no need to use muting. Simply turn on the power amp a few seconds after the preamp, and turn it off a few seconds before you turn off the preamp / crossover. Alternatively, the crossover can be powered permanently - current drain is very low, and it will draw less power than a typical TV set or VCR on standby.

- The crossover as described is phase coherent, in that the phase of each signal applied to each

loudspeaker driver is essentially in phase with all other signals that have passed through the crossover. Because filters are used, the crossover is ***not*** phase neutral - there are wide variations in absolute phase as the frequency changes. This is the case with all crossover networks, from the simplest to the most complex, active or passive.

I mention this because of possible interactions between the main (Left and Right) speakers, and the centre and rear speakers in a surround sound environment. The possibility exists that in some circumstances, the phase interactions between this crossover and other crossovers in a home theatre system may be incompatible with some material. These interactions will always (***always!***) be present unless all speakers in the system have identical crossover networks - not just the same crossover frequencies, but identical networks, drivers and cabinet layouts.This is rarely (if ever) the case in reality.

- If you examine the output waveform, be aware that if your audio generator has more than 0.1% distortion, the high pass output will appear very distorted when you select a frequency more than one octave below the crossover frequency. This is *not* a fault of the crossover. Because the fundamental is attenuated the most, the harmonics are effectively increased by 24dB (for the second harmonic) and about 36dB for the third. This makes the output waveform look very distorted, yet your input signal will appear to be clean on an oscilloscope. It is difficult to see any distortion below 1% on an oscilloscope, but this amount of distortion will make the output look very nasty indeed. Do not despair - all is well.

ESP Linkwitz-Riley Component Calculator

The completed Linkwitz-Riley component calculator is available for you to download. It includes the circuit diagrams for both the high-pass and low-pass sections, and has the following features:

- Calculate resistance from a known frequency and capacitance
- Calculate capacitance from a known frequency and resistance
- Calculate frequency from the resistance and capacitance values (good for checking after standard value components have been selected)
- Includes a chart for the E12 and E24 series. Capacitors generally follow the E12 series, and 1% metal film resistors are always available in the E24 series.
- Calculate the values as a low-pass, then select high-pass. The new values are displayed, along with the circuit.
- Calculates both 12dB/octave and 24dB/octave filters.

This program (ESP-LR12.EXE) is the actual executable file. This is version 1.2 of the program, and is just under 67k, so it is not too big. There are no setup programs or such like, so you simply have to decide where to put it, and create your own shortcut. Feel free to distribute the program to friends, since I have released it as freeware - just don't change the program in any way is all I ask.

The program requires the Microsoft run-time library file VB40032.DLL which can supposedly be obtained from Microsoft's web site (a link to the exact location can be found in the Downloads page) if it is not installed on your machine. Note that the program is 32-bit, so it won't run on pre WIN95 operating systems. The following is a guide as to where the DLL should be installed ...

Windows95/98 - c:\windows\system
WindowsNT - c:\winnt\system32
XP - c:\windows\system32

In all cases, the above assumes that the C: drive is the installation drive. This will usually be the case, but some installations may differ.

Note that although all care has been taken to ensure the file is virus free, ESP cannot absolutely guarantee that this is the case - I don't appear to have any viruses on my machine, but one cannot be too careful. As with all executable downloads, use your own virus scanner to check it before execution.

Elliott Sound Products **Glossary of Electronic Terms**

20 Nov 2000

Introduction

Many of the electronic terms you hear mean something to you already, and others will have you wondering. This list is far from complete, but should cover most of the more common terminology, and hopefully in a meaningful way.

Glossary of Terms

[A] [B] [C] [D] [E] [F] [G] [H] [I] [J] [K] [L] [M] [N] [O] [P] [Q] [R] [S] [T] [U] [V] [W] [X] [Y] [Z]

Algorithm: a set of mathematical "rules" applied to an input. Generally used to describe a section of computer code which performs a specific function

Alternating Current (AC): A current whose polarity alternates from positive to negative over time. The rate of such "alternations" is measured in cycles per second - more commonly known as Hertz (Hz)

Amp / Ampere: The basic unit of current flow

Ampere Hour (Amp hour, Ah): a measurement of the capacity of a storage medium (a single cell or a battery). A cell which can supply 1 Amp for 1 hour before it is discharged to a specified minimum level is said to have a capacity of 1 Amp hour

Amplification: a method for increasing the amplitude (or loudness) of electrical signals

Amplifier: An electronic device which generates a high power signal based on the

information supplied by a lower powered signal. A perfect amplifier would add or subtract nothing from the original except additional power - these have not been invented yet

Amplitude: the loudness of sound waves and electrical signals. Amplitude is measured in decibels (dB) or volts

Analogue to Digital Converter (ADC): A device that converts the infinite range of an analogue signal into discrete "steps". Normally, a good audio ADC will use sufficient "steps" to resolve the smallest musical detail. For CD, this is a 16 bit converter, having 65,536 discrete levels covering the most negative signal level to the most positive

Attenuation: the decrease of a signal's amplitude level over any distance during transmission or through purpose designed attenuators. Attenuation measures signal loss in decibels (dB)

Bandwidth: the measure of a range of frequencies containing an upper and lower limit

Battery: a bank of individual cells connected together to provide the required voltage

Binary: the basic counting system used in computer logic. Two values are available - 0 and 1. A zero is normally represented by a 0 Volt signal, and a one by a voltage of approximately 5 Volts - these levels are dependent upon the type of logic used

Binary Code: a coding scheme that communicates information by using a series of "1s" and "Os" that are represented, respectively, by the digital "ON" and "OFF" states

Bit Stream: the bit rate, or flow of information, between a sender and receiver in digital communication. Also called Digital Bit Stream

Bit: a unit of the binary code that consists of either a single "1" or "O."

Bus: a pathway that connects devices, enabling them to communicate. May be digital or analogue, including power and earth (ground)

Bypass: the practice of using (typically) low value capacitors to conduct high frequency signals either to earth or around a device with limited frequency range

Byte: a unit of the binary code that consists of eight bits. One byte is required to code an alphabetic or numeric character, using an eight-bit character set code

---

Cable: a type of linear transmission medium. Some of the common types of cables include: hook up wire, coaxial (shielded) cables, lamp amd mains cable, figure-8 (zip) cable and fibre optics

Capacitor: A pair of parallel "plates" separated by an insulator (the dielectric). Stores an electric charge, and tends to pass higher frequencies more readily than low frequencies. Does not pass direct current, and acts as an insulator. Electrically it is the opposite to an inductor. Basic unit of measurement is the Farad, but is typically measured in micro-farads (uF = 1 x 10^{-6}F) or nano-farads (nF - 1 x 10^{-9}F)

Cell: one section of a battery. The common carbon or "alkaline" cells used in battery operated equipment is an example

CMOS: (Complementary Metal Oxide Semiconductor) - one "family" of digital logic devices. Some CMOS devices can operate with power supplies from 3 Volts to 15 Volts - others are limited to the traditional logic 5 Volt power supply

Coaxial Cable: a metallic cable constructed in such a way that the inner conductor is shielded from EMR (electromagnetic radiation) interference by the outer conductor. Coaxial cable is less susceptible to more transmission impairments than twisted pair cable, and it has a much greater bandwidth; thus coaxial cable is used by most analogue and digital systems for the transmission of low level signals

CODEC: COder / DECoder - the component of any digital ssubsystem which performs analogue to digital and digital to analogue conversions

Colour Code: used to identify resistors and some capacitors, as well as wires in telephony. For telephone cables, the basic colour code for the first group of pairs is Blue, Orange, Green, Brown, Slate (grey), with white "Mates". The Mate is the most positive lead, and is the Tip connection

Compression (1): the component that joins together with a rarefaction to make a sound wave

Compression (2): the act of compressing (making smaller) a digital data stream - e.g. converting from 16 bit signals to 8bit signals. Most compression schemes are "lossy",

which is to say that some of the original data is discarded and cannot be reconstructed

Compression (3): a circuit used to restrict the amplitude variations of a signal (often combined with a limiter to set an absolute limit). Unlike digital compression, analogue compression can be "undone" to restore the original signal with little degradation

Crossover: A filter network which separates frequencies into "bands" which match the capabilities of the loudspeaker drivers within an enclosure

Crosstalk: a noise impairment when a signal from one pair of wires affects adjacent wires or one channel affects the adjacent channel

Cutoff Frequency: Normally defined as the frequency where the output from a filter has fallen by 3dB from the maximum level obtainable through the filter

---

dB - Decibel - (0.1 Bel): defined (more or less) as the smallest variation of volume detectable by ear. This is measured on a logarithmic scale, so a change of 3dB from 1 Watt is equivalent to 0.5 Watt or 2 Watts. A change of 10dB from 1 Watt is equivalent to 100mW or 10 Watts. In electronics, 0dBm is a reference value corresponding to 1mW at 600 Ohms - this equates to approximately 775mV. The threshold of sound is 0dB, and typical sounds can reach 140dB or more. Any prolonged sound above 90dB may cause hearing damage

Digital/Analogue Conversion: a method used to recreate an analogue signal that has been coded into binary data and transmitted as a digital signal.

Digital/Analogue Converter (DAC): a device used to generate a replica of the original analogue signal that has been coded into binary data and transmitted as a digital signal

Direct Current (DC): A current flow which is steady with time, and flows in one direction only

Distortion (1): Any modification to a signal which results in the generation of frequencies which were not present in the original

Distortion (2): Of phase, any modification of the phase relationship between two or more signals which causes the observed waveform to differ from the original

DSP: Digital Signal Processor - a dedicated computer circuit which performs complex changes or analysis on a digital signal, generally encoded from an analogue source

---

Electronic: The use of active electronic components (integrated circuits, transistors, valves etc) which require a power supply to function. Such "active" components will always be used in conjunction with passive components

Earth (1): also known as ground - commonly used to describe the chassis and other materials that provide a return path for power supplies and signals within any electronic device

Earth (2): also known as ground - a protective connection from wall outlet to equipment chassis to conduct fault currents away from human contact

Electromagnetic Interference (EMI): an unwanted (possibly interfering) signal emitted by any electronic apparatus. The emission of EMI is heavily regulated in most countries.

Electromagnetic Radiation (EMR): a transmission medium that includes radio waves and light waves.

Farad: the base unit of capacitance - equal to the capacitance of a capacitor having an equal and opposite charge of 1 coulomb on each plate and a potential difference of 1 volt between the plates (Abbreviation - F). The Farad is a very large value, and is more commonly referred to as the pico-Farad (pF, 1×10^{-12} Farad), nano-Farad (nF, 1×10^{-9} Farad), micro-Farad (uF, 1×10^{-6} Farad), and (less common) milli-Farad (mF, 1×10^{-3} Farad)

Filter: a circuit which is frequency dependent. The "pass band" is the range of frequencies allowed through, and the "stop band" is that range of frequencies which are blocked

Filtering: a process used to remove or accentuate specific frequencies or frequency ranges of a signal

Frequency: The rate at which an alternating current changes in a cyclic manner from positive to negative and back again (one cycle). The basic unit of measurement is the Hertz (Hz), which equates to one cycle per second

Frequency Modulation (FM): a modulation technique that records changes in an information signal by modifying the frequency of the carrier signal according to changes in the amplitude of the information signal.

Henry: The basic unit of inductance in which an induced electromotive force of one volt is produced when the current is varied at the rate of one ampere per second (Abbreviation - H)

High-pass: A filter which allows high frequencies to pass while blocking low frequencies

Hertz (Hz): the measurement of frequency. Hertz represents the number of cycles of an electrical signal measured in one second

---

Impedance: A load applied to an amplifier (or other source) which is not a pure resistance. This is to say that its loading characteristics are frequency dependent. Impedance consists of some value of resistance in conjunction with capacitance and/or inductance. The equivalent circuits can vary from two components to hundreds.

In-Phase: a condition of two waveforms when they cross the reference line at the same time and in the same direction.

Inductor: A coil of wire which exhibits a resistance to any change of amplitude or direction of current flow through itself. Inductance is inherent in any conductor, but is "concentrated" by winding into a coil. An inductor tends to pass low frequencies more readily than high frequencies. Electrically it is the opposite of a capacitor. Basic unit of measurement is the Henry (H), in crossover networks it will typically be measured in milli-henrys (mH = 1 x 10^{-3}H) and for RF micro-henrys (uH) are common

Insulator: A material that prevents the passage of electricity, heat or sound. The plastic coating on wires is an insulator, preventing the wires from coming into electrical contact with each other. Insulators are extensively used in electronics. Most good electrical insulators are also good thermal insulators

Integrated Circuit (IC): A collection of active and passive devices (e.g. transistors and resistors) mounted on a single slice of silicon and packaged as a single component. Examples include operational amplifiers, Central Processing Units (CPUs), random access memory (RAM), etc.

Intermodulation Distortion (IMD): the intermixing of two frequencies. It is often caused by non-linear distortion within an amplifier or loudspeaker system

---

Laser: Light Amplification by Stimulated Emission of Radiation. Originally, lasers were either gas or precious stone (e.g. ruby), but are now made using semiconductors. Laser light is coherent, meaning that the emitted light waves are in phase, which gives the light a strange appearance since our eyes were never designed to observe coherent light

Low-pass: A filter which allows low frequencies to pass while blocking high frequencies

---

Octave: Musical terminology, meaning the doubling (or halving) of frequency. For example, one octave above "Concert pitch" A440 Hz is 880Hz, and one below is 220Hz. Musically, each of these frequencies is "A"

Oscilloscope: An electronic measurement tool which allows one to view a waveform. The vertical axis shows amplitude and the horizontal axis shows time

---

Passive: Containing no devices which require a power supply. Passive devices include resistors, capacitors and inductors

Phase: Hmmm. Tricky..... Ah-ha! Think of a bunch of soldiers all marching happily (?) to the sergeant's cries of "Hep, rah, hep-rah-hep" - except for Pt. Johnny who is blissfully "Rah, hep, rah-hep-rah"-ing. He is 180 degrees out-of-phase with the rest (or vice-versa). So it is with musical signals, where some signals have a "phase angle" (phase is measured in degrees of rotation) which is different from other signals

Power Amp: An amplifier that is designed to drive loudspeakers or other relatively low impedance loads. Usually combines voltage and current amplification. May be integrated with the preamp (see below)

Preamp: Multiple meanings, but in hi-fi generally refers to a separate section of circuitry that includes source switching, volume and balance controls (as well as tone controls in many cases). Used to raise the level from tape decks, turntables, CD players and other music sources to a level suited to the power amplifier

---

Quasi: to some degree or in some manner, resembling. For example, a quasi complementary-symmetry output stage in an amplifier is *not* in fact complementary-symmetry, but appears to be, and acts in a similar manner

Quiescent: being still or at rest, in an inactive state. The *quiescent* current in an amplifier is that current drawn when the amplifier is "at rest" - i.e. not amplifying a signal, but supplied with power

---

Resistor: An electrical device which impedes (resists) current flow regardless of frequency. Basic unit of measurement is the Ohm

Resonance: The natural frequency at which a physical body will oscillate. An example is when you blow gently across the top of a bottle, the enclosed air resonates at a frequency determined by the internal volume. Also refers to the natural resonance of loudspeaker drivers, cabinets and ports, or the frequency where an inductance and capacitance have the same impedance (this causes maximum impedance with a parallel circuit, and minimum impedance for series circuits)

rms: Root Mean Squared. Applies to voltage and current, but is commonly (although incorrectly) applied to power. Defined as an alternating voltage (or current) which has exactly the same energy content (power) as the same value of direct current

---

Thermal Coefficient (1): Of expansion, describes the amount by which a material expands when heated. Commonly expressed as a percentage per degree Celcius so the exact size at various temperatures may be calculated. Knowledge of the expansion characteristics of different materials is important in high power semiconductor manufacture, since differing expansion rates may cause device failure due to temperature cycling fractures

Thermal Coefficient (2): Of resistance, describes the change in resistance at various

temperatures. Most metals have a positive temperature coefficient of resistance, which means that the resistance increases with increasing temperature. Carbon and some alloys have a negative temperature coefficient of resistance, so as temperature is increased, resistance decreases

Thermal Resistance: The resistance of various materials to the passage of heat energy. Most electrical conductors are also thermal conductors, with the higher electrical conductivity materials usually having higher thermal conductivity. Important in the design of high power electronics, heatsinks, semiconductor casings, etc.

Total Harmonic Distortion (THD): the sum of all amplifier distortion components, plus system noise. THD measurements are sometimes quoted as THD+noise. Usually measured at specified frequencies and power levels

---

Velocity: speed of motion or rapidity. In audio and electronics, we are concerned with the speed of a signal in air and a conductor. Speed (velocity) of sound in air is approximately 345 metres per second at sea level, but it varies with temperature and humidity. Speed of an electrical signal in a wire is approximately 3×10^8 metres per second, but may be influenced by ...

Velocity Factor: a situation that occurs in conductors that are close to another conducting material. For example, a coaxial cable has an inner and outer conductor, with insulation between the two. The velocity factor of such cables varies from 0.7 to 0.9 (i.e. the signal travels slower than in free space)

Volt: The basic unit of "electromotive force". One Volt applied to a resistance of one Ohm will force a current of one Ampere to flow (Abbreviation - V)

Watt: The basic unit of power. 1 Volt across 1 Ohm (giving 1 Amp) dissipates 1 Watt (all as heat with a resistive load)

Wavelength: the length of one cycle of an AC signal. Determined by $Wavelength = c / f$ where "c" is velocity and "f" is frequency. The wavelength of a 345Hz audio signal in air is one metre

---

Xenon: A gas commonly used in flash tubes, HID (High Intensity Discharge) automotive headlamps, and having an intense white light output with a colour temperature close to that of daylight

Speaker Damage

This is the old "how does clipping blow up a woofer" problem. I know that woofers rarely blow up, even with severe overload, and in essence they seem to be immune (although that might overstate things a bit!). This is (or would be) true, but for one small detail. Few speakers (including woofers) can tolerate their full rated power on a continuous basis. The rating is more for "amplifier power" than speaker power.

Imagine that a 100W amp is just on the verge of clipping with a full range or band limited signal. Although the amp will be peaking at 100W, the average power will be closer to 5-10W, or maybe a little more or less depending on program material. If you push the amp harder, the peaks will clip, which you might not even notice if the mid+high is still clean. The average power may be 50W or so now, and the speaker's voice coil will start to get quite hot. Push it harder again, until even the lower level signals are clipping too, and the average power is now well over 100W.

Note that a 100W amp driven with a square wave or severely overdriven sinewave will give close to 200W. This problem is worse with semiconductor amps than valves, because valves have inherent inefficiencies that reduce the maximum output.

If this is kept up for too long, the voice coil will literally burn up from the heat, the adhesive lets go of the voicecoil windings, and the whole assembly starts to disintegrate. Exit one woofer.

Having said all this, it still doesn't happen too often, but generally you are better off with an amp that is rated for more power than the speaker can handle, rather than less (except for guitar, but guitar amps are driven into clipping a lot (most) of the time).

There are - naturally - limits. A 10W woofer won't last long with a 300W amp driving it at anywhere near full power on transients, but a 100W woofer will last forever with a 10W amp in permanent overload. Some common sense must be applied, but a typical 100W woofer will probably last forever with a 200W amp used sensibly.

The comment above is aimed more at the risk of tweeter damage, but it can happen with midrange drivers and woofers too, given the right (or wrong) set of circumstances. One issue with many modern recordings is excessive compression, and this can increase the average power level dramatically, even before amp clipping.

It is worth noting that tweeters are rarely blown up just by the additional harmonics generated when an amp clips. Although they are undeniably present (and sound undeniably terrible), the actual power of the harmonics is not as high as you may have been led to believe. It is the

combination of these harmonics and the "compression" effects described above that do the damage, and clipping compression is the greatest offender.

Loudspeaker Protection and Muting

Rod Elliott (ESP)

Introduction

Please see Updates 1, 2, 3, 4 and 5 on this project.

Many hi-fi amplifiers and professional power amps (and loudspeaker systems) provide some of protection, either to protect the speakers from an amp fault, and/or vice versa. Some of these are implemented at a very basic level - for example the use of a "poly-switch". The poly-switch is a non-linear resistor, having a low resistance at normal temperatures and a much higher resistance at some designated temperature. Unlike "ordinary" thermistors whose characteristics are more or less linear, the poly switch has a rapid transition once the limit has been reached.

I don't like poly-switches, because I know that the introduction of a non-linear element is going to add some degree of distortion, and because of a finite resistance, will degrade damping. This (i.e. damping) is not an issue IMHO, but to many audiophiles it is of prime importance. (I shall not pursue this argument here, however - see Impedance for more info.)

The basic requirement of a speaker protector requires that any potentially dangerous DC flow to the speakers should be interrupted as quickly as possible. There are a few issues that need to be solved to ensure that this will happen fast enough to stop the loudspeaker drivers from being damaged, and this becomes more critical if a biamped (and even more so with triamped) system is being used.

Naturally, one can simply rely on fuses. Although these also have finite resistance it is small, and use of fast blow fuses can be quite effective. The rating becomes quite critical, and fast blow types are essential. The problem with this approach is that if the fuse is of a suitable value to provide good protection, it will be subjected to considerable thermal stress since it is operating at close to its limits. Metal fatigue will create the problem of nuisance blowing,

where the fuse blows simply because it is "tired" of the constant flexing caused by temperature variations.

This project explains the principles, and shows a suitable detection method that may be applied. The speed of the relay used is another critical factor, and we shall see that the conventional method of preventing the relay's back-emf from destroying the drive transistor also slows down the response to an unacceptable degree.

The circuit also includes a mute function, which leaves the speakers disconnected until the amplifier has settled, and disconnects the speakers as quickly as possible after power is removed to prevent the turn-off noises that some amps generate. These can range from a low level thump 5 to 10 seconds after power is turned off, to whistles, squeaks and other strange noises that I have heard from amps over the years.

Description

It is important to identify the lowest frequency likely to be passed to a speaker, because this determines the delay that must be introduced to prevent low frequencies from triggering the protection circuit (nuisance tripping). For practical purposes, a low frequency limit of 20Hz is satisfactory for a full range system, and this means that a minimum 25ms delay is essential. In reality, due to the combination of low frequencies, and asymmetrical waveforms at higher frequencies, a greater delay will normally be required. Unfortunately, the greater the delay, the greater the risk of drivers being damaged. In a full range system (i.e. using passive crossovers), midrange and tweeters will be offered some protection by the capacitors used in the crossover network, but these are missing in a biamped or triamped system. For this reason, it is important that the circuit can be easily modified to change the initial time delay before the system detects the DC and disconnects the speakers.

The Detector

This is the most important of the functions. It must be capable of detecting a DC offset of either polarity, and be immune to the effects of asymmetrical waveforms and low frequencies. This is a common requirement, and it is most expedient to use a simple (single pole) filter to keep the complexity to a minimum. With this arrangement, a low frequency cut-off of about 0.1Hz is about right. Without boring you with the mathematics behind this, it works out (eventually) that a filter having a time constant of 1.0s will still provide the ability to detect high level DC reasonably quickly, but allow low frequencies through without triggering. With this, the relay could have its supply removed within about 50ms from the time the output voltage reaches the supply rail (this is supply voltage dependent) - due typically to a shorted transistor in the output stage. By changing the time constant of the filter, we can adapt the circuit for operation at other higher frequencies to suit a biamped (or triamped) system.

The detector can be built using an opamp, and will work very well, but this introduces the need

for low voltage supplies within the power amp. This is not always possible (or desirable), so the design uses discrete transistors throughout to allow for the different supply voltages found in typical power amplifiers.

The detector circuit shown in Figure 1 (1) is simple and works well, and as shown will not trigger with a 30V RMS signal at 5Hz, but operates in 60ms with 30V DC applied, and in 50mS with a 45V DC supply. This should be sufficient for most applications, and allows the use of a non-polarised electrolytic capacitor in the filter. These are cheap, small and quite adequate for this purpose.

NOTE: *The power supplies (+ve and -ve) shown in these diagrams will normally be the power amp supply rails. Do not try to substitute different supplies unless you know exactly what you are doing, or the circuit may not work properly. This is especially true of the muting circuit, but incorrect supplies will (may) also affect the DC detection circuit. Like most of my projects, this is intended for experienced constructors.*

Updates 1 & 5: The original circuit could damage Q3 under some conditions due to excess base current. To remedy this, a resistor must be added between the collector of Q1 and the base of Q3, as shown in the amended diagram. This prevents excess base current if the gain of Q1 or Q2 is higher than expected. My thanks to Vince for pointing this out.

21 Mar 2003 - Q3 was shown as an NPN transistor, but was marked as a BC556 - this was wrong. It is a PNP, and the symbol was incorrect. The type shown (BC556) was correct. This is now corrected (thanks David ;-)

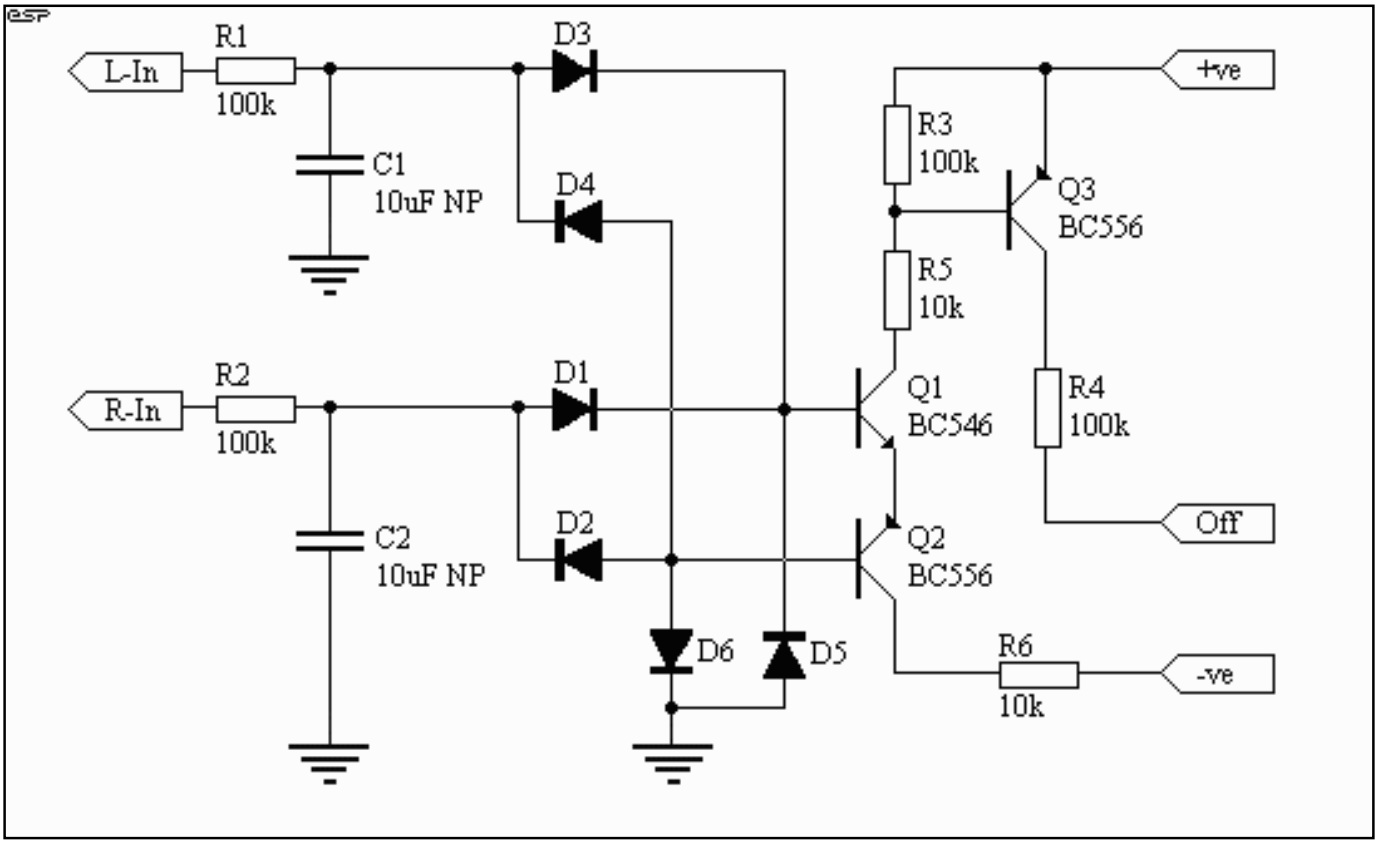

Figure 1 - Basic DC Detector Circuit

Update 4 (18 Dec 2002): It has been found by a couple of people that the detector transistors will self destruct under some conditions. The addition of R6 in the negative supply prevents this. The PCB version uses a single transistor detector and does not have this problem.

The input filter is a simple single pole (6dB/ octave) version, and although it would seem that a "better" filter would be preferable, a two pole (or more) filter will actually degrade the DC detection. This basic circuit is not new (see reference), and has actually existed in one form or another for some time. It is ideally suited for our requirements, as it is symmetrical, and with the input diodes as shown, a single detector can be used with multiple amps and different input time constants for each individual filter. The unit itself can operate on a separate supply if desired, so the complete protection circuit can be in a separate enclosure. Regulated supplies are not needed, and no hum or other "artefacts" are introduced into the speaker lines. (Please see NOTE above.)

The table (below) shows some suggested values for the filter, for use in bi- and tri-amped systems. You will need one filter and two diodes for each amplifier channel connected, and a suitable number of relay contacts to handle them all. In some cases, this will mean multiple relays.

Frequency (Hz)	**C1 Value**
Full Range	10 uF (non-polarised)
100 Hz	1 uF
300 Hz	330 nF
1 kHz	100 nF
3 kHz	33 nF

The resistor should be left at 100k for all frequencies. Do not use a conventional electrolytic capacitor for C1, because any small reverse bias will eventually ruin it. You may discover that with some types of music (especially if at high volume) may cause the circuit to false trigger. If this happens, increase the value of C1, up to a maximum of 47uF. Anything higher than this will slow down the response unacceptably.

Relay Specifications

The relays should be easy enough to obtain. At least one of the Australian component suppliers has relays that are quite suitable, but they are not particularly cheap. The current

rating is very important, and assuming a supply voltage of +/- 40V, this will cause a current of about 6A in an 8 ohm speaker if a transistor shorts. Although 6A may not sound like much, it is at DC, and because there are no periods of 0V as with AC, the arc is longer, fatter, and far more destructive of contacts than the same current using AC.

Do not be tempted to use miniature relays, because if the normal AC speaker signal is too far in excess of the relay contact rating, the contacts may become welded together - this will almost certainly happen if the DC rating is too low. You also need to consider that contact resistance is additional resistance in the speaker lead and may affect damping (albeit very marginally) and will introduce some small power loss, and the miniature types will not be suitable in this regard.

I had a look in the catalogue of one Australian supplier, and they have several relays with a 10A contact rating. I would suggest that anything lower is unwise for long term reliability. Most of the commonly available relays will have a 12V coil, and this will cause problems if the supply voltage is 30V or more. Power relays often draw significant current (typically > 60mA), and it will usually be best to connect the coils in series.

Update 1: A reader (I cannot recall who it was so I can't give the credit) mentioned that in some areas there is significant sulphur content in the air, and this causes heavy tarnishing of silver contacts. If you live in such an area, it would be advisable to obtain hermetically sealed relays if possible, to prevent the contacts from tarnishing.

It is well known that the current required to activate a relay is far greater than that needed to keep the contacts closed, and a common trick is to use an "efficiency" circuit to minimise the relay holding current. I do not feel that the additional complexity is warranted, and have not included this facility. If you really want to do this properly, see reference 1 (below). It has been claimed that an efficiency circuit also speeds up relay drop-out time because of the lower stored magnetic field. I conducted some tests, and the savings are marginal at best, although this could be different with different relays.

Figure 2 shows the relay activation circuit, and includes the connection for the mute and protection signals. No components are critical, but some will need to be modified based on the relays used. I have assumed that a minimum of two relays will be needed (one for each channel), and this increases the total relay coil voltage to 24V. If you are going to use more than two (for example, four single pole relays are needed for a biamped system), then if the supply voltage is 48V or more, all 4 relays can be connected in series. In most cases you will need to work out the value of a suitable dropping resistor from the formula below.

The terminal labelled "Off" is common to all three modules, and these points are simply joined together, as are the +ve and -ve supply connections. A positive current into the Off terminal will de-energise the relays, by turning on Q1. This steals all the base current for Q2, which

then turns off, as does Q3.

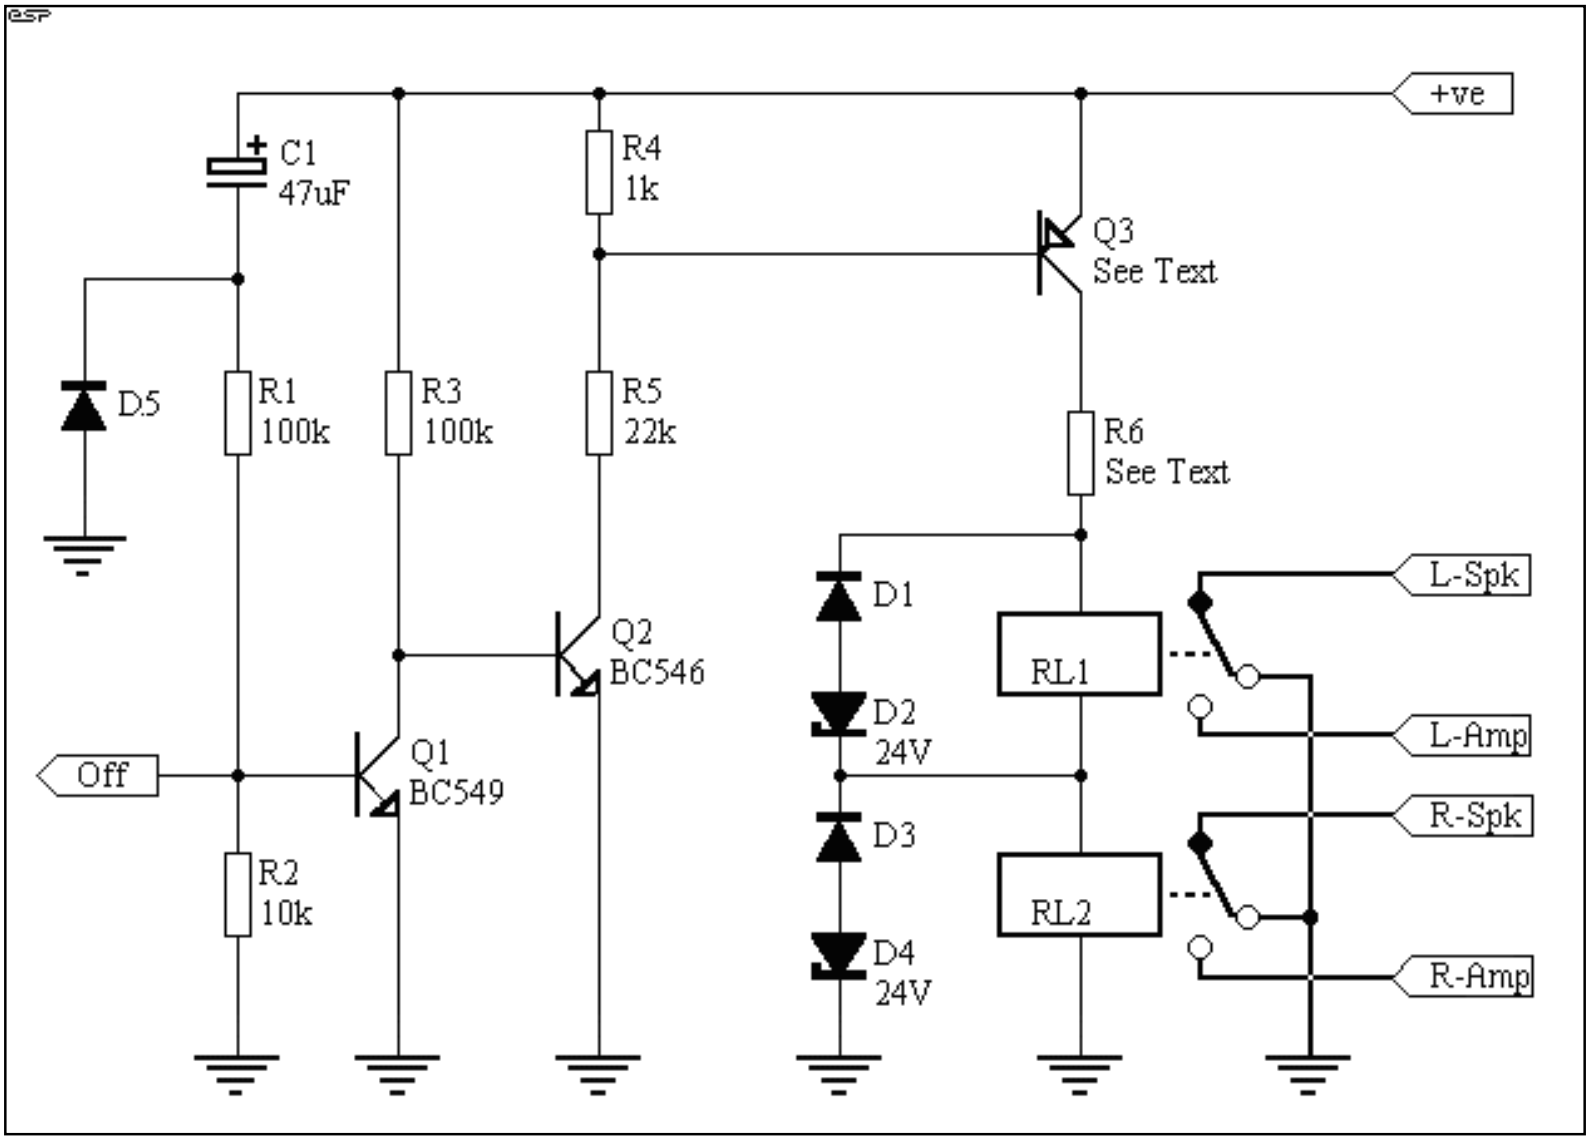

Figure 2 - Relay Activation Circuit

The relay(s) must be turned off in the shortest possible time, so the use of the normal protection diode across the coil should not be used, as it slows the response considerably. Instead, the arrangement shown still protects the driver transistor, but allows the relay magnetic field to collapse without generating a current in the coil (this the what slows the relay's release). I cannot predict the exact delay you will achieve, since the choice of a suitable relay is outside my control. You will have to pester and annoy your local suppliers to find a relay that has suitable characteristics, and be prepared to pay what will seem like an obscene amount of money for a simple electro-mechanical device.

D5 (a late addition) will discharge C1 as the supply collapses. It will not help much in the case where someone switches the power off then straight back on (not that anyone would do that!), but will reset the circuit much faster than would otherwise be the case. My thanks to Vince for the idea.

Update 3 (10 Aug 2000) It has been brought to my attention that the DC arc can (and does) destroy even 10A relays under some circumstances. To provide greater speaker protection, the relay wiring in Figure 2 has been modified to short the speaker to earth in case of a fault. This way, even if the contacts do arc it will be directly to earth. This is much safer (for the speakers), and the arc to earth will blow the fuse a lot faster than if an 8 ohm load is a part of the circuit. It is strongly recommended that this new scheme is used as a matter of course. It is worth noting that any DC protection system that does *not* use this method will almost certainly fail to protect the speakers with a medium to high powered amplifier. (My thanks to Phil Allison for the information.)

Note also that this circuit cannot be used as shown with the 12V relays in series if the supply voltage is less than +/-24V (but you knew that already ;-)

In order to work out the value of R6, subtract the combined relay voltage from the supply voltage (you must know the relay coil current!). To calculate the coil current from its resistance, use the following (I have assumed a 40V supply for the examples):

I = V / R Where V = coil voltage and R = coil resistance

So for a 180 ohm coil (fairly typical) this works out to

I = 12 / 180 = 67mA

The resistor value is worked out with:

R = V / I Where V = the "left over" voltage from the subtraction and I = coil current

You will also need to work out the power rating for the resistor:

$P = V^2 / R$ Where V is the voltage and R is the resistance

Again, for the above example, this works out to

R = (40 - 24) / 67mA = 16 / 0.067 = 239 Ohms (220R should be fine)
P = (16 x 16) / 220 = 1.16W

So for an adequate safety margin, a 2 Watt resistor should be considered the minimum (5W would be better).

To determine the transistor for Q3, add the supply voltage and the zener voltages to give the maximum collector to emitter voltage. In this case it is 40 + 48 = 88 Volts, and I would suggest that a transistor with a breakdown voltage of at least 100V be used to give some

safety margin. The MJ350 (300V rated) will be suitable in nearly (if not) all applications, or you can use a MPSA92 - lower current, but still has a 300V rating.

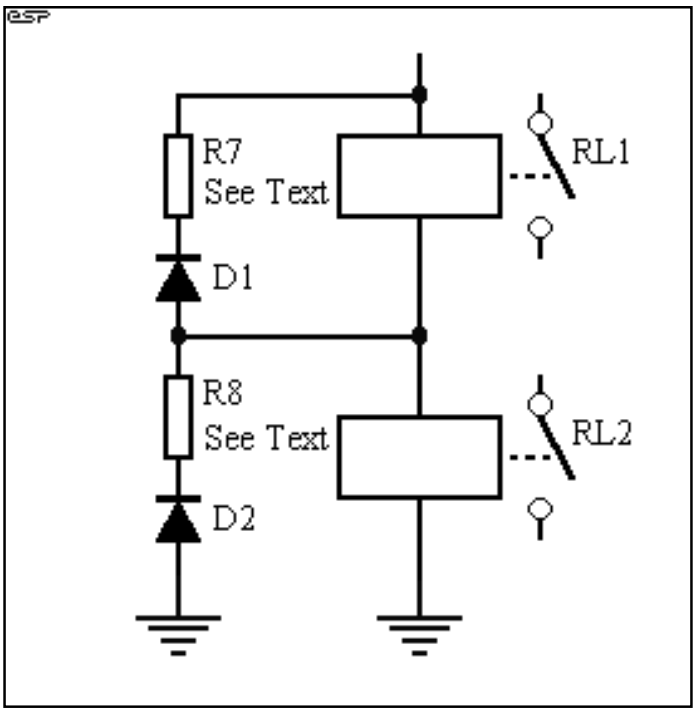

Figure 16a - Alternative Back-EMF protection

Figure 16a shows an alternative method you can use to damp the back-emf from the relay, but to implement it properly, access to an oscilloscope is helpful (if not essential). If the resistors have approximately the same resistance as the relay coils, the back-emf should (!) be limited to about the normal relay voltage, give or take 50% or so. In the tests I carried out (see Tests, below) using a 24V relay, the back-emf was limited to about -30V, which would be fine in most cases.

This method is slightly cheaper than using zeners, but is less predictable. An additional alternative is to use a catch diode to the -ve power supply. A 1N4004 between the top of the relay string and the -ve amp supply will limit the back-emf to the voltage of the -ve supply, so for the example case this would be -40V. I expect that this would be quite acceptable, but have not tried it. Make sure that the diode is connected the right way around - the cathode goes to the top of the relays, and the anode to the negative supply.

Muting

Since we have all this new circuitry, it is most worthwhile to incorporate a muting function, so that when power is removed from the system, the relay will open to stop turn-off transients from being heard. Likewise, we will normally want to mute the system for about 2 seconds after power is applied to stop the turn-on transients as well. C1 and R1 in the circuit of Figure 2 provide the turn-on delay, by supplying current to the "Off" terminal as C1 charges. Once charged, the current falls to zero, and Q1 turns off, allowing Q2 and Q3 to turn on, thus

energising the relays. (Note that this timer will not be reset if the power is turned off and back on again quickly, but since this is a procedure that should be avoided anyway, no provision has been made for it. :-)

To be able to do this effectively, we must have access to the AC from the power amp's transformer, or have the external unit controlled by the main power switch in the system. In some hi-fi installations, there will be a multiplicity of different units to turn on (and off) each time the system is used. I will leave it to the reader to decide which unit to use as the control, but would suggest that where a separate preamp is used, this could be an ideal controller for the entire system. It is unfortunate that hi-fi has not followed the sensible approach of a lot of computers, with a switched IEC connector on the back of the preamp to control power amps and other outboard devices. (I did this on my VP-103 valve preamp, and it is most useful :-)

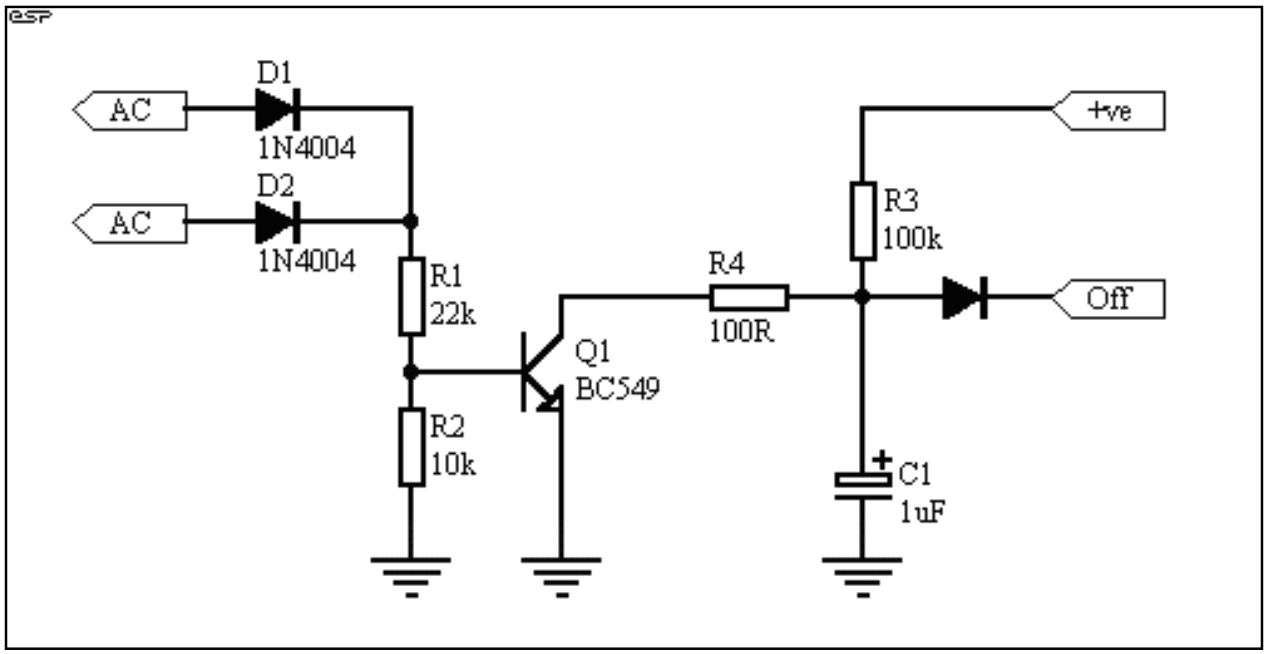

Figure 3 - Loss of AC Detector

The power detector cannot rely on the DC supply, as this may take a considerable time to collapse. The common approach is to use a rectified but unsmoothed output from the transformer secondary. Because it is not smoothed, this disappears instantly when power is removed, and is ideal. Figure 3 shows the basic circuit, and this will remove relay drive within about 50ms of the power being turned off. We could make it faster than this, but there is little point.

The circuit simply uses the current pulses to keep a capacitor discharged via Q1. When the pulses stop, the cap charges until the threshold voltage of the "Off" terminal is reached (0.65V), and the relays are turned off. After power is first applied, the timer circuit will activate the relays after about 4 seconds (typical). This can be increased if desired, by increasing the value of C1 in Figure 2.

Tests

I carried out some tests to see just how quickly the relays could be operated. The results were something of an eye-opener (and I *knew* about the added delay caused by a diode!). The relay I used was a small 24V coil unit, having a 730 Ohm coil and with substantial contacts (at least 10 Amps). With no back-emf protection, the relay opened the contacts in 1.2ms - this is much faster than I expected, but the back-emf went straight off the scale on my oscilloscope, and I would guess that the voltage was in excess of 500V. When a diode was added, the drop-out time dragged out to 7.2ms, which is a considerable increase, and of course there was no back-emf (Ok, there was 0.65V, but we can ignore that). Using the diode / resistor method described above, release time was 3.5ms, and the maximum back-emf was -30V, so this seems to be a suitable compromise.

I was not able to test the zener method prior to publication, since I did not have the 24V zeners needed on hand. I would expect this scheme to be as good or better than the diode / resistor combination. The graphs below show the behaviour of the circuit with and without the resistor and diode. The estimated 500V or more is quite typical of all relays, which is why the diode is always included. This sort of voltage will destroy most transistors instantly. It is exactly the same process used in the standard "Kettering" ignition system used in cars, but without the secondary winding, or the "flyback" transformer used in the horizontal output section of a TV set.

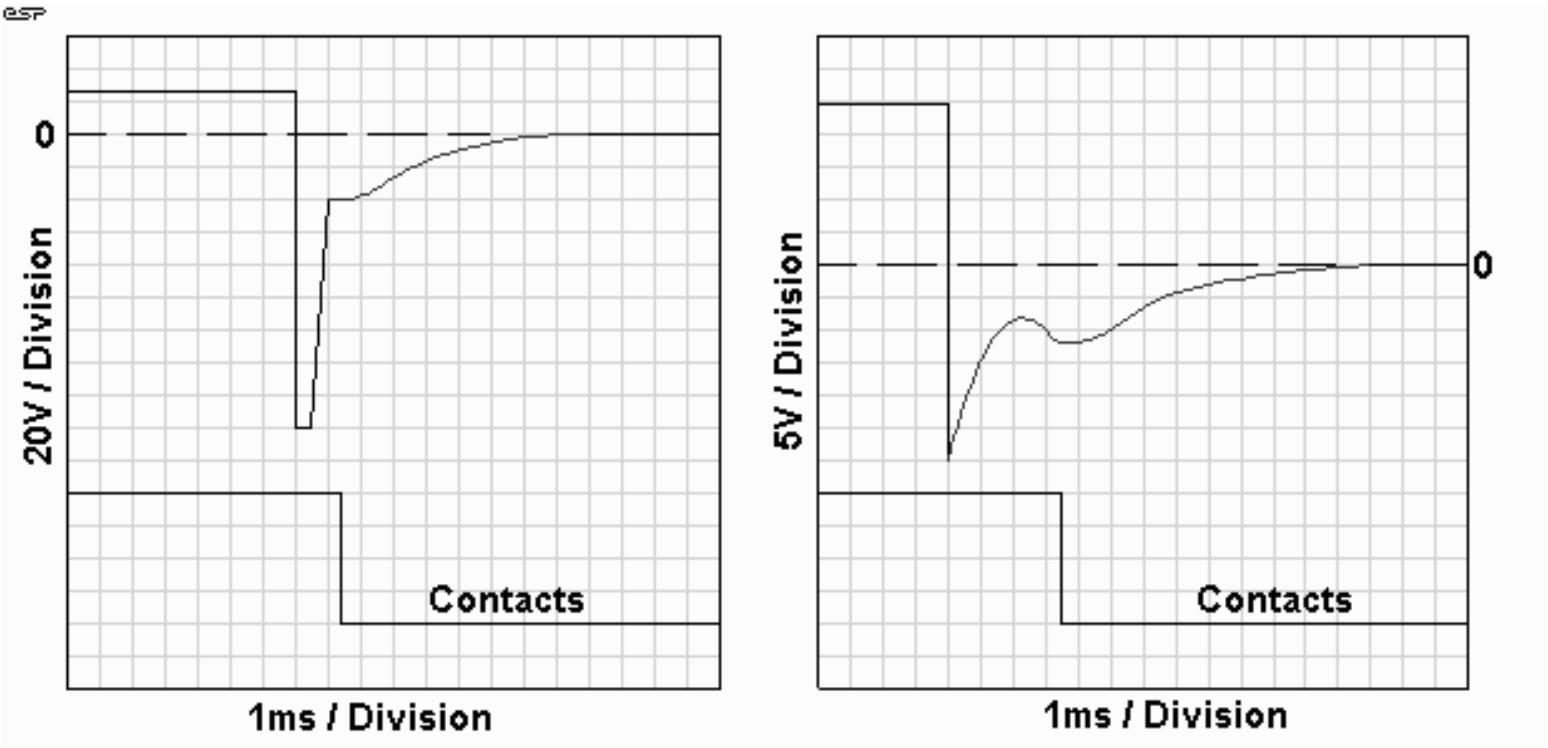

Figure 4 - Relay Voltages

The trace labelled "Contacts" is representative only, and is not to scale. The peak relay voltage (above left) exceeded my oscilloscope's input range (and I was too lazy to set up an

external attenuator), and as shown is cut off at my measurement limit. I estimate that the voltage is greater than 500V.

Note that the kink in the relay voltage curve is caused by the armature (the bit that moves) coming away from the relay pole piece, and reducing the inductance. This causes the stored magnetic "charge" to try to increase the voltage again, but it is absorbed by the resistance and dissipated quickly. The contacts open at the point where the previously closed magnetic field is opened as the armature moves away from the pole piece. As can be seen, this is 3.5ms after the relay supply is disconnected.

These graphs are representative only, as different relays will have different characteristics. As noted above, I cannot predict what sort of relay you will be able to obtain, but the behaviour can be expected to be similar to that shown. All tests were conducted using a 24V relay, having 10A contacts. Upon contact closure, I also measured 2.5ms of contact bounce. Provided your amplifier is stable by the time the contacts close, this will be completely inaudible.

C Thanks for your comments. Bi-amping is something that not very many people understand, no less the average bride or groom looking for a DJ for their wedding reception. You are exactly correct when you said it doesn't tell the whole story. If we went into the detail that your web site has, people would get completely lost. Most don't understand two speakers versus four, let alone bi-amping.

Bottom line, bi-amping creates a better sound, you know it, I know it and we are one of only a few DJ services in the Twin Cities that does it this way.

C I just read your article on bi-amping, and I'm quite impressed. I don't think you left anything out! I am writing to congratulate you an a particularly easy (and entertaining) to read article. I am a devotee of the bi-amping principle myself, and I am currently building my third set of loudspeakers. This time, it's a no-compromise design. It will, naturally, be bi-amped, though I'm beginning to think that it'll have to be tri-amped.

Q What a fascinating web site! Rarely do I come across folks on the web who know how to articulate and present an argument as well as you have done.

This is not to say that I agree with everything you have said, I am still digesting some of your comments about damping factors and remain a little sceptical about the advantages of bi-wiring but your web site was immediately bookmarked under the "good" list!

In your career have you done any lecturing or other form of teaching?

My own 5.1 HT system at home runs 2nd order crossovers somewhere in the region of 2200Hz and the intelligibility is woeful (not helped by poor choice of operating bands for the drivers). I am going to bite the bullet and do a Bi-Amped system. actually, Tri-Amped, since I already run an active 4th order LP crossover into the sub channel.

I am very interested in hearing more about your idea's on minimum phase active crossovers - any further light you can shed on this? I am an Electronics Engineer by Profession by definitely *not* by experience, so my expertise is a little limited. I work in the Telecommunications industry in management now...

A *I don't recall suggesting that you agree, but thanks for your comments.*

I am (at the time of writing - this has since changed) a "technical training engineer" (telecoms speak for teacher), but I was previously invloved in teaching real electronics and audio.

Regarding bi-wiring - I know I bagged it, but it is still better than running the whole shebang down the one set of cable. It does rely on the amp having a good damping factor, but if you look at the specs closely, you will see that damping factor dies as the frequency increases. This is because of internal frequency limiting in the power amp (required to prevent the amp's phase shift exceeding 360 degrees while it still has gain - Murphy's Law - amplifers will oscillate, and oscillators will amplify).

There are some phase coherent designs, but many rely on subtraction - it works, but gives a lopsided crossover response (e.g. 12db/6db) - these were originally described in various magazines over the years, but they can a lumpy response across the xover frequency.

C Just stumbled across your website. Very interesting, especially since I am currently designing a system that conforms to (most of) your beliefs expressed on the page!

I already built an active filter (simple 2th order Sallen-Key, Butterworth) that works but I'm always looking for improvement! The next version might be implemented on a DSP, if that doesn't bite my budget too much.

Keep up the good work.

Q I have been thinking about implementing active cross-overs in my system and came across your web-site. It makes interesting reading and, as I intended starting with only an active low-pass for bass frequencies, is exactly in line with my intentions. I see that you have designed and built your own active crossover; is your circuit publicly available? My speakers (KEF R105) have a completely separate low-pass filter in the low frequency driver enclosure, and I would like to eliminate this completely but am a bit reluctant to because of the nature of the filter. I believe that the filter is shaping the loudspeaker response as well as limiting its supply of higher-frequency signals. Have you taken this into account? It's an interesting article you've written and I look forward to your updates.

A *As regards active crossovers - go for it. Project 09 is the recommended design. Regarding your speakers, all filters shape the response of subsequent stages, it's a matter of minimising the "damage", and this is where active crossovers can make a huge difference. For starters, you get rid of the large bass frequency transitions from the amp, so intermodulation distortion is reduced - this is one of the main contibutors to a "muddy" sound. Problem is that it gets a bit expensive, but that's hi-fi.*

C Thank you for your very thorough and interesting WEB article "Benefits of Bi-Amping". After reading "Benefits of Bi-Amping", I have implemented the following Bi-Amplification HIFI system to drive a pair of JM Megane loudspeakers.

- Integrated Amp: NAD 317 (with Vampire P#YF RCA Adapter on the PRE-OUT connectors to allow multiple power amplifier connection).
- Second Power Amp: NAD 214 (duplicate of the power amplifier in a NAD 317).
- The JM Megane has two drivers, a 1.5 in. inverted dome tweeter and a 7 in, woofer with dual voice coils configured as a 3-way system with crossover frequencies at 3.5 kHz (18 dB/octave) and 1 kHz (6 dB/octave).

This HIFI system began with the NAD 317 integrated amplifier - It was very acceptable beginning ... a good sounding system. I then implemented Bi-Wiring.

Bi-Wiring produced a noticeable improvement in sound stage and detail. I have learned that Bi-Amplifcation should allow for an even more dramatic improvment in sound because this technique is much more efficient in reducing Intermodulation Distortion (undesirable modulation of the high frequency signal by the low

frequency signal) than simple Bi-Wiring.

So far, I have observed that the Bi-Amplifcation has dramatically improved Bass (2nd Amp??) and additional improvement in sound stage over the Bi-Wire system. Bi-Amplifcation also seems to have changed the character of the sound presentation ...

I think I now know what is meant by sound having a liquid like quality.

R *I'm not at all surprised that you experienced a fairly dramatic change in sound quality, this is exactly what I was waffling on about in the article. As for further improvements, I can only suggest that you keep experimenting - there are so many variables in any amplifier/speaker system that you can probably keep yourself occupied for years!*

One thing to be careful about when bi-amping a two-way:- Make absolutely sure that no DC is present at the amplifier speaker terminals (this can arise when the amp is powered on or off, and is usually only fairly brief). Tweeters are not forgiving of even small amounts of DC, and to be safe you should use a capacitor in series (I can't suggest an accurate value, since I don't know the crossover frequency, but I would think that you would need about 20uF or so as an absolute minimum. This will create its own crossover at about 995Hz (for an 8 ohm speaker) and would be (just) ok if you are crossing over at 5kHz or above. If the value is too low, it will create its own phase problems, and if too high, will allow low frequency "surges" to pass through to the tweeter. Only problem is that suitable high value polyester type caps are expensive !!!

C Thank you for writing an excellent article concerning biamping and putting it on to the web for all to see/understand/enjoy. You have confirmed my belief in biamping as an alternative to standard passive xovering. One of the problems I've seen (as a speaker builder) is the complex passive xovers with all the Zobel junk in them. I've seen speaker designs that the xover cost MORE than either one of the drivers (sometimes more than both the drivers). Seems kinda crazy to me. All that loss with the inductors, etc you get with xovers greater than 6 db/ octave.

I'm currently designing a biamped (and eventually a tri amped) system. I'm trying to fully understand the whole section concerning xover freq. I understand the critical range of human hearing part as an area to try to avoid an xover. I'm planning to use one of Vifa's nice 6 1/2" woofers (P17WJ-00-08) xovered to a Morel MDT30 tweeter. The tweeter is good down to just below 2Khz. The Vifa looks good (flat response) to almost 5Khz. Your recommendations make it sound like I should xover at the higher freq, like 4Khz or even 5khz. The pblm I see with most woofers is the not so good response curves for off axis. The Vifa's published specs show the 30 degree response curve start to break away about 3Khz from the on axis curve. By 5Khz, they are approaching 10 db difference. Therefore, before reading your article, I was planning a 3Khz active xover to reduce the off axis response pblms. But after reading it, I'm now thinking closer to 4Khz. Whatta think?

Hey, I'm on a budget, and can't justify spending the big bucks for an "audiophile" system. I have a friend here in town (XXXX, Texas) that has more money in this system than in his house. (Magnapans, All Mark Levisons, including a pair of the monster Levison amps... I think 33s.. I don't remember off hand). I love listening to his system, but little (currently) cheap system is not that much worse than his. But has given me the upgrade fever. I just what to do it at a reasonable price. I guess it is like wine, once you spend a little money on a bottle on wine, you have good wine, the expensive stuff is only marginally better. Almost an exponential curve.

R *Glad you liked the article. In my opinion, there is really no better way to go, since as you said, all the nonsense you have to go through with passive xovers with all their matching networks etc just does not seem worth the trouble.*

I had a similar question from another reader, and suggested that he would need at least 20uF caps. 20uF will create its own crossover at about 995Hz, and will introduce phase shifts above and below (as always). Only problem is that suitable polyester caps are expensive, but I do believe that using electros is a bad idea in high level signal paths.

I agree with your comments on the Vifa (or any other driver with a cone diameter greater than about 100mm (4")) having to provide decent dispersion at higher frequencies. This has been a major hurdle for me in my quest for the Holy Grail of speakers, and so far I have not solved it either. A vertical array of two 100mm drivers has some appeal, but then you start having impedance problems (4 ohms is not an amplifier friendly impedance. Decisions, decisions.

If you can get to 4kHz xover frequency, this is preferable, but at the expense of HF dispersion and lobing.

With your power supply, consider adding a few extra caps (10,000uF 50V) to ensure minimum hum, and this also provides real current capability in the short term. There are many amps about now which use massive amounts of capacitance for just this purpose, and all the reviews and articles I have read indicate that there is a definite improvement in the sound.

Q I am about to purchase some music equipment (I'm not sure if it qualifies as hi-fi) I bought the loudspeakers first. Contrary to my normal buying habits I didn't do a lot of market research. I listened to a range of speakers in one of the few stores (2 actually, at least that I know of) equipped with hi-fi speakers and ended up with buying a pair of Chario Hiper 1000 towers with the following characteristics:

Low frequency load: vented NRS/2pi
Configuration: 3 way vertical array (with the subwoofer mounted in the bottom of the tower)
Drivers: 130 mm doped paper subwoofer
130 mm doped paper midrange

27 mm textile dome tweeter
Sensitivity: 88 dB SPL 2.83 V/m/W
Frequency @ -3dB: 55 Hz
Acoustic crossover freq.: 135-1350 Hz
Acoustic alignment: LKR4
Rated impedance: 4 Ohm
Suggested amps: rated for 50-120 W/8 Ohm
Cabinet: 20 mm thick MDF (no idea what that means, but I guess it is some kind of pressed wood fiber)

They surely sounded the best of all the speakers available in that price category (about 900 EURO), but the choice was very limited (one or two competing models). Any technical assistance from the sales crew was absent, although they remained friendly and were at least willing to switch back and forth between the different speaker systems while I was testing them.

From the instruction manual that came with the speakers I learned that they were suited for bi-wiring or bi-amping. I tried to learn some more about these possibilities via the net and came across the article of Rod Elliott. The possibilities of bi-amping sound attractive. According to the analysis (or what I understand from it) the basic idea is to connect an electronic crossover and 2 amplifiers.

My questions to you (and/or anybody else who is willing to help me out on this) are:

1) given that (for the time being) I don't want to spent more than ± 1000 EURO on the equipment (speakers not included) is there any gain to expect from bi-amping my system, say using two commercial low- end amps (e.g. SONY TA-FB920R) or even using my old Philips amplifier (1984) (I know that to some (most) of you this probably sounds horrible).

N.B.: The other components of the system will be: Sony MiniDisk MDS-JB920, Sony CD player CDP-XB920 (product codes refer to those from the Sony Europe catalogue). Please also feel free to comment on the choice of Sony. Would Kenwood be a better (less worse) option?

2) if the answer to the above question is a yes, I will then need an electronic crossover. Can you get these in specialized shops? do you have to built these yourself? What does it cost?

3) Should I eventually stick with bi-wiring, do I need some sort of signal splitting device (cf. fig 5 at http://sound.au.com/bi-amp.htm).

4) can you give me a rough idea what I would pay for (average quality) speaker wires.

5) are there any introductory books written on the issues in Hi-Fidellity and that pay much attention to the basic concepts of the underlying electronics.

A *Thanks for your response to my web page. First (and foremost, I guess) has to be a comment about Sony. (... this section has been removed - it is not very complimentary and is based on personal experience ...) Otherwise, as I indicated in my article, I am unwilling to make recommendations (or otherwise) about any specific brand or configuration. However - the speakers you mention sound a little suspicious: Sensitivity is 88 dB SPL 2.83V / 1m*

Since the speakers are rated at 4 ohms, 2.83V equates to 2W, so they have a real sensitivity of 83 dB /W/m (i.e. 85 dB SPL at 1 Watt at 1 metre). This is a fairly low sensitivity, even by current standards, so you will need as many watts as they will take to get a reasonable SPL in your listening room. Also with a -3 dB of 55 Hz, you WILL need a subwoofer to fill in the missing bottom octave. As for bi-wiring versus bi-amping. Bi-wiring will provide some benefits to overall imagery and clarity - although the benefits are fairly subtle. Bi-amping will provide a potentially vast improvement in imagery, perceived sound level, and overall clarity.

I will not (apart from my first-hand comments about Sony) pass judgement about your choice of amps (see my disclaimer in the web page). What I will suggest is that you be prepared to experiment - most of the advances made in audio have been from just that. If you stay with bi-wiring, your speakers are already set up for this (based on your description). To bi-amp, you will need an electronic crossover. There are many manufacturers of these, but you should try to get hold of one which provides phase coherency. Have a further read of my article to see why.

As for whether it is hi-fi or not - who cares! If you like it, and it makes you feel good (along with the music you like), then all requirements are satisfied. I know this is an heretical statement, but it really is up to you. If you enjoy what you hear, that's all that really matters - think about it.

MDF stands for "Medium Density Fibreboard", which is about 700 orders of

magnitude better than "chipboard" - the basic ratty stuff that people make into speaker cabinets, dog houses, junk boxes, etc.

C Thanks for your quick and elaborate reply.

First on how I feel about my system. Well ... after having read that the only components I currently own rate as "suspicious" I think I'll ask myself this question again in the morning.

I got suspicious too, though, after I having found no significant information on this brand of speakers on the net. It's an Italian brand which exists for about 20 years. The company made it's first appearance on the international market in 1986. Their most prestigious line is the Academy series. And I must admit that the more I look at them (I haven't listened to them though) the more I come to appreciate their design. Their walnut veneered finishing goes well with the rest of the furniture. But all this is of minor importance when finally I will be disappointed by the way they sound. But what also matters to me is that the sensitivity of my speakers is what one could expect of speakers within the price category mentioned (I paid them about 900 US$). Anyway, I can't turn them back, so I better learn to love them.

On your calculation. I admit honestly that I forgot all about the basics of electricity (and that for someone who even got a course on MOSFET amplifiers. But that has now been 10 years ago). Their most prestigious speaker has a sensitivity of 91 dB SPL (all the rest being the same). So much for their claim "Acknowledged as the world's best speaker by specialized journalists all over the world". The fact that I "WILL" need a subwoofer sound very depressing since they already have one.

As for bi-amping my system. I will buy a new amplifier anyway, so eventually I just might and try to bi-amp the system using my old Philips amplifier. The only thing is the price of the electronic crossover. It should be worth while buying one in the face of using two fairly low-end amplifiers for bi-amplification. So my basic question to you is, whether the mere splitting of the signal to the different drivers already gives considerable improvement, regardless of the quality of the amplifiers used.

R *To give you an idea, to obtain an average SPL (at 1 metre) of 97dB (which is fairly loud, but not ridiculous), you will need an average amplifier power of about 16 Watts.*

Since this is the average, you have to assume an absolute minimum of 10dB headroom (20dB is better). 10dB above 16 Watts is 160 Watts, so if you have an amp rated at about 100W into 8 ohms, this will give the 160 Watts into 4 ohms that you need - provided the amplifier is able to drive 4 ohms! Have a look at the table below.

This is in agreement with the manufacturer's claim that amps rated up to 120 W into 8 ohms are suitable (such an amp should be able to give 200 Watts into 4 ohms, or thereabouts). Also note that the above average 97dB SPL is at one metre. As you move further away, you lose another 6dB each time the distance doubles until you are into the reverberant field. This is entirely dependent on your listening room, but you could hazard a guess that for an "average" room (whatever that is), you would enter the reverberant field at somewhere between 2 and 4 metres.

As for the quality of the amps - bi-amping will not make bad amps sound good. The overall result may be better than conventional operation (internal passive crossover), but if possible, the better of the amps should be used for the mid-high section. The better this amplifier is, the nicer the combination will sound. Some distortion (harmonic and frequency) in the bottom end will not sound as bad as in the mids and highs, because the low frequency distortion is "masked" by the clean output of the top end, and the woofer will not be able to reproduce the really nasty harmonics very well anyway due to its restricted frequency range (sounds good in theory, at least).

As for the manufacturer's claims - don't dismiss them until you have had a listen (I don't know these speakers, so I cannot comment - not that I would anyway).

Based on the sensitivity of your speakers, the following shows roughly what you can expect:

dB SPL (at 1 metre)	Single Amp (Watts - each channel)	Bi-Amped (per amplifier)
85	1	0.25
88	2	0.5
91	4	1
94	8	2
97	16	4
100	32	8
103	64	16
106	128	32
109	256	64
112	512	128

This assumes that the crossover is at the "equal power distribution" frequency of about 280 to 300Hz. You will need to experiment to see if your internal sub-woofer can get that high without sounding horrible if you want to get the maximum benefit of the increased SPL due to frequency splitting with an electronic crossover.

This also assumes that you want (need?) high SPL. If you don't, then you will probably not have an issue with power, so can have more flexibility with crossover frequencies.

Q Your article is excellent- very easy to read yet informative! I graduated from the University of Idaho ten years ago - majored in Electrical Engineering. I am a power engineer and am a little nervous about tweaking with my system. I work with kilo-volts not milli-volts. I have Infinity 8A Kappa speakers, 1 set of Adcom GFA-565 mono amps and an Adcom GFP-565 pre-amp.

I currently have the set bi-wired. I noticed a definite improvement after bi-wiring the system. Saw a bigger sound improvement after replacing my 10-year old Denon CD player with a good transport and D/A converter. I am now kicking around the idea of bi-amplifying my set. If I understand correctly, I would have to remove the passive low-pass crossover in series with the woofer circuit and remove the passive high-pass circuit in series with my mid-base coupler, mid-range and tweeters. Then I would install an electronic crossover to separate the signals to the high and low frequency amplifiers. This is correct?

The speaker manufacturer's literature claims that the woofers passive crossover is tuned to extend the bass response by approx. 1/2 octave to 33Hz. Wouldn't I lose the lower frequencies by removing the passive crossover and using an electronic crossover in its place? I know you don't get something for nothing. What is the downside of having the woofer circuit tuned to extend the low end?

Does it make any sense to install an electronic crossover to split the signals sent to each amp and then keep the passive crossover circuits in the speakers? I expect this would probably cause to much of a roll-off near the crossover frequencies.

I appreciate any response you might have. My wife is particularly nervous about me pulling the speakers apart and snipping inductor coils and capacitors out of the circuits. "Don't you think they knew what they were doing when they designed those speakers???!!!"

I know you don't give advice on equipment brands. If this were your system, however, would you consider upgrading to a bi-amplified system or upgrading one of the other components first?

A *I'm glad you enjoyed my article. You are absolutely right about not getting something for nothing! The bass extension filter almost certainly reduces the effeciency of the woofer at higher frequencies, so it can "give it back" when it is needed in the last 1/2 octave. If you were to biamp the system, this part of the crossover circuit would need to be retained, or a matching bass boost could be done electronically (which is better, but requires more circuitry and effort, and also means that you must know the exact tuning frequency used, and the amount of loss introduced in the higher frequencies).*

All the above is possible, but will take some research and maybe a bit of lateral thinking! A signal generator and oscilloscope or good multimeter would not go astray if you can lay your hands on them - this way you can plot the response of the existing crossover unit - remember to terminate the crossover outputs with a load resistor equal to the loudspeaker impedance, or the results will be meaningless.

If you leave the speakers connected, speaker and cabinet resonances will make meaningful measurements more difficult. If you want to do it this way, make sure that the box sealing is not compromised, and that you drive the system with a power amp to ensure a constant-voltage source. A signal level of 1 or 2 volts is sufficient, otherwise your ears will hate you!

You are also right about having to disable the existing crossover from bass to mid +high. If this is left in place the effect will not be a happy one! Remember that the mid to high crossover must be retained unless you are contemplating tri-amping. Too much too soon I would think.

As for your wife's consternation, she is right, but with a caveat ....

The speakers - like all speakers - were manufactured to suit the majority market in their price range. Few people will jump at the chance to purchase an expensive pair of speakers knowing that they will also have to buy an electronic crossover and another power amplifier to make it work. As a result, the final design is a compromise between simple economics and harsh reality.

Biamping WILL create a dramatic improvement, but it must be done with great care and attention to details, or a disaster will surely be the result. I would not recommend attacking the existing low to mid+high crossover with anything other than a screwdriver (for its removal intact) - this way you can always revert to the original if it doesn't work out, or while you perfect the next stage of your project.

(After all, who wants to be without their sounds?)

If this were my system I would biamp first, then experiment with the result until I was satisfied that it could be improved no more. Only then would I look at the other components (which sound as if you have a reasonable investment in them). I hope this helps.

Q I enjoyed your article very much. I am interested in using a Bryston 3B for the bottom end and a single ended triode amp for the mids and upper. can this setup be made to work?

A *I'm glad you enjoyed the article. I don't know the Bryston 3B, but I'm sure that the combo will work as long as the crossover point is selected to get equal power distribution. You might find that this will require a crossover in the middle of the "intelligence band", but if well done this can still work - thousands of speaker manufacturers do it all the time, so why not you too.*

Q I have acquired a QUAD ELS-57 speakers, that I like very much. Unfortunately, a while ago my old amplifier stopped functioning, and I was advised to buy a new one, instead of paying for a repair. I have searched on Deja-vu News, and found that people suggest certain amplifiers as more appropriate for the QUADs then others. (Bedini 25/25, Spectral DMA-XX were some examples.)

Given the fact, that the input impedance of the QUADs is highly capacitive, and ranging from 2 to 34 ohms, I believe that some amplifiers are more suited than others. What I also noticed was that some, apparently unrelated, people recommended a "fast," "class A," "low power" amplifiers. Do those modifiers have any substance or are they only buzzwords?

Given the price of these amplifiers, is there a DIY amplifier I could attempt to build? Thank you very much.

A *Congratulations on your ownership of the QUAD speakers. They are one of the all time classics, but they are hard to drive. Most amplifiers do not like the load presented by electrostatics or anything else which is highly reactive, so I'm afraid that you really do need something a little different in the amplifier department.*

As for the "recommendations", they are all meaningful in one way or another, but are completely unrelated to your needs - "fast" is not a requirement, nor is Class-A or low power. If I remember correctly, the original QUAD amp was about 50 or 60W (???), but the biggest problem is finding an amp that will drive the capacitive load without a mental breakdown.

I would tend to suggest an amp which is capable of driving a two ohm load (these are not as common as amps which can handle 4 ohms) since such an amp will probably be also capable of driving highly reactive loads such as the ESLs.

The suggestions you mentioned may well be good, as no doubt they have been tried and tested with the ELS series speakers. Having said that, I cannot make a specific recommendation - although P101 has been tested with good results.

Valve (vacuum tube) amps are usually much happier about driving really difficult loads without undue distress, but I have heard of tests conducted on high power PA amps (Australian Monitor), when they were shown to be completely stable driving a 5uF load. Not a recommendation, but it shows that "solid-state" amps are quite capable of driving strange load impedances.

You did not say what sort of amp you were using - and did it die while driving the ESLs? If so, this shows that the load can indeed "blow up" otherwise good amps. If it is a valve amp - get it fixed. Anyone who tells you not to bother has never heard one. My project pages also have many amps, but other than P101 I have never tested them with electrostatics.

Q Hi, enjoyed your web site. i have built jlh 10 watter using 2n3055 &tip35 but as yet have done no subjective comparison. may also try mjl21194 (bit costly in australia). what do you think

A *Did you build the amp from the plans on my site? (I guess you probably did, or you would not be responding to me ...). I know the design is old, but if you find that you like it I'd really like to hear more (I re-published the design, but have not built one yet). A bit of good feedback is always nice, and if you don't mind I will include your comments after a comparison in the Readers' Page.*

*Using the MJL21194 is probably overkill, but these are one of the most linear transistors on the market - as such I would expect the performance to be about as good as it can be. But yes - they are *expensive*.*

Glad you enjoy my site - visit often, there are new things appearing all the time.

Q HI, JUST RECENTLY I PURCHASED A SET OF B&W SPEAKER (DM-603) AND CONNECTED THEM TO MY ONKYO M-508 POWER AMP (2 CHANNEL). I'M A NEWBIE IN HI-FI HOWEVER I'VE LEARNED QUITE A BIT BY READING MAGAZINES AND ARTICLES AND ESPECIALLY YOUR WEBSITE REGARDING BI-AMPING. I'M STILL CONFUSED THOUGH. IS IT POSSIBLE TO BI-AMP MY DM-603 USING ONLY ONE POWER AMP? CAN I USE SPEAKER "A" FOR HI/MIDS, AND SPEAKER "B" FOR LOWS INSTEAD OF BUYING ANOTHER POWER AMP? YOUR ASSISTANCE IS GREATLY APPRECIATED. I BELIEVE IN YOU.

A No, you cannot bi-amp with only one amp. You can bi-wire, but the results are nowhere near as good. I would strongly suggest that you live with your system for a while yet, because bi-amping is NOT trivial - it is possible to damage speakers (or amps) if you are not completely confident, and are experimenting.

Experimenting is good, but please do it with a cheap speaker system and an amplifier you can afford to lose.

Q Was wondering if you had anymore information about designing Capacitance Multiplier power supplies. I am planning on building a pair of Leach amps and am looking at various power supplies. Supply is +/- 57V with average current of around 5 Amps, peak as high as I can reasonably get (The amp itself has current limiting). Any help,information, or recommended reading you could provide would be greatly appreciated.

A *I assume that you read the article in my project pages, and this should have enough info for you to do your own design. Most of it is pretty straightforward, and requires not much more than ohm's law and a bit of calculation of capacitive reactance.*

Have a thorough read of the article, and e-mail me with any specific questions. I don't know of any other sites offering more info than I have.

Q Its been quite awhile since I've done any analogue design, so I'm a but rusty. I assume for increased current the main thing would be to ensure the driver transistor and diode can handle the increased load. Any suggestions for suitable transistors??

The only thing I'm having trouble wrapping my head around is modifying this for the higher voltage. By the looks of it the 200R and caps remain the same and its just a matter of adjusting the 12k resistor. Do I want a 10V drop between the voltage rail and the driver base, or a 10V drop between the base and ground?? Of course I could be completely wrong :o)

A *A re-think on your problem: Since you are running a fairly high voltage and current, you will need some fairly "beefy" devices. However for the Leach amp, I think that anything other than a well filtered supply is not needed - 10,000uF caps are not cheap, but you will need close to that anyway before the filter.*

The Leach amp (like most modern designs) will have quite good power supply rejection, and I would only consider using a capacitance multiplier where hum becomes audible.

I have run some tests on my own power amp, and even with quite high ripple on the DC supply, this does not make itself evident until the amp clips. Below this, my

distortion meter shows zero 100Hz supply ripple at any power level. I doubt that the Leach will be any different. Save your self some money (and energy) and try it out with a simple supply first. If you are not happy, then look at using additional filtering - I bet you will never bother.

If you want to do it anyway, I would suggest MJ15003/4 for the power transistors (250W) and MJE340/350 for the drivers. The rest of the circuit should work as shown, but you might need to use higher wattage resistors. The 10V drop is between the input and output of the supply, and the idea is to ensure that this voltage is higher than any momentary droops (including ripple) as the amp is driven. This is adjusted with the 12k resistor as you guessed. The diodes do not need to carry the current - they are there to stop reverse voltage if the main filter cap manages to discharge too quickly. They don't need to be changed.

C Vulnerability of Tweeter to DC Transient:

There used to an organisation in the UK called the Active Loudspeaker Systems Organisation (ALSO) which had set a standard for active crossovers, active speakers and amplifiers manufactured for bi-amping. The active speakers are without any passive crossover at all to protect the tweeters from DC transcient. Basically, when complying with ALSO standard, there should be no danger having the tweeters blown out.

I am still using the following antiquated British system which are ALSO compliance:
Active Crossover and power amplifier for one channel:
A&R Cambridge SA60X
Control and power amplier for another channel:
A&R Cambridge A60P
Active speakers:
ARC 050 two way speakers with detachable passive crossovers

A&R Cambridge is now Arcam of UK, and ARC is now defunct. I am not sure if ALSO is still active.

R *I did not know of the ALSO organisation, but my suggestion to use protection was based on the fact that most users will not even be aware that a DC "transient" is possible. Many amps produce small transients at power on and off, and these CAN damage tweeters. I prefer to err on the side of safety.*

Q I'm designing a subwoofer module, including an electronic crossover. Could you tell me how to take a speaker level input and have that signal go through an electronic crossover? Can I use a voltage divider or is there another way to attenuate the high level signal?

A *Generally a simple voltage divider is all you need. This can be set up so it will sum the outputs of left and right amps, and give you mono line level for the sub amp.*

If you have (say) 100W / 8 Ohm amps, the maximum voltage is 28V RMS, so you need a divider of about 28:1 - since a lot of bass info is mono anyway, you may need more (you did not say if your sub amp or crossover has a level contol - you will need one). Design of voltage dividers is covered in an article on the ESP site.

Q Your projects page is just what I've been looking for! Do you have PCB's for projects #08 and #09 ? I logged on to Microsofts web page, trying to locate the VB40032.DLL file so that I can use your Linkwitz-Riley Component Calculator Program. However I couldn't find any information on the file. Please, tell me how I can find it. With your help, " My Rig " can sound much better. Thanks.

A *Many project PCBs are available (although not at the time of writing).*

The VB40032.DLL is available from Microsoft

Q Congratulations on a very good page. undoubtably one of the better presented and more informative on the web. <end gratuitous sycophancy>

I was considering building your project 2 - the preamp and just had a quick question. I wish to eliminate the balance control from the design. As I understnd it, this pot seem to add some negative 'feedforward' which reduces the gain for a given channel. If I simply remove this component and sever the link from the balance pot(s) between the two channels will the circuit stillfunction correctly?

Thanks in advance, and keep up the great work!

A *If you don't want the balance pot, just leave it out of the circuit. You will have a little more gain (about 3 dB), but need do nothing else. By the way, I don't really recommend leaving it out, as it can be useful. If you are sure - no problem. There is no feedforward or other nasty stuff involved - it is simply a passive control.*

Q Finally just what I've been looking for! A simple, but pratical amp for my turntable and well under $2,000! Tubes are nice but I already have a tube amp with mmphono inputs! I seem to recall seeing something about circuit boards and or parts mentioned on one of your pages. I am interested in a parts pcb package, minus the heavy stuff. Thank you for the excellant info! well I see that you are away for a few weeks, looking forward to hearing from you, I think I'll put my poor bloodshot eyes to bed!

A *At the moment, I am not in a position to provide kits in any way shape or form (sorry). I am looking into this, and will do so if there is enough interest (at the moment, there is not, unfortunately).*

Which amp were you looking at? I am currently examining the possibilities of a new amp (based on the 60W design) which should be capable of 100 to 150W into 8 Ohms. It's only on the drawing board at present, but should be quite nice when completed. (This is the P3A amp, which has been available for some time now.)

Q Hi, i read your article on bi-wiring/amping and am very interested in it. i was thinking of getting the paradigm moniter 7's or 9's, which can be bi-wired. i have a yamaha r-v1105 reciever and an old denon avr-1200 reciever. the yamaha r-v1105 has preouts, which i can connect to the denon avr-1200. now, is this and some speaker wire all that i need to biamp????

so now am i right in assuming that the volume dial on one of the recievers would control treble, and the other the bass???

i am really unsure if i know what i am talking about so i would appreciate any information. thankyou very much.

A *Be very careful here. The concepts of bi-amping and bi-wiring are very different. The bi-amp approach requires that you do not use the crossovers in the speaker cabinets at all - you need an electronic crossover. It is possible to bi-wire using separate amps, and there might be some advantages over "simple" bi-wiring, but you will not get the full benefit without the electronic crossover.*

*The whole idea is to make one amp and speaker combination responsible *only* for the bass section of the frequency range, and the other only handles the mid +high component. I suggest that you re-read the article very carefully - there are lots of traps for the unwary! If you do it this way, then what you suggest is correct. This is not really bi-amping though, since all frequencies are still handled by each amp. You may get marginally less amplifier intermodulation distortion, but will not gain the real advantage of true bi-amping.*

C First of all, great site! While I really haven't got much experience with bi-wiring, I do love to bi-amp. I build my own speakers and basically am put off by the cost and technical complexity of low frequency passive crossovers.

All the info you've provided is wonderful. I'm thinking of building that phono pre-amp (if I ever aquire the requisite technical expertise to do so).

Here's a couple of jokes for your humour section (maybe?):
A conversation between two audio research technicians (the field of study, not the company):
Tech 1: Gee, this new horn speaker is efficient. At what db level does it become dangerous?
Tech 2: What?

Okay, that was bad. But the following is a play on words (or a saying) and technically accurate.
Q: What did the chemist say when his assistant fell into a vat of acid?
A: Apparently, the problem is, you are part of the solution.

Well, thanks for a great site. I thoroughly enjoyed the visit.

R *Thanks for the vote of confidence (and the jokes).*

It's not only the complexity of passive crossovers, you are just losing so much other good stuff - power, clarity, phase (etc, etc ....)

Q I've been combing the web, looking for an answer, but just can't find anything. Your page appears to be the best on just about everything else, so I guess I'll check if you know.

Basically, I want to construct a Hafler Dynaquad style surround matrix processor. The catch is, I don't want to do it at speaker level. I'd like to do it at line level. I have enough amplification available, and I figured it wouldn't be a difficult item to construct.

The problem is, I can't find any info to guide me. There was, within the past five or so years, a product called the Phasearound, which operated on this principle. According to a review I found, it used an audio transformer to derive the center and surround channels, but the article didn't elaborate beyond that. If I knew more, that would've been enough. I don't need a center channel, as I intend to use it in an audio only system. Any help you might be able to offer would be appreciated.

A *I think I know exactly what you are looking for. The circuit is easy to build (it was also published in an Australian electronics magazine very recently), and I will look at making this a new project within the next month or so (if you can wait that long).*

The magazine article also describes a digital delay - this apparently enhances the "surround" effect quite a bit, by delaying the rear channels. I will not be including this in my project (or I might, I haven't decided yet). (See projects index for details.)

Q I was searching through altavista and found your site, which is definitely the best among the many I've found. I'm not a analog engineer, so there are many things I don't understand, but I find your site very informative. I just have one question. It might have been answered in your site already, but after reading it over and over, I couldn't come up with a definite answer.

Would bi-amping without an active crossover be possible? (source - 2 amps - passive crossover built into the speaker which is bi-wireable) and would it help?

It'd be like a "temporary" path between bi-wiring and true bi-amping. I'm not sure if the HI and LO input of the speaker are truly independent or if there are some interactions between them.

BTW, I have Magnepan 1.6s, which are quite obscenely (what a word!) inefficient at 83dB, 1W, 1m and I find my Bryston 3B-ST struggling (or so I feel anyway). Thanks for your time.

A *You are right - what you are looking for is not in there (at the time - the information has been there for some time now).*

*The approach you are asking about has been suggested by a few other readers as well. It is not really bi-amping in the true sense of the term, because the amps still have to reproduce the full frequency range - its just that there is no actual power being produced at the out of band frequencies. There is probably some merit to doing this, but you will *not* get the power advantage, which is important with really inefficient speakers.*

Q Thank you very much for your informative article on Amplifiers. I am an Engineering student in Washington. Over the next few weeks I will have a great deal of time to experiment and would like to built an Amp. I was wondering if you have a complete schematic of your design as it seemed the design was complete but in pieces that were spread across the document.

I am also interested in whether your design could be applied multiple times off of one power supply as I would like to build a 6 channel Amp for Dolby Digital and THX. If you have the information available what is the approximate cost of all of the components for your Amp design. Again thank you for taking the time to write your guide.

A *Thanks for the nice words. Which article were you interested in? There is one that describes the general design goals, but that is fragmented (as you said). If you want complete schematics, you need to look in my projects pages, since this is where all the complete constructional articles live.*

I suspect that this is not where you were looking, since these are complete in all respects.

*Any number of amplifiers can be run from the one supply (with some interactions of course), but as you do need to ensure that the transformer, rectifier and filter caps are sufficient for the total loading. One trick used by a lot of manufacturers is to use a *really* big tranny, and then use separate rectifiers and filter caps for each amp.*

To give you an idea, using 5 x 60W amps needs a transformer of about 500VA for continuous operation at full power (I would not suggest anything less than this). The filter caps for each amp should be at least 4,700uF for +ve and -ve (i.e. 2 of them) for each amp (10,000uF is better, but expensive). Rectifiers should be at least 10A continuous rating - most manufacturers use less that the above, but you get better reliability when you use bigger rectifiers and caps. I hope you have some money, 'cause this will not be cheap! (It will be lots of fun, though.)

Simple Class A Amplifier

A 10-W Design giving subjectively better results than class B transistor amplifiers

by J. L. Linsley Hood, M.I.E.E.

*** Editors Notes by Rod Elliott**

During the past few years a number of excellent designs have been published for domestic audio amplifiers. However, some of these designs are now rendered obsolescent by changes in the availability of components, and others intended to provide levels of power output which are in excess of the requirements of a normal living room. Also, most designs have tended to be rather complex.

In the circumstances it seemed worth while to consider just how simple a design could be made which would give adequate output power together with a standard of performance which was beyond reproach, and this study has resulted in the present design.

Output power and distortion

In view of the enormous popularity of the Mullard "5-10" valve amplifier, it appeared that a 10-watt output would be adequate for normal use; indeed when two such amplifiers are used as a stereo pair, the total sound output at full power can be quite astonishing using reasonably sensitive speakers.

> * For today's speakers and expectations, this is clearly not the case. 10 Watts is likely to be sufficient for tweeters in a tri-amped system however, and this is the reason for publication of this circuit.

The original harmonic distortion standards for audio were laid down by D. T. Williamson in a series of articles published in Wireless World in 1947 and 1949; and the standard, proposed by him, for less than 0.1% total harmonic distortion at full rated power output, has been generally accepted as the target figure for high-quality audio power amplifiers. Since the main problem in the design of valve audio amplifiers lies in the difficulty in obtaining adequate performance from the output transformer, and since modern transistor circuit techniques allow the design of power amplifiers without output transformers, it seemed feasible to aim at a somewhat higher standard, 0.05% total harmonic distortion at full output power over the range 30Hz-20kHz. This also implies that the output power will be constant over this frequency range.

Circuit design

The first amplifier circuit of which the author is aware in which a transformerless transistor design was used to give a standard of performance approaching that of the "Williamson" amplifier, was that published in Wireless World in 1961 by Tobey and Dinsdale. This employed a class B output stage, with a series connected transistors in quasi-complementary symmetry. Subsequent high-quality transistor power amplifiers have largely tended to follow the design principles outlined in this article.

The major advantage of amplifiers of this type is that the normal static power dissipation is very low, and the overall power-conversion efficiency is high. Unfortunately there are also some inherent disadvantages due to the intrinsic dissimilarity in the response of the two halves of the push pull pair (if complementary transistors are used in asymmetrical circuit arrangement) together with some cross-over distortion due to the I c /V b characteristics. Much has been done, particularly by Bailey, to minimise the latter.

An additional characteristic of the class B output stage is that the current demand of the output transistors increases with the output signal, and this may reduce the output voltage and worsen the smoothing of the power supply, unless this is well designed. Also, because of the increase in current drive with output power, it is possible for a transient overload to drive the output transistors into a condition of thermal runaway, particularly with reactive loads, unless suitable protective circuitry is employed. These requirements have combined to increase the complexity of the circuit arrangement, and a well designed low- distortion class B power amplifier is no longer a simple or inexpensive thing to construct.

> * The thermal runaway referred to is now known to be secondary breakdown, where the transistor suffers from a localised heating on the silicon die. This effect is very rapid, and can lead to almost instantaneous destruction of a transistor. This is one reason that MOSFETs are preferred by many amplifiers designers (the editor is not one of these!).

An alternative approach to the design of a transistor power amplifier combining good performance with simple construction is to use the output transistors in a class A configuration. This avoids the problems of asymmetry in quasi- complementary circuitry, thermal runaway on transient overload, crossover distortion and signal-dependent variations in power supply current demand. It is, however less efficient than a class

B circuit, and the output transistors must be mounted on large heat sinks.

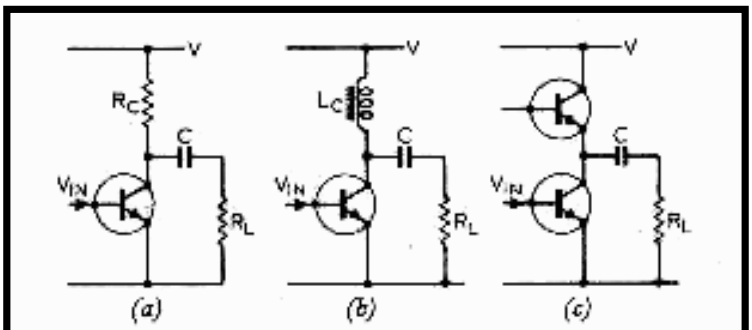

Fig. 1. Basic class A circuits using (a) load resistor R_c giving power conversion efficiency of about 12%, (b) l.f. choke giving better efficiency but being bulky and expensive, and (c) a second transistor as collector load.

The basic class A construction consists of a single transistor with a suitable collector load. the use of a resistor, as in Fig 1(a), would be a practical solution, but the best power-conversion efficiency would be about 12%. An l.F. choke, as shown in Fig1(b), would give much better efficiency, but a properly designed component would be bulky and expensive, and remove many of the advantages of a transformerless design. The use of a second, similar, transistor as a collector load, as shown in Fig 1(c), would be more convenient in terms of size and cost, and would allow the load to be driven effectively in push-pull if the inputs of the two transistors were of suitable magnitude and opposite in phase. This requirement can be achieved if the driver transistor is connected as shown in Fig. 2.

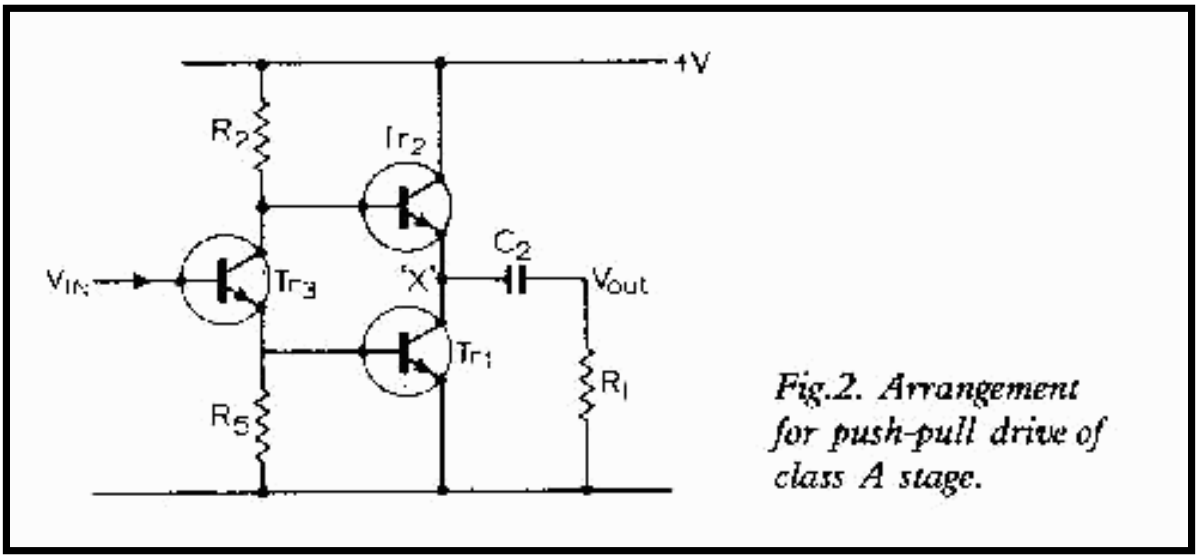

Fig.2. Arrangement for push-pull drive of class A stage.

This method of connection also meets one of the most important requirements of a low distortion amplifier :- that the basic linearity of the amplifier should be good, even in the absence of feedback. Several factors contribute to this. There is the tendency of the Ic / Vb non-linearity of the characteristics of the output transistors to cancel, because during the part of the cycle in which one transistor is approaching cut-off the other is turned full on. There is a measure of internal feedback around the loop Tr1 Tr2 Tr3 because of the effect which the base impedance characteristics of Tr1 have on the output current of Tr3. Also, the driver transistor Tr3, which has to deliver a large voltage swing, is operated under conditions which favour low harmonic distortion :- low output load impedance, high input impedance.

* A potentially worthwhile improvement to this circuit is the addition of a 0.1 ohm resistor in the emitter circuit of Tr1. This applies local feedback to the entire gain stage, providing a significant reduction in distortion. If used, this should be a 5 Watt wirewound type to handle the current.

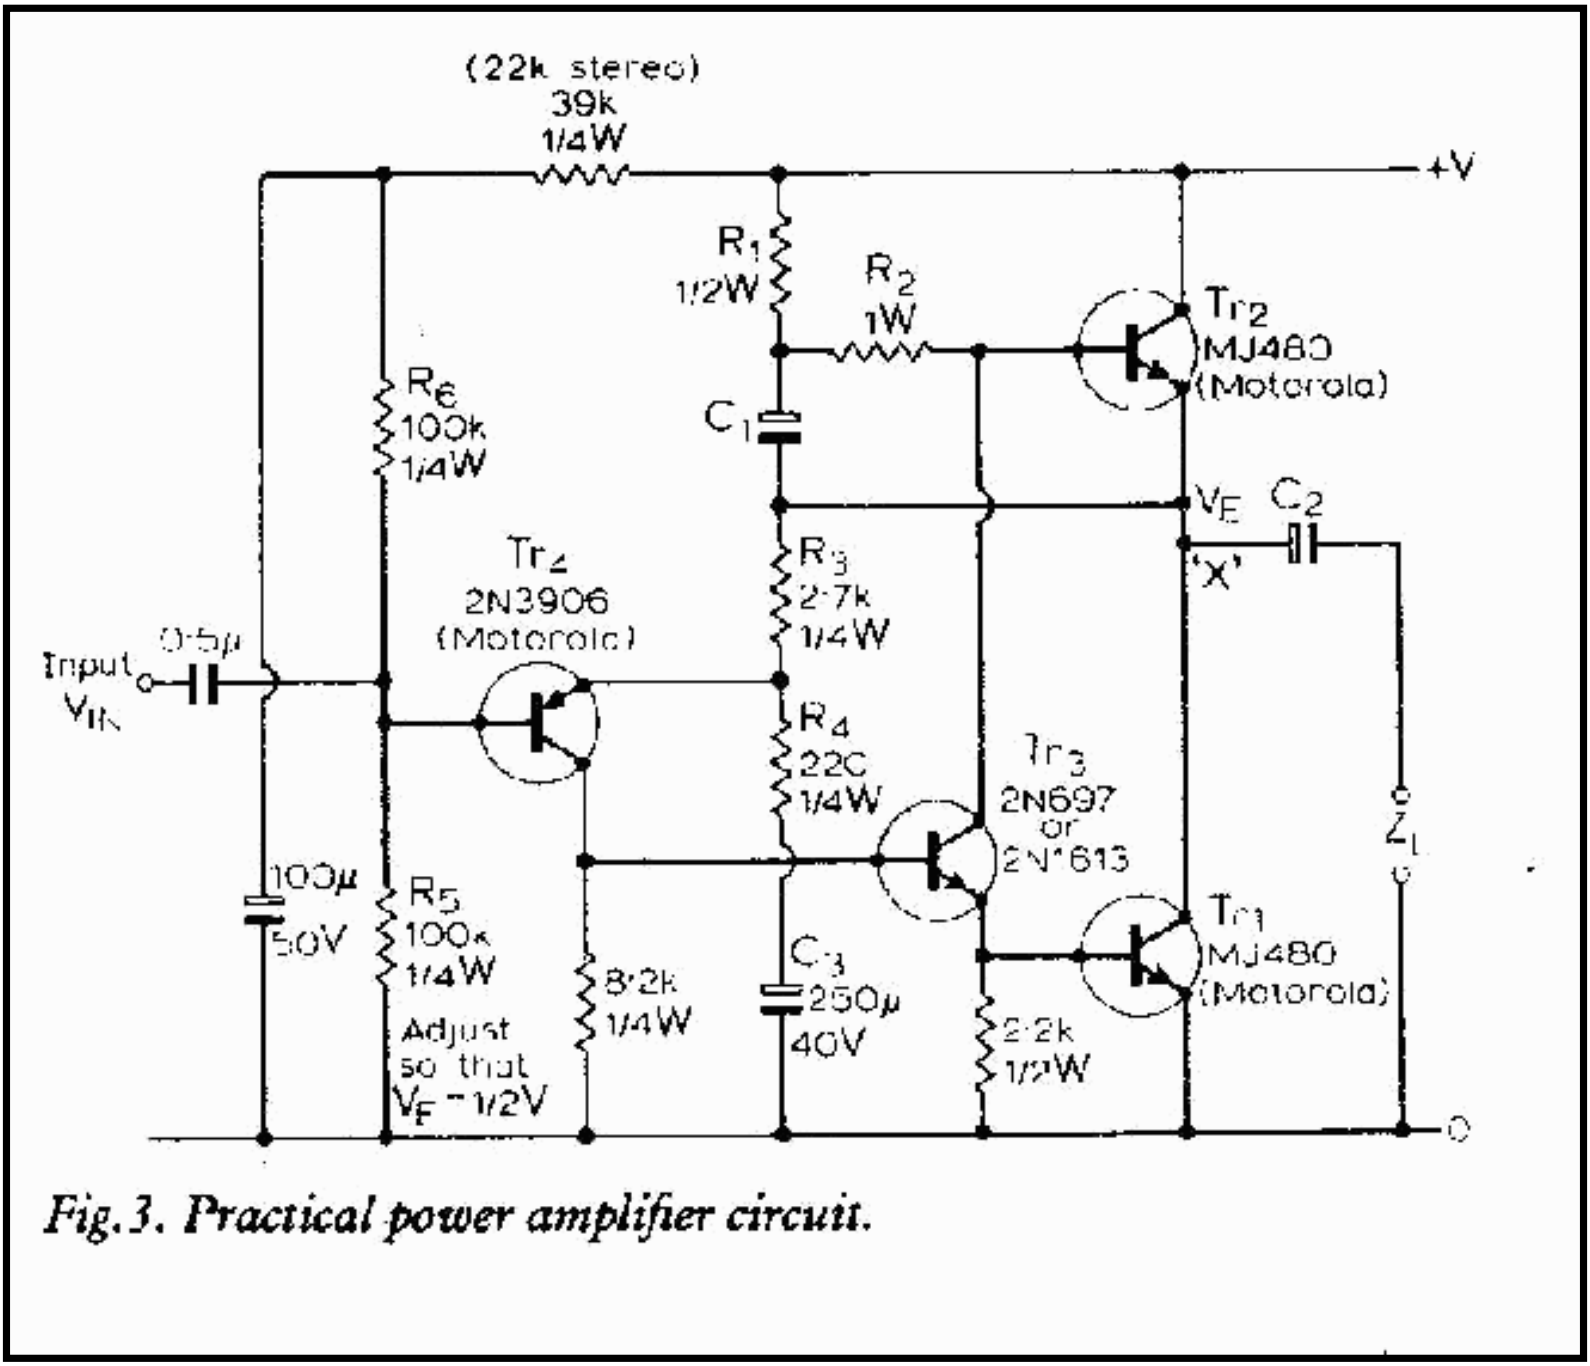

Fig. 3. Practical power amplifier circuit.

A practical power amplifier circuit using this type of output stage is shown in Fig. 3.

* The upper transistor (Tr2) is operating as a current source, whose output current is modulated. This allows the circuit to operate at about half the quiescent current that would be required if no modulation were applied. The values for R1 and R2 must be selected, based on the gain of Tr3. For a 40 Volt supply, if Tr3 were to have a gain of 50 at 1A, then ...

(R1 + R2) = 20V / 20mA (base current) = 1000 ohms.

One problem with this approach is that the current provided by Tr2 will vary with temperature. Readers wishing to experiment with this circuit should ensure that the current is checked at normal operating

temperature (i.e. HOT). There is no mechanism in the circuit to prevent thermal runaway, other than the use of a suitably large heatsink. At some point, the circuit should stabilise the quiescent current. If it does not (and the current continues to increase), then the heatsink is too small. To ensure a useful life for the transistors, they should not operate at greater than 50º C, which in normal conditions should be quite achievable. Since each transistor operates at (or near) 25 Watts, the heatsink for each transistor should have a thermal capacity of about 1º C / Watt. A better (i.e. larger) heatsink will do absolutely no harm, and will ensure freedom from thermal runaway.

There is also a newer version of this amp, but I have no plans to re-publish at any time.

The open loop gain of the circuit is approximately 600 with typical transistors. The closed loop gain is determined, at frequencies high enough for the impedance of C3 to be small in comparison to R4, by the ratio (R3 +R4)/R4. With the values indicated in Fig. 3, this is 13. This gives a feedback factor of about 160 milliohms.

Since the circuit has unity gain at D.C., because of the inclusion of C3 in the feedback loop, the output voltage Ve, is held at the same potential as the base of Tr4 plus the base emitter potential of Tr4 and the potential drop along R3 due to the emitter current of this transistor. Since the output transistor Tr1 will turn on as much current as is necessary to pull Ve down to this value, The resistor R2, which together with R1 controls the collector current of Tr2, can be used to set the static current of the amplifier output stages. It will also be apparent that Ve can be set to any desired value by small adjustments to R5 and R6. The optimum performance will be obtained when this is equal to half the supply voltage. (half a volt or so either way will make only a small difference to the maximum output power obtainable, and to the other characteristics of this amplifier, so there is no need for great precision in setting this.)

* Not mentioned is the purpose of C1 (in conjunction with R1 and R2). This capacitor provides "bootstrapping", which attempts to maintain a constant voltage across R2. If the voltage remains constant across a resistor, it follows that the current through the resistor must also remain constant. The performance of this circuit will be severely impaired if the value of C1 is too small - based upon the lowest frequency of operation, and the parallel value of R1 and R2. For operation down to 20Hz (assuming R1 + R2 = 1000 ohms), the capacitor should be at least 220uF.

Likewise, the reactance of C1 must be low with respect to the speaker impedance (preferably less than 1/2 of the speaker impedance at the lowest frequency of interest - 20Hz is assumed). This works out to be about 2,000uF. A working voltage of not less than 50V is suggested for all electrolytic capacitors, and for optimum h.f. performance, a 1uF polyester may be paralleled with each electro. In my experience this is not needed, but many will disagree, so if you want it, add it.

Silicon planar transistors are used throughout, and this gives good thermal stability and a low noise level. Also, since there is no requirement for complementary symmetry, all the power stages can use n-p-n transistors which offer, in silicon, the best performance and lowest cost. The overall performance at an output level of 10 watts, or at any lower level, more than meets the standards laid down by Williamson. The power output and gain/frequency graphs are shown in Figs. 4 and 5, and the relationship between output power and total harmonic distortion is shown in Fig. 6. Since the amplifier is a straight-forward class A circuit, the distortion decreases linearly with output voltage. (This would not necessarily be the case in a class B system if any significant amount of cross- over distortion was present.) The analysis of distortion components at levels of order of 0.05% is difficult, but it appears that the residual distortion below the level at which clipping begins is predominantly second harmonic.

Stability, power output and load impedance

Silicon planar NPN transistors have in general, excellent high frequency characteristics, and these contribute to the very good stability of the amplifier with reactive loads. The author has not yet found a combination of L and C which makes the system unstable, although the system will readily become oscillatory with an inductive load if R3 is shunted by a small capacitor to cause roll-off at high frequencies.

The circuit shown in Fig. 3 may be used, with very little modification to the component values, to drive load impedances in the range 3-15 ohms. However, the chosen output power is represented by a different current/voltage relationship in each case, and the current through the output transistors and the output voltage swing will therefore be different. The peak-voltage swing and mean output current can be calculated quite simply from the well-known relationship $W=I^2R$ and $V=IR$, where the symbols have their customary significance. (it should be remembered, however, that the calculation of output power is based on RMS values of current and voltage, that these must be multiplied by 1.41 to obtain peak values, and that the voltage swing measured is the peak to peak voltage, which is twice the peak value.)

When these calculations have been made, the peak-to-peak voltage swing for 10 watts power into a 15-Ohm load is found to be 34.8 volts. Since the two output transistors bottom at about 0.6 volts each, the power supply must provide a minimum of 36 volts in order to supply this output. For loads of 8 and 3 ohms, the minimum h.t. line voltage must be 27V and 17V respectively. The necessary minimum currents are 0.9, 1.2 and 2.0 amps. Suggested component values for operation with these load impedances are shown in table 1. C3 and C1 together influence the voltage and power roll-off at low audio frequency performance is desired than that shown in figs. 4 and 5.

> * I suggest a power supply voltage of 40 Volts, which will actually allow close to 20 Watts into an 8 ohm load. Make sure that the heatsinks are sufficient to handle the additional power dissipation caused by the higher supply voltage. Those suggested in the construction notes are probably too small for operation at this supply voltage.

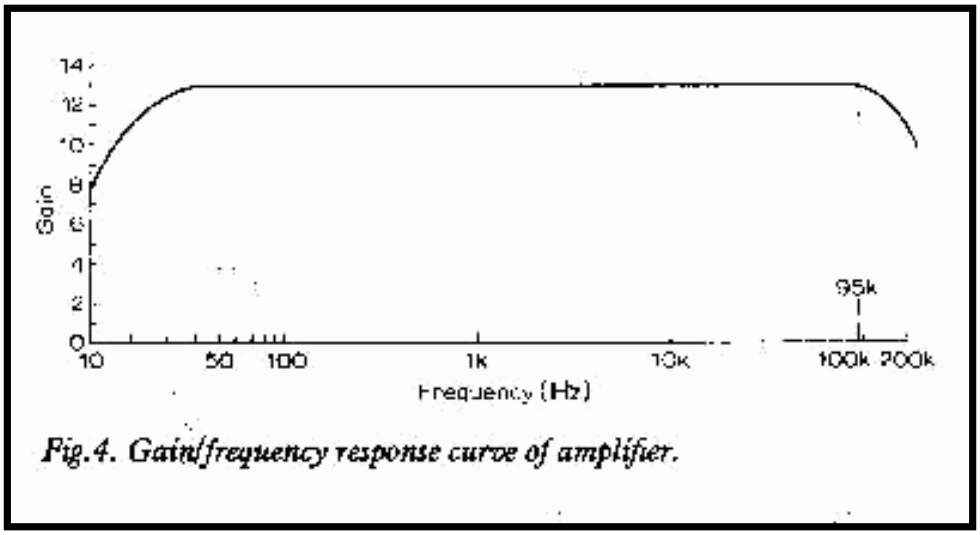

Fig.4. Gain/frequency response curve of amplifier.

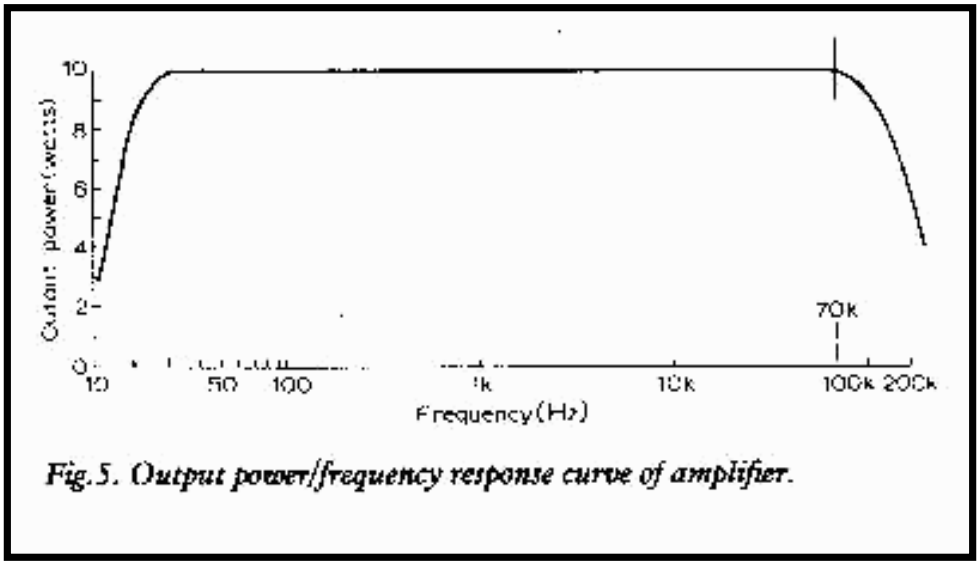

Fig.5. Output power/frequency response curve of amplifier.

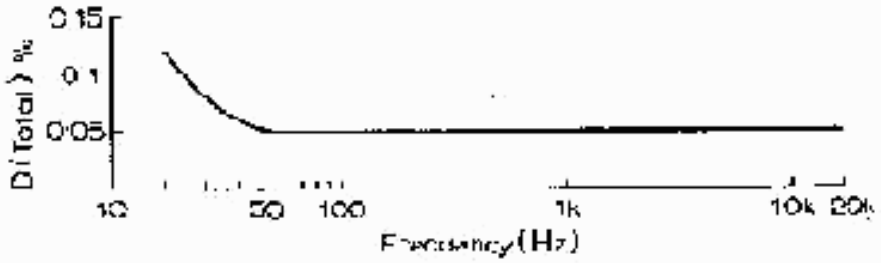

Fig.6. Distortion/frequency curve at 9W.

Since the supply voltages and output currents involved lead to dissipation in the order of 17 watts in each output transistor, and since it is undesirable (for component longevity) to permit high operating temperatures, adequate heat sink area must be provided for each transistor. A pair of separately mounted 125mm by 100mm (5" by 4") finned heatsinks is suggested. This is, unfortunately, the penalty which must be paid for class A operation. For supplies above 30V Tr1 and Tr2 should be Mj481s and Tr3 a 2n1613.

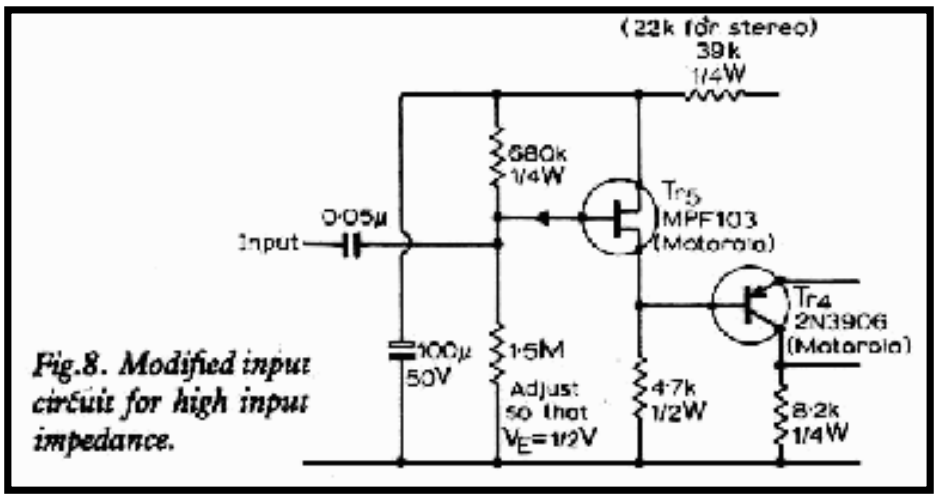

Fig.8. Modified input circuit for high input impedance.

If the output impedance of the preamplifier is more than a few thousand ohms, the input stage of the

amplifier modified to include a simple f.e.t. source follower circuit shown in fig 8. This increases the harmonic distortion to about 0.12%, and is therefore (theoretically) a less attractive solution than a better pre- amplifier.

A high frequency roll-off can be obtained, if necessary by connecting a small capacitor between the gate of the f.e.t and the negative (earthy) line.

Suitable transistors

Some experiments were made to determine the extent to which the circuit performance was influenced by the type and current gain of the transistors used. As expected the best performance was obtained when high-gain transistors were used, and when the output stage used a matched pair. No adequate substitution is known for the 2N697 / 2N1613 type used in the driver stage, but examples of this transistor type from three different manufacturers where used with apparently identical results. Similarly, the use of alternative types of input transistor produced no apparent performance change, and the Texas Instuments 2N4058 is fully interchangeable with the Motorola 2N3906 used in the prototype.

The most noteworthy performance changes were found in the current gain characteristics of the output transistor pair, and for the lowest possible distortion with any pair, the voltage at the point from the loudspeaker is fed should be adjusted so that it is within 0.25 volt of half the supply line potential.

The transistors used in these experiments were Motorola MJ480/481, with one exception, in which Texas 2S034 devices were tried. The main conclusion which can be drawn from this is that the type of transistor used may not be very important, but that if there are differences in the current gains of the output transistors, it is necessary that the device with the higher gain shall be used in the position Tr1.

When the distortion components were found prior to the onset of waveform clipping, these were almost wholly due to the presence of second harmonics.

Constructional notes

Amplifier

The components necessary for a 10 + 10 watt stereo amplifier pair can be conveniently be assembled on a standard 'Lektrokit' 4" X 4.75" s.r.b.p. pin board, with the four power transistors mounted on external heat sinks. Except where noted the values of components do not appear to be particularly critical, and 10% tolerance resistors can certainly be used without ill effect. The lowest noise levels will however be obtained with good quality components, and with carbon-film or metal-oxide resistors.

* Metal film resistors should be used throughout, as these are superior to carbon film types in all respects. These are generally only available as 1% or better tolerance, which will not pose any problems.

Power supply

A suggested form of power supply unit is shown in Fig. 9(a). Since the current demand of the amplifier is substantially constant, a series transistor smoothing circuit can be used in which the power supply output voltage may be adjusted by choice of the base current input provided by the emitter follower Tr2 and the potentiometer VR1. With the values of the reservoir capacitor shown in table 3, the ripple level will be less than 10mV at the rated output current, provided that the current gain of the series transistor is greater than 40. For output currents up to 2.5 amps, the series transistors indicated will be adequate, provided that they are mounted on heat sinks appropriate to their loading.

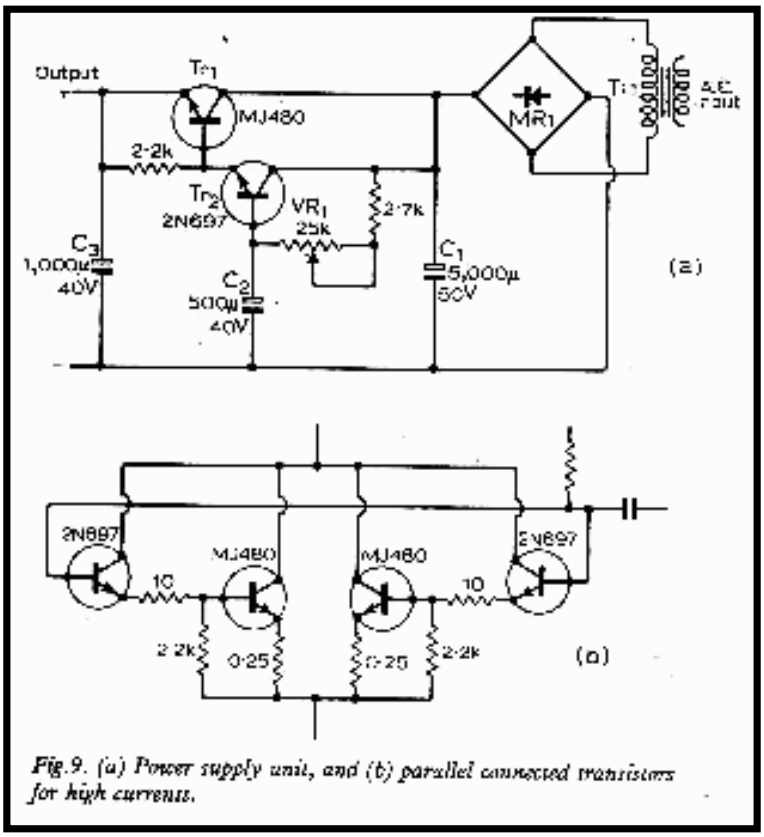

Fig. 9. (a) Power supply unit, and (b) parallel connected transistors for high currents.

However, at the current levels necessary for operation of the 3-ohm version of the amplifier as a stereo pair, a single MJ480 will no longer be adequate, and either a more suitable series transistor must be used, such as the Mullard BDY20, with for example a 2N1711 as Tr2, or with a parallel connected arrangement as shown in Fig. 9(b).

The total resistance in the rectifier "primary" circuit, including the transformer secondary winding, must not be less than 0.25 Ohms. When the power supply, with or without an amplifier, is to be used with an r.f. amplifier-tuner unit, it may be necessary to add a 0.25uF (160V) capacitor across the secondary windings of T1 to prevent transient radiation. The rectifier diodes specified are International Rectifier potted bridge types.

* This supply is not a regulated supply, but is a simple capacitance multiplier. For a more complete description of a better circuit, see Capacitance Multiplier Power Supply Filter in these pages.

Current Limiting

* Although there was no mention of this in the original article (and I managed to "lose" the schematic file for

a time), a current limiter was included. This will ensure that the current through the output devices does not exceed a preset value, although I believe that the concept is flawed, and is of limited value in this overall design.

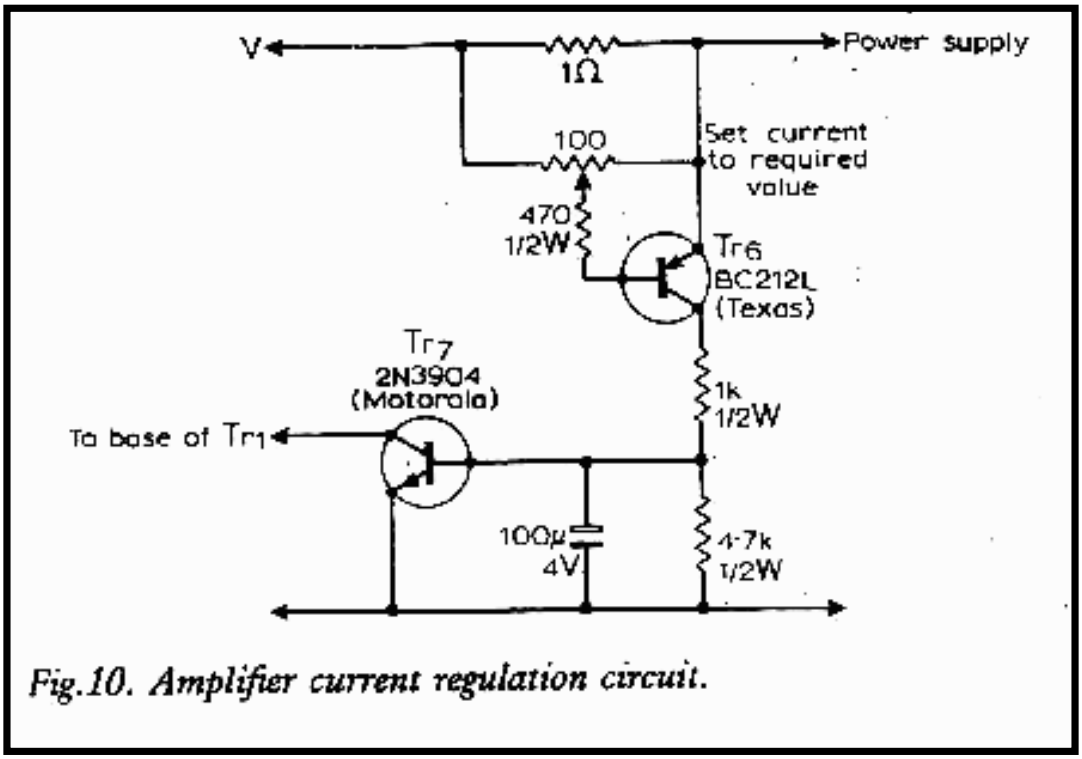

Fig.10. Amplifier current regulation circuit.

The circuit above shows the way the current limiter is connected. It will not stabilise the quiescent (no signal) current, but is only capable of ensuring that the absolute maximum current does not exceed the value determined by the 100 Ohm pot. To be useful, a current stabiliser is needed, which will ensure that the no-signal operating current remains constant regardless of temperature or supply voltage variations. No information is provided to achieve this goal.

Additional Notes

This article (with editorial notes) is reprinted as a service to readers, who are reminded of copyright laws, which may restrict the rights of readers for reproduction, commercial production (etc). The information presented is not intended as a guide for construction, but is primarily for its interest value, and to serve as a starting point for other designers.

The original article is now many years old, and some of the transistor types referred to are now superceded by vastly better designs. I will leave it to readers to experiment with device types. While much of the design is still quite relevant to a new design, I think that this amplifier may be found lacking compared to more recent design trends. In particular, the biasing system is not stable with temperature, and DC drift will be evident. In addition, the open-loop gain is very low, so feedback is far less than might be desirable (although many will feel that this is a good thing!). As mentioned above, additional local feedback (0.1 ohm resistor in the emitter of Tr1) may reduce open-loop distortion, but further reduces the gain. I suggest experimentation (I have only done some computer simulations so far) and would appreciate feedback from anyone who tries out this circuit.

I would also suggest that a single supply power amplifier is not really a proposition for new designs (although the DoZ uses the same principle), and a bi-polar (+/-) power supply may be preferable. DC stabilisation then becomes

a major issue, since small DC offset voltages can prove a disaster to tweeters in particular.

The diagrams are not of high quality, but are the originals from the source WWW page. I do not propose to redraw these, as this design is provided as information only.

The Author

John L Linsley-Hood is a prolific author of amplifier designs, and still presents new ideas and circuits in the UK magazine Electronics World (formerly Wireless World). His influence on the design of quality audio amplifers has been considerable, and continues to this day. This is not to say that I agree with or endorse all his ideas or theories, but at least he has the guts to say what he thinks, and the magazine has the guts to print it, too.

MJ15003 / MJ15004

Beware of MJ15003 and MJ15004 transistors in aluminium cases (genuine Motorola [now On-Semi] devices use steel cases, and have done since 1982). Don't count on this, though - there are fake Motorola devices in steel cases too. I suggest that you test the markings with a solvent (such as acetone - nail polish remover). Most genuine transistors are marked with non-removable ink, counterfeit devices may be marked with normal screen printing ink that comes off easily.

Test the breakdown voltage with a transistor tester if one is available. Genuine devices are rated at 140V, but will usually be higher than this. Counterfeit transistors will generally have a much lower breakdown voltage. Be warned that the latest batch of fakes will actually pass this test !

Always ask for confirmation from the supplier that the devices are genuine. Feel free to refer them to this page if they claim you are mad :-)

Some time ago, I asked one of the local suppliers (who was inadvertently selling counterfeit devices) to check the authenticity of their stock. I will not name the supplier(s), as it is quite probable that they are innocent, and have been defrauded along with everyone else. Needless to say, I cannot do this checking with any supplier outside Australia, as I do not have ready access to the components they sell or to anyone who might know something.

This Australian supplier had a 'Stop Sale' on their computer for these devices, so it has been noticed by them, at least. In particular, look for a manufacture code of MEX190, with the date code 9H34. Some of the counterfeit devices even have the wrong polarity (an NPN MJ15004 - I don't think so!).

Double Headed Duds!

I have been advised that the frauds - or at least some of them - have two transistor silicon dies internally, wired in parallel in a desperate (but futile) attempt to meet the specifications. These are both quite small for the claimed power rating, and are directly bonded to the steel case. The use of two dies is in itself most unusual, but they are not even bonded to a copper heat spreader as is the normal practice, so

thermal transfer will be much worse than it should be, and thermal expansion coefficients possibly place the silicon at much greater risk of cracking - not from anything the user does, but from normal heating and cooling cycles.

I managed to convince the salesperson at an electronics outlet to sell me one of the 'MJ15003' devices, despite the 'stop sale' warning from the computer. This is fine, since I already explained why I wanted one. Most discouraging was that the salesperson obtained 'advice' from someone else in the store that the one I had (MEX190) was genuine. Well, excuse me. There were some others in the drawer that looked as if they might be real Motorola devices, but not these.

I got it home, and promptly ran some tests before I cut the top off. Gain was (barely) passable at 25 at 0.5A, and the breakdown voltage was above the 140V rating. Then I removed the top, and guess what I found? If you said "Two dies?", you are quite correct. They are exactly as described to me - two small dies, bonded directly to the steel case, and wired in parallel with what I thought were rather flimsy bonding wires. The whole construction was coated with a thin layer of silicone.

Given the sophistication of this fraud, it seems more than likely that these transistors are made in a proper fabrication plant, rather than just being relabelled junk or factory rejects. The construction overall (of my sample at least) was quite neat, and was obviously performed with the proper equipment - if I were to go to that much trouble, it would be worth the effort to use the correct die in the first place! This begs the question of where they come from, and I for one would be very interested to find out. From the latest information to hand, China and India are implicated.

One way to be sure that you have the real thing is to buy ONLY from accredited and authorised Motorola or Toshiba (or whomever) distributors. This may be irksome for home constructors, as these dealers usually have a minimum order value (locally it is AU$100 but will vary in different countries). It is not known at this stage how widespread the rort is, but since I have (over the last few years) received information from the UK, USA, Canada, New Zealand, Sweden and India about similar rackets, we can justifiably assume that no-one is safe. If anyone has further information to add, please e-mail me.

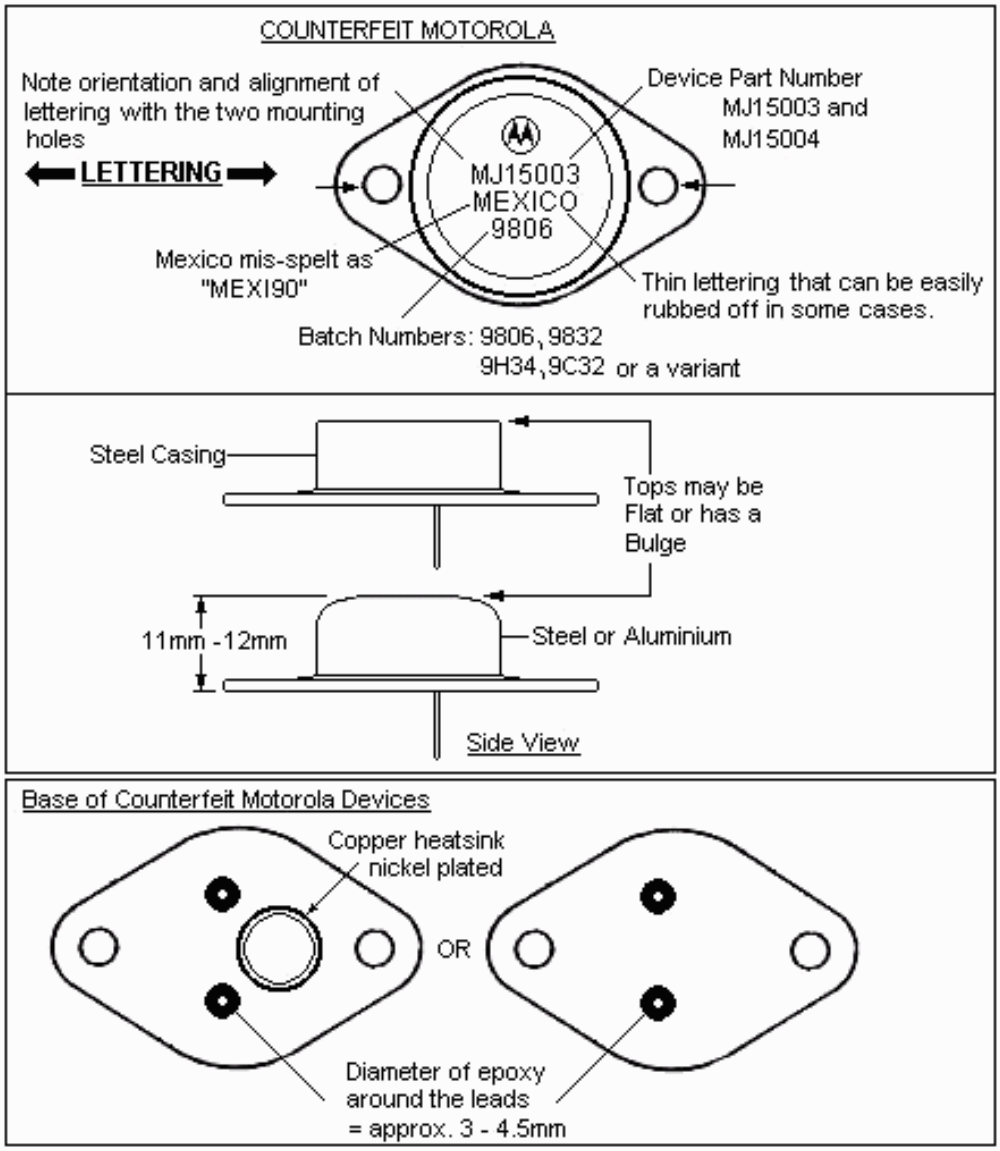
Some info received from a local supplier in response to my e-mail (reproduced verbatim) ...

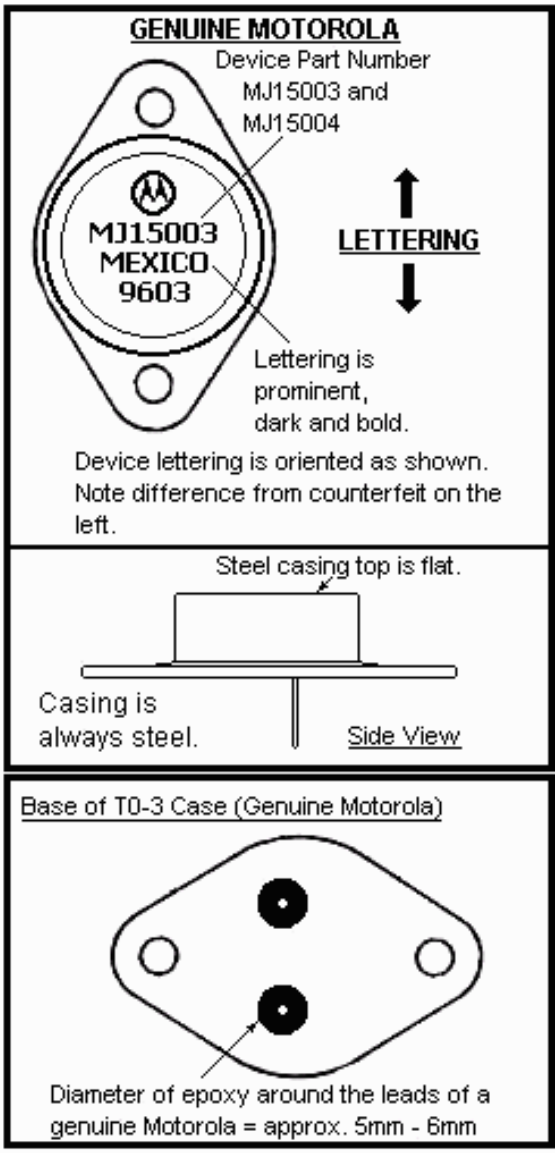
> Dear Mr. Elliott,
> Thank you for your email regarding the above matter. We have already been alerted to the problem about a couple of weeks ago when it was first noticed that some of the MJ15004 were found to be incorrectly polarised - that is, NPN instead of PNP. Our suspicions were raised and we proceeded to cut the devices open, finding their internal construction to be as per your description. Not only that, the chip dies were smaller than the known genuine Motorola types and the internal finishing was abysmal - not the usual high standards that is expected of a Motorola device. The counterfeiters were, fortunately, not too professional and it was possible, on close inspection and comparison to a genuine Motorola device, to tell them apart.
>
> From our knowledge of Motorola manufacturing processes, such a shoddy quality would never have been passed and they are definitely not from Motorola. Upon ascertaining this, we contacted Motorola or rather, ON Semiconductors in the U.S. and notified them of the counterfeits. Together with that, we also provided them with whatever information we have on hand regarding the source trail of our stock which came through a local Australian importer who brought them in through an until-now trusted source in Hong Kong. We have little to doubt the trustworthiness of our supplier as we have been dealing with him for a number of years without any problem encountered. From ON Semiconductor's reply, it would appear that they are already aware of the existence of a counterfeit ring operating out of India and China. We have left any further investigations that ON Semiconductors may want to carry out with them on an international level.

There was some more information regarding store policies that I shall not disclose, since this may identify the supplier to locals, at least. I was suitably impressed with the explanation and the efforts taken to fix this problem, and can only hope that other suppliers are equally responsive.

Oct 2000 - Dick Smith Electronics Issues 'Motorola' Recall Notice

Australian electronics retailer (and wholesaler) Dick Smith Electronics has issued a recall notice on the fake Motorola transistors, and provides a detailed description of how to identify the genuine article from the frauds. This is a good move, and offers some hope to the poor purchaser, however so far no-one else has even acknowledged that this fraud exists, despite that fact that at least one Sydney based firm is still happily selling the counterfeit devices. This is a shameful situation, and one that I would like to see corrected as soon as possible. I am not about to hold my breath, as I expect it will be a long time (if ever) before the others admit their mistake (assuming that it actually *was* a mistake!)





Finally, click either image below to enlarge - they are fairly big photos, and will take a while to load if you are on a dial-up connection. It is worth the effort though, just so you can see some real samples.

06 Jun 2001 - and now, another report (reproduced verbatim)

From South Africa ...

> I live in South Africa and build audio stuff for a hobby (sometimes making the odd amp for a friend and I am presently finishing a friends amp.) I was surfing the web and stumbled onto your site again. Having looked through all the project stuff, I finally went onto the editorials and came across the counterfeit transistor story.
>
> The hairs on the back of my neck started to rise the more I read because the amp that I am finishing is using MJ15003/15004 output devices, but I was at work and had to wait till I got home to check what devices I have installed in the amp. Needless to say they seem counterfeit, see attached jpeg image file, with MEX190/MEX1CO as the place of manufacture and 9H34/9R32 as the date codes (as per Richard Freeman's email to IndustryCommunity.com). I have as yet to open these device but I am sure that they will have two dies internally, when I get the time I will open them and take a photo of the internals. So the counterfeit devices are not only confined Australia, but are probably available throughout the world.

The JPEG image I was sent later confirmed the devices are fakes. They were virtually identical to those shown above.

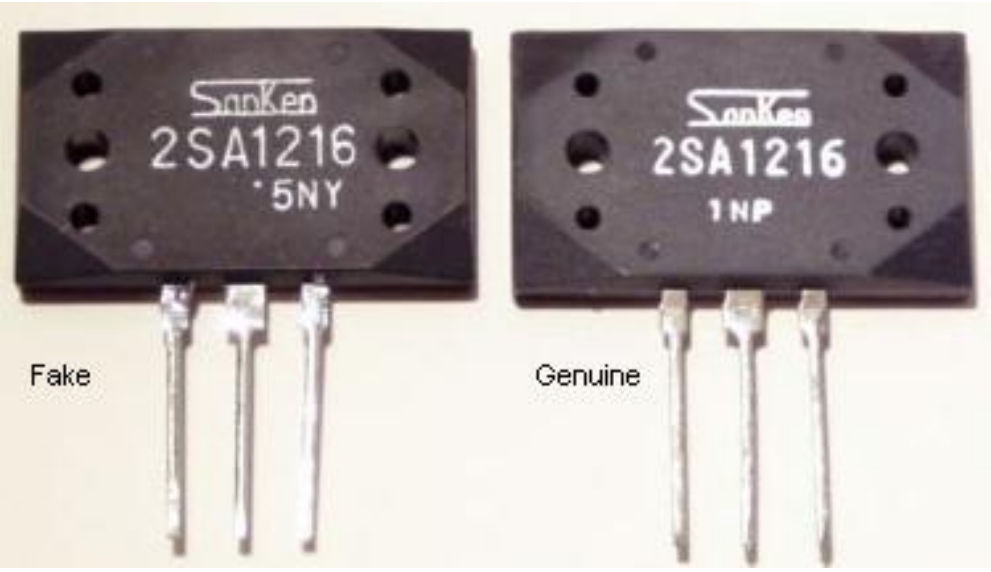
Sanken 2SA1216, 2SC2922

25 May 2003 - From Singapore, Michael Chua provided this information ...

The Sanken on the ***right*** is the original part in each photo, with the fake on the left, as indicated on the photo.

Obvious Features of Original (Front) ...

1) The lettering is thicker and smaller.
2) The production

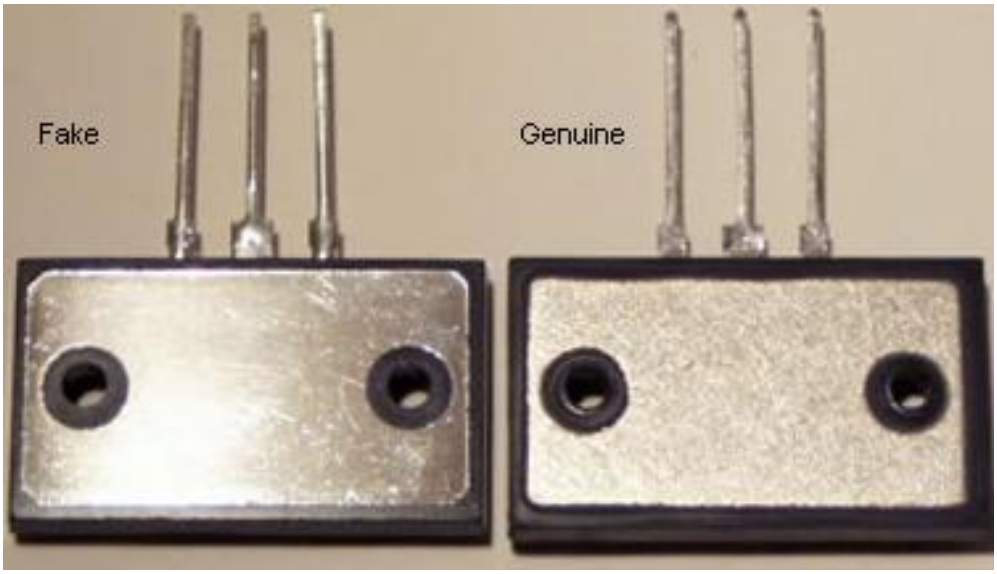


run number is in the middle, below the part number.

Less Obvious Features (Front) ...

3) Overall size - the original is slightly bigger, about 0.5mm on either edge.
4) In the originals, the angles are not as sharp (slightly rounded).

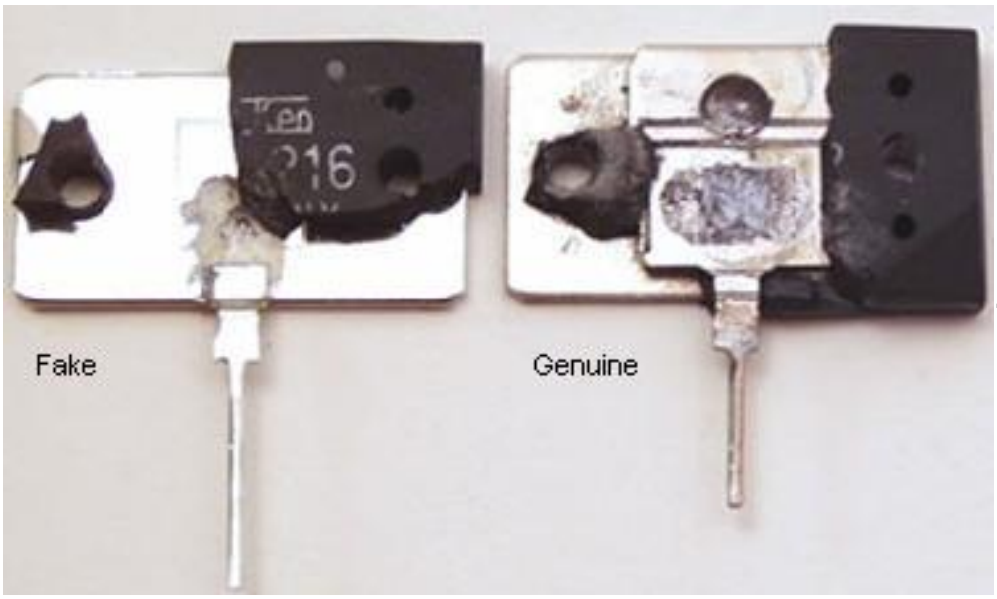
Obvious Features (Rear) ...



1) In the original, the back metal plate is slightly frosted.
2) The fake ones are shiny, almost a mirror finish.

Common

Features: Both weigh approx 10 grams.



... And when cracked open, the difference is very obvious

1) The die on the original is attached to a TO3P type heatsink which is in turn bonded to a larger heatsink contact face.
2) The the die in the original is much larger.

It is difficult to tell exactly, but the die in the fake looks to be around 3mm² which seems to be a common feature of most of the fake devices seen. That it is a great deal smaller than the original, and that it has less ability to spread the heat to the metal heatsink face is quite apparent.

I can only assume that the metal backing plate is slightly thicker in the fake, so that the weight of each unit is reasonably similar. This will not necessarily assist heat removal though, and these fake devices would be lucky to withstand 100W dissipation (based on tests I have done on other fakes with a similar die size).

When I asked if it was ok for me to 'borrow' the info from his site, Mike sent me the following e-mail ...

> I am delighted with your offer. For the sake of the audio community, it is important that these people are exposed. I was told these fakes originated from China. What surprises me is how close they are to the real thing. I will keep you posted if I come across more fakes.

See the original page at AmpsLab, and my thanks to Michael for allowing me to use his photos and info. If these are available in Singapore, you can guarantee that they will be in wide circulation very quickly, since Singapore is a major distribution centre for Asian semiconductors.

Toshiba 2SA1943 / 2SC5200

12 April 2004 - From the UK, Mark W has provided the following ...

I regret to report to you that you may now add 2SA1943 to the list of possibly fake transistors. My story will probably sound familiar. I was powering up an amp of my own design (more or less) for the first time when the fuses blew. I removed the output devices and discovered that one had failed short. I checked the schematic and the pcb layout for design/construction errors. I did this twice. I first decided that the fault was mine since earlier I had a small problem because of forgetting a sil-pad (though not on the failed 2SA1943). But also felt that the circuit and layout were essentially OK - it wasn't THAT original. I try to power up again and when the rails reached ±35V the prior story repeated. I was still inclined to suspect my own ineptness but on a lark, I smashed open one of the 2SA1943's if only to alleviate my frustration.

I won't send the samples. You could mention however that one visual characteristic of the fakes is that the Toshiba making is on a smooth shiny rectangular area of the package. On the fake it is easier to read the markings than the real ones.

What I found looked exactly, I MEAN EXACTLY, like the photo on your site of the inside of a fake 2SA1302. I conclude it's the same bastards just printing a different label on the package, At first I just thought I couldn't find the die or didn't know what I was looking for. Then I saw this 3mm x 3mm square thing pasted on with white glue. There is a clue on the outside. On a real one (I sacrificed one just be sure) the Toshiba label is typically hard to read on the dull surface. On the fake the surface has a glossy area where the label is quite clear.

The 2SC5200s from the particular supplier seem to be real. They don't die when abused and the exterior is dull flat black, somewhat difficult to read unless the light is right.

This was a foregone conclusion - I knew that the criminal bastards would go for the latest Toshiba devices sooner or later, but I must admit I'm a little surprised that it took them so long. This means that it is inviting disaster to use *any* Toshiba power transistors unless you are 100% certain of the source - unlikely in the extreme.

This is a pity, because they have a very good performance (well, the genuine ones do), but the criminals have once again ruined the reputation of a perfectly good transistor, and created a situation where it would be folly to use them in a design.

NTE36, NTE37

23 Jan 2003 - Alleged NTE devices have been found in the US (NTE36/37) that failed instantly, and just to add insult to injury, took the bridge rectifier and transformer with them. An edited quote from the reader who found these latest gems ...

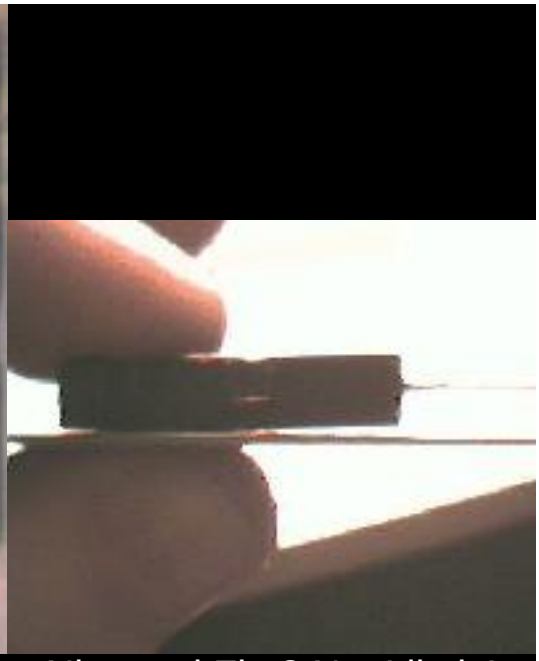
> I just got done reading your article on the counterfeit semiconductors and it all clicked for me. A little while back i was repairing an old amp of mine and purchased 2 pretty expensive matched pairs of BJT's from <name withheld> here in the States. NTE37 and NTE37 are the same as C2581 and A1106 devices. Well these NTE brand semis looked weird to start off with - one transistor of a matched pair was in a green case but the rest were in black ... under the NTE36 and NTE37 I could see a shadow of a device number on each semi that had been taken off. I had no clue about this counterfeiting thing at the time and put them in my amp - they immediately burned out but this time it took out the transformer and rectifiers with them. I thought i was just loosing my touch at fixing stuff at the time but now i see what the real problem is 'cause I cracked open one of the cases a few minutes ago and it definitely didn't look like the original semiconductor die. Tomorrow I'm going to contact the supplier and let them know, because I paid them US$40 for 4 transistors and ended up with about US$150 in damage.

Toshiba 2SA1302, 2SC3281

A reader in Sweden sent me some pictures of fake Toshiba devices, purchased from a local dealer - this shows just how bad these counterfeits can be ...

2SA1302

2SC3281



Nice and Flat? Not Likely!

Notice in particular the rightmost picture - the transistor base (the heatsink surface, not the internal connection ;-) is so convex that it won't sit even *close* to flat. In this case, there is about 0.5 mm convex curvature, which is so completely unacceptable that words fail me!

I have heard other reports of bases that are concave, so the device will never make proper contact with the heatsink, but you can't see it. Either is unacceptable (in the extreme). The printing on the 2SA1302 looks like it was done with a felt-tipped pen (well, maybe a little better than that) - not quite what one expects from a reputable manufacturer, is it? These devices passed the acetone test, so the markings are quite permanent (not all do though - the printing can be removed quite easily from some fakes).

This is an appalling state of affairs. I also recently had an e-mail from a reader in the UK. He built the P68 subwoofer amp, and was only running it into 8 ohms and it failed. After a quick exchange of e-mails, it transpired that he purchased some 'Toshiba' devices from a local supplier for less than the normal price - say no more! His first set came from a reputable dealer (but not the distributor), so almost no-one can be trusted on this score.

From New Zealand ...
A reader sent me a sample 2SA1302 and 2SC3281 to test for him, after his P68 sub-woofer amp blew up during quite gentle testing. The 2SA1302 died well before I could reach my target of 5A at 30V (the limit of the SOA curve for these devices for steady state current at that voltage). The tests were done with the transistor firmly clamped to a heatsink, and were of short duration to prevent the die from overheating - but it still failed!

Someone *must* be joking!

The die is 2.5mm square! This is tiny, and I am actually surprised that the transistor managed even to get to 2A at 30V before it blew. This is well short of the specification, and obviously the reason the amp failed. One can hardly expect a 60W (at best) transistor to provide close to 120W output (the approximate power expected from each pair of devices). Naturally, the devices that I was sent were clearly branded as Toshiba, and are just as clearly fakes.

The 2SC3281 actually managed to survive my SOA (Safe Operating Area) test, but given that the printing was almost identical to the other device, I would be highly unwilling to trust it - it may well be genuine, or simply a "better class" of fake. There were also subtle differences in the case construction of each device, with the 2SA1302 being almost identical in all respects to the Chinese devices that I have (not branded as Toshiba, but also incapable of the rated power during an SOA test). The 2SC3281 was different from any of the other samples I have.

Just in case anyone was wondering, I know it's not my P68 amp design, since I would have had

> a great many complaints by now if the design were flawed, so that only leaves the transistors as being highly suspect. My original amp works fine as well, and has been "punished" many times without failure.

Please take great care when buying semiconductors - especially 'premium' devices. Since these have the highest markup (i.e. they are fairly expensive), they are the ones most likely to be fakes.

From another reader ...

> "Add 2SA1302 and 2SC3281 (Toshiba) to your counterfeit list. I found them (counterfeit ones, that is) here, in dinky Malaysia! The ink printout is totally different from the real thing, being WHITE in colour."

Toshiba plastic transistors are usually marked in white, so this could be misleading. However I do know for a fact that Chinese (unbranded) 2SA and 2SC devices are available, but these make no pretence at being Toshiba. Perhaps (although I think we can be definite on this score) someone has bought the Chinese ones and re-branded them as Toshiba - a worthwhile effort for the criminal element, since the Chinese devices are quite cheap.

Since the Chinese devices are not branded, they cannot be deemed counterfeits, but what sort of quality you could expect is anyone's guess, so one should be wary. It is possible that these transistors are OK, but equally they may be completely useless.

Further Update (06 Jan 2002)

I have checked the Chinese versions, both a load test and visual inspection. The device I checked blew up at well below the normal peak power, and a look at the innards revealed a silicon die about 3mm square - too small for the documented power rating.

On the positive side (if there is one), at least the base plate was copper, and passably (!) flat, unlike the new fakes shown above. These devices would probably be OK in a low power amp, but cannot be used at anywhere near the full capabilities of the real Toshiba transistors.

Are these being purchased by the unscrupulous and re-labelled as Toshiba - *you can count on it* ***!***

One thing that *is* known, is that Toshiba has not made 2SA1302 and 2SC3281 transistors since 2000 (or thereabouts), so the chance of obtaining genuine devices is very low. I

would like to be able to suggest that MJL1320/3281 or the current Toshiba 2SA1943 and 2SC5200 be used, but fakes of the Toshiba devices are already spreading, and even the latest ON-Semi devices can't be far behind).

OP-07 Opamps

Where (or what) next? I received an e-mail from a reader in India, who purchased some premium opamps (at a premium price, naturally). Having paid for OP-07 opamps, one would be disheartened to put it mildly to discover that they were really 741s. I don't know if this has happened anywhere else, but it is fair warning that you could be next.

'Toshiba' 2N2773

Now we have Toshiba branded 2N2773 power transistors. This in itself is interesting, as a search on the Toshiba site reveals that they don't even seem to make this transistor! It would be unusual for a Japanese manufacturer to make a '2N' device at all, but doubly so since this is a very old device now, and seems to be discontinued by just about every other maker.

Again, these have all the earmarks of counterfeits - and naturally enough someone was caught out, and his amp failed with these transistors installed. If you happen across any of these components, be afraid - be **very** afraid!

National LM3915

... And Still They Come ... From a reader in India, and reproduced (almost) verbatim:

> I was reading the article about duplicate/fake transistors. Well, they started faking ICs too!. Don't get me wrong though. I live in India. In my best knowledge, there are no IC/Transistor making factory anywhere in India. So I don't think the fakes are MADE here. But there is a possibility that India is a kind of dropoff-point.
>
> The real purpose of this mail is to add one more IC to the known frauds. (Hundreds more maybe there). I bought this IC, LM3915, supposedly made by National Semiconductor for your LED VU Meter project. It costs about 50Rs (our currency, that's about $US1.00). But it burned out the instant I connected it to the 15-0-15 supply. I bought another one from another store. It looked a bit different. Anyway after reading your article, I got suspicious. I used a simple knife to remove the top cap like thing of the IC (Normal ICs cannot be stripped like that).

> I found another IC. When I scratched the silicon, I saw what I was expecting, LB1405. A vastly inferior (in my experience) and cheap IC. I got ripped by 5 times the cost. I might not have found out this if I didn't power it with 15 volts. I don't know how 'THEY' managed to do this. But it wouldn't have worked anyway. The pin configs are very different. I showed it to the store owner. He discarded it as my mischief. But I couldn't help my poor friend who was making a 10 channel EQ. Poor fellow. He burned out all of the ICs he bought from this store. He doesn't have the budget to replace all the chips. So he's using the EQ without the VUs. Poor chap.

The above was actually received some time ago, and I forgot about it. I have now remembered :-) As you can see, this is widespread, and many store owners are unlikely to admit that they have fraudulent stock.

I think I can say with reasonable certainty that this is the tip of the iceberg. How much reject stock (factory seconds, out of tolerance, incorrectly marked, etc) is gathered up by unscrupulous dealers and sold off as first quality? My guess is - a lot.

Always remember ... Any deal that ***seems*** too good to be true almost certainly ***is*** too good to be true!

2N3773

From Canada ...

> About three weeks ago we received a batch of transistors from Digikey... To be more specific: 2N3773's... (about... 100 of them at $1.25 ea.)
>
> I have worked with the original MOT's and I know the way they are built and labeled. These "new" parts, didn't look like anything I have ever seen, and I have been in this field for almost 20 years working in audio related goodies.
>
> The Manufacturer: MEV (you tell me if you know them)
> Case: Steel or something like that
> The finishing: lead immersed. the whole case looked as if it had been immersed on molten solder to "give" it a "silver coat" look alike. (the pins even looked as if they were used devices and had been cleaned off to strip excess solder material.
>
> The label (markings): looked like cheap paint barely stamped onto the top of the case. some acetone and it rubbed off. (YIKES!!!) And it looks like this:
>
> MEV
> 2N3773
> 94N3
>
> And, if this wasn't scary enough yet, here's the best part of the movie...
>
> I installed one new pair on a switching amp used on a GE servo. Each board makes 1 half of an

H Bridge. So a total of two boards are necessary to form a dual direction servo unit (Each amp uses a total of 12 2N3773's for a total of 90 Amps at 90Vdc, at full load when the trannies are completely either on or off depending on the direction of rotation) all the original devices on the amp were ok, except two that were shorted. After double and triple checking of the board, I installed it on a test bench we have built. (to simulate the working conditions required by GE's service manuals).

The "new" trannies lasted 15 seconds... they started off fine and gradually deteriorated until they went off with a bang!!! The rest is history... replaced them again with two more from the same batch and they worked for an hour...

So I decided to crack the first pair open... (considering i had read your stories on your website...) The Dies are smaller than those of a 2N3055. 25% smaller than the original Motorola devices.

Silicon is Silicon any way you slice it and (normally; did I hear... counterfeit???) current densities are the same from one device or manufacturer to another ... regardless of it's use or purpose. Once you go beyond this set parameter, you're in trouble. Even worse if the TO-3 case (like this aforementioned device) has a coin no bigger than 1 CM wide by 2.5 mm high. (Yes I love Metric system too.)

Footnote: I just remembered another device I ran into that same day... A 2N3055 (supposedly MOTOROLA, as it was labeled. Yet the ink used for the label was the cheap kind.) that looked almost identical to a genuine MOT device, BUT it was made in MEXICO. So far that sounds believable... Right???

Wrong!!! I opened the casing after i had blown one up at only 6 amps, and came to see that the die was slightly bigger than that of a TIP 41C. Like I might have said before, I know very well the dies in these devices. I cracked many of them open to see their guts after they blow. Weird, eh? No coin, or any internal heat spreader at all. The chip looked like it was glued to the case. No traces of the usual solder material that's normally used.

My dear friend...
As much as I love my hobby and my profession (which happens to be the same. I HATE THIS CRAP!!!! (Excuse my french!). I mean... seriously. What's next?????

Let's hope that someone sees this and takes some action!!!. I am, and WILL do my part! I hope this matter (someday) might be resolved, or at least tamed. (Yeah, right.)

I apologize for my rather dry sense of humour. Yet this is no laughing matter. Please feel free to modify this email at your will and post it on your site (if you feel it's worth the effort.)

MJL21193 / MJL21194

Update - 21 Feb 2006
I have just been informed by the Australian supplier referred to below that these transistors are also branded as ON-Semi. The only way to be certain is to check the package. Genuine ON devices have square-edged steps on the pins, and (needless to say) have completely flat metal rear surfaces. The fakes have tapered pins and a stepped case as shown in the photo, and non-flat backs (although some may be 'better' than others).

The supplier has issued a recall of the ON branded fakes (having recalled the Motorola branded fakes as soon as they were alerted to the problem), but many constructors may have purchased the fakes before they were identified. If you find *any* transistors in your collection that look like the fakes shown below, return them immediately.

These first turned up in Australia in around October 2005. They were first brought to my attention by a reader early in 2006, and although I didn't get to see any in person, I have the photograph reproduced below. The supplier shall remain un-named, because they acted swiftly and decisively, protecting their customers from potential harm.

The thing that gave the game away with these was the date code. According to the code, they were made by Motorola in 2000, but Motorola had handed *all* discrete semiconductor manufacture to ON-Semi in 1998, so a Motorola branded part allegedly manufactured after that date cannot possibly be genuine.

The same (or similar) fake devices are almost certainly still available in Australia, and can probably be picked simply by the price - I

have heard AU$2.50 mentioned for small quantities. Since you can't buy the devices from ON-Semi for that, any MJL21193/4 offered for such a paltry sum is almost certainly counterfeit.

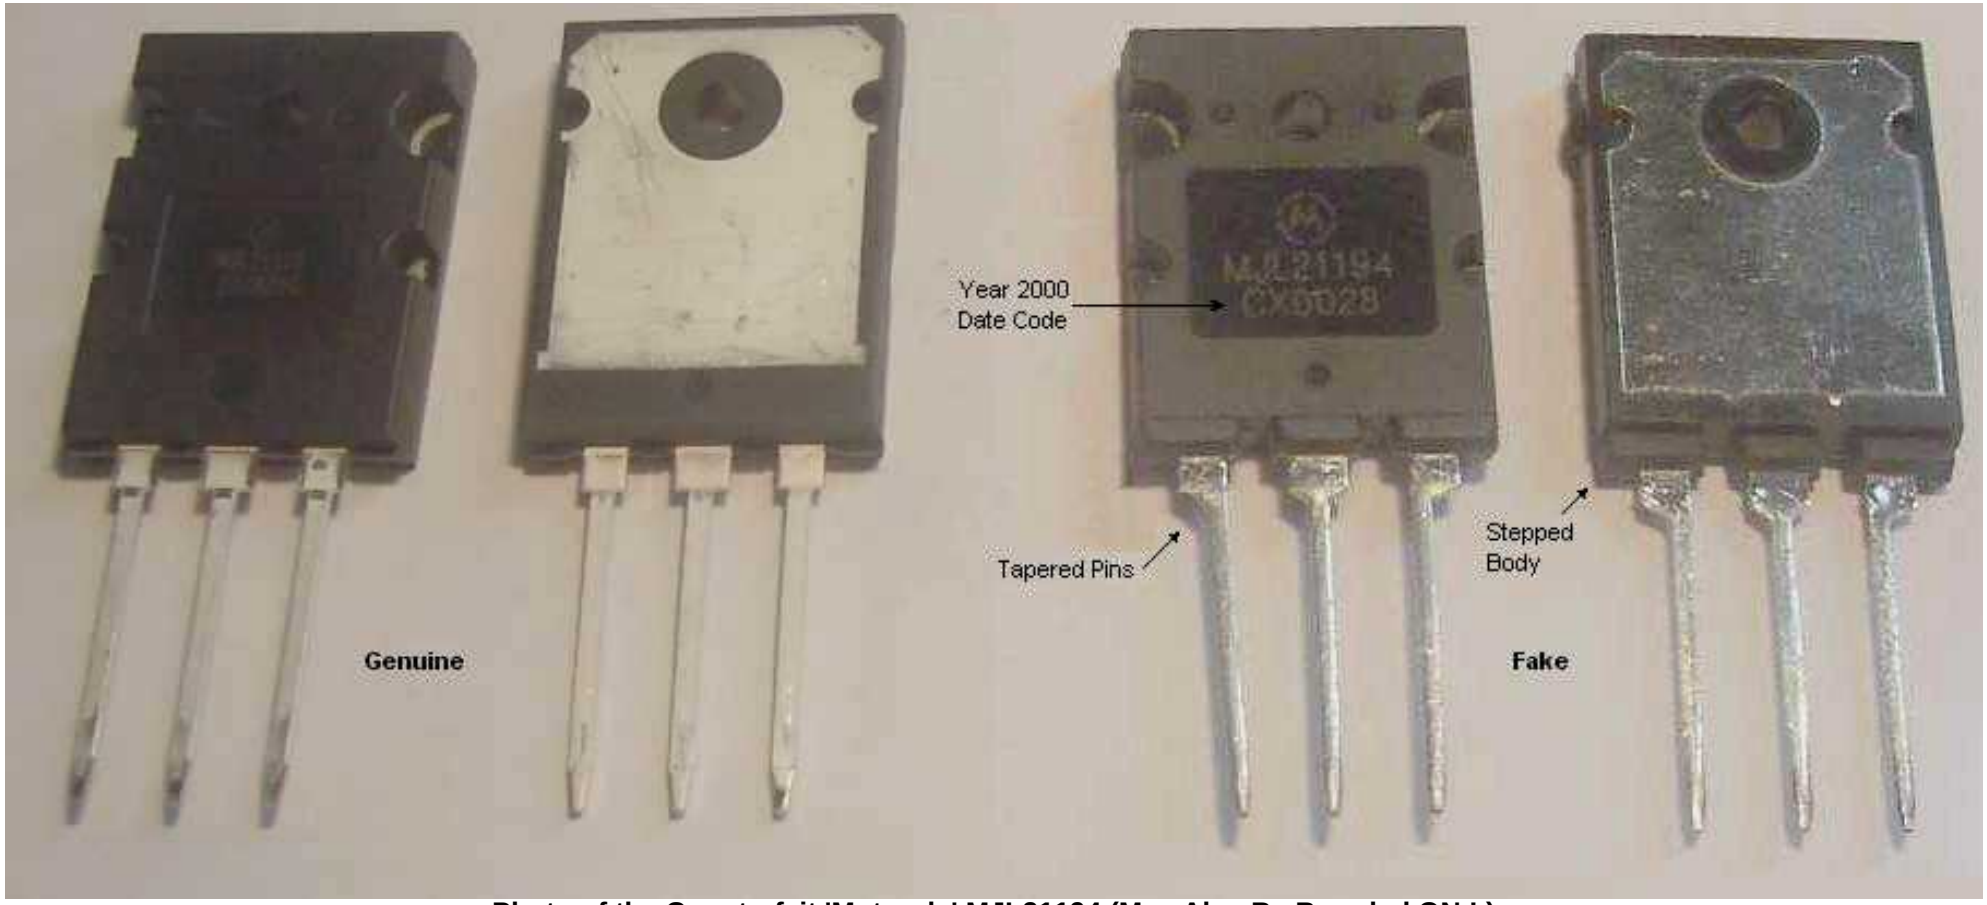

Photo of the Counterfeit 'Motorola' MJL21194 (May Also Be Branded ON !)

The e-mail exchanges are reproduced below, but as you will see, the supplier name has been removed. I did ask, and was told that they would prefer not to be named, and so shall it be. Likewise, the reader's name is not reproduced.

> I have read your article on fake transistors and thought you may be able to shed some light on a possible counterfeit transistor.
>
> I have been working on a project using MJL21193 and MJL21194 transistors and have found what seems to be an anomaly in the packaging. The ON - MJL21193's have come directly from ON-Semi as samples and in all respects conform to the drawings on the data sheet. The Motorola MJL21194's were sourced through (a supplier) and there are some discrepancies between the package and the drawing.
>
> The Motorola data sheet (old version, dated august 31 1995) and the ON data sheet (latest version from on, dated 9 June 2005) both show the same package information, both which match the authentic ON samples.
>
> The suspect devices (see attached image) have steps in the plastic where the legs come out and the outer legs taper towards the center of the

> package rather that the center of each leg. Also, the heatsink surface is not flat but curved (convex). if I hold two together where they bolt on there is a 0.5 mm gap at the other end (0.25 mm each). The ON devices are dead flat (I cannot see light between two devices held together).
>
> (The supplier) was adamant they get their stock from a large Australian supplier and that they had no concerns. Does this sound like cause for concern or is it normal that a manufacturer would use a different style package and is the flatness of the back of the package an issue? Note that the ON devices are lead-free so the metal finish may be different for that reason and is not necessarily another notable difference.

At this stage, the supplier wasn't overly sympathetic, but things changed quickly. The next part to the story comes from ON-Semi, after they were contacted about the devices. The following reply was forwarded to me ...

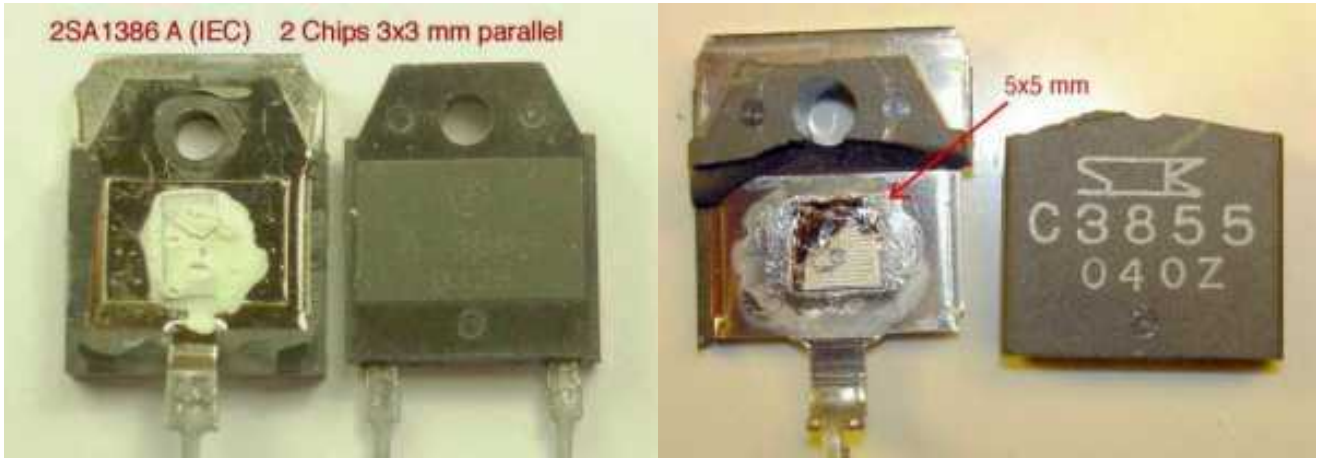
> Response From ON Semiconductor Service Request #66471
> ON Semiconductor Technical Information Center
>
> Thank you for contacting ON Semiconductor
>
> This device does not match our packaging and marking specifications. It is not ON Semi's or Motorola's device, because there is the year of production: 2000. ON Semi had take over the portfolio from Motorola in 1998. Also Motorola is not producing any semiconductors from this date, only whole electrical appliances.
>
> Regards,
> ON Semiconductor
> Technical Information Center

I contacted the supplier and passed on the concerns as soon as I had confirmation that the devices were counterfeit. Later that same day I was able to confirm that all stores were instructed to check existing stock and return any fake devices to the warehouse.

2SA1386 / 2SC3519 (?)

The next batch of fakes are not marked as Sanken, but use the same type number as a Sanken transistor. While this does not make them (technically) counterfeits, they are still fraudulent. A transistor marked as a specific type should perform to a similar standard as the original, and this is very common with a lot of 'second sourced' components. This is where more than one manufacturer makes the same type number. In general, these second sourced devices can be expected to perform as well as the original.

That was definitely not the case with these devices. They are branded as 'IEC', but don't be surprised if this is not a known semiconductor supplier. There was nothing in the information I was given to indicate that the complement was also available as an 'IEC' device, but it is safe to assume that it will be in circulation.



Photos of the IEC 2SA1386 (Left) and for comparison, Sanken 2SC3855 (Right)

The original message I received on this topic came from Germany, but beware of these devices regardless of where you are ...

> Hi Rod,
> there are not many sites dealing with counterfeit transistors. great!
>
> recently I ran into some transistors made by IEC which weren't that wonderful, at least they haven't been relabeled SANKEN.
>
> The original SANKEN 2SA1386 is rated 130Watt with a SOA of 1,5A @ 60V continuous - The IEC survived a 1A 60V pulse of 1 sec.
>
> When I tried it with 1,5A @60V it died after 0.4sec. Case temperature was only 20 (Celsius).
>
> When I opened the case I saw that it has two dies parallel, each about 3 mm square, total area is 18 sqmm.
>
> For comparison, The smaller SANKEN 2SC3855 (100W) has already a die of 5x5 mm = 25sqmm.
>
> If you like you may put the pictures in your gallery, though these types are not used in your projects.

What we see here is a flat-pack version of the 'double-headed duds' described first for the MJ15003/4. This is the first time I have seen this done in a plastic package, and was obviously an attempt to make the transistors perform to *some* standard. Needless to say it failed. The smaller Sanken device (2SC3855) is not the complement to the 2SA1386 (that is the 2SC3519), but was included as a comparison - a smaller transistor with a bigger die area than one supposedly rated for higher power. Need we say more?

It's a very sad situation, but as I have mentioned elsewhere in this section, I consider it unwise to buy *any* Japanese transistors unless you are 100% certain of their pedigree. Whoever is doing the counterfeiting seems to have targeted the Japanese devices hard, and they won't stop now.

Introduction

The projects presented here are a mixture of basic (and not so basic) designs. Of these, most are originally designed by me, and have some unique quality which makes them worthy of publication, while others are simple extensions of basic theory. Not all have been built and verified, but with those that have not this is not an issue, since they cannot help but work. Of those which are not tested, they have all been simulated to verify that no stupid mistakes have been made, and will work (if correctly built) on the first attempt.

These projects are not intended for the novice electronics hobbyist, since they all require some basic (or in some cases advanced) knowledge of electronic circuit construction, mounting power transistors, soldering techniques, mains wiring, etc. Make sure you read (and heed) all warnings and the disclaimer before starting construction.

Each project description has one or more "flags", that indicate the status of the project itself. These are as follows ...

Flags	Description
new	The design (or update) is less than 2 months (or thereabouts) old.
	Mains wiring is involved, and is potentially dangerous - heed all warnings ! Note that this symbol is displayed on specifically mains powered projects, but other projects may also need a power supply which also requires mains wiring.

PCBs are (or will be) available for any project marked with this symbol. Boards may not be available immediately, but are expected within a month of publication of the project or posting of the PCB symbol.

Date The page was added or updated on the date shown (new updates are shown in red)

Updates

ESP reserves the right to change or update projects without notice, so it is important to be aware that a change may have been made. You should always watch for updates of previously published items. These are shown as a date beside the project (in the "Flags" column). Do not build any of the circuits presented here without checking for updates first. A "new" symbol indicates an update within the last two months or so (but this might vary). Special cases might be listed from time to time - these are likely to be important! Updates less than 3 months old will have the date in **red**.

Note Carefully

Please see the ESP disclaimer for important information

WARNING

Mains wiring should be carried out by suitably qualified persons only. Under no circumstances should any reader construct any mains operated equipment unless *absolutely* sure of his/her abilities in this area. Death or serious injury (to the constructor or others) may be uncommon with home construction of mains powered projects, but the risk is ever-present. The author takes no responsibility for any injury or death resulting from, whether directly or indirectly, the reader's inability to appreciate the hazards of household mains voltages and the correct wiring practices for your country. Please read the disclaimer now if you have not done so already.

Although I am happy to provide assistance to prospective builders, I cannot (and will not) be drawn into prolonged e-mail exchanges if the project does not work as expected. I can say with complete confidence that all projects presented will work ... *if properly constructed according to the published design*. This is not to say that no help will be available - I will help where I can.

It is inevitable that in some cases (due to component tolerances, for example), a project may require a different value resistor, capacitor (or whatever) to correct for an unexpected variation. Since I cannot control or predict the quality of components sourced by readers, nor the standard of workmanship in assembly, it is not possible to allow for every contingency.

Please do not attempt the construction of any project which you do not fully understand, or if you do not feel completely confident that you can build the project without further assistance. Do not expect me to be able to diagnose an obscure fault remotely, and especially if the project has been modified in any way whatsoever.

Elliott Sound Products **Contacting ESP**

Thank you for taking the time to respond. Normally I will respond to e-mails within a few days, but sometimes it may take longer. If it seems that I have forgotten you - probably not, it just means that things are a little hectic. I typically get about 30 or more e-mails each day, and yours is no more or less important than any other.

PLEASE BE CONSIDERATE: I regularly get e-mail from people using anti-spamming services. This is fine, but don't expect a response, since these services just throw my replies away. Please advise me in your e-mail that you are using one of these services, and provide a real e-mail address - *preferably at the beginning of the e-mail rather than at the very end where I might not see it*. It is very frustrating to compose a reply, and later discover that it cannot be delivered. It is a waste of time that I can do without.

As you can tell from the STOP image below and some of the comments, I continue to have a lot of e-mail problems. Apart from stinking spam, one of the biggest issues I have (ongoing) is irritating questions where people are too lazy to look up the information for themselves.

E-Mail Policies - Please *READ!*

Yes. **All** of it!

- ***ESP is not a free information service. Limited support only is available to those who do not purchase PCBs.***
- ***If you send me invitations to join a "friend's network" or similar, it will be deleted without answer. No exceptions.***
- I am happy to answer questions about my own projects and articles, but I will not

be drawn into lengthy exchanges if you build something and cannot make it work (*especially* if you make your own board). In 99.9% of cases where a circuit does not work **you have made a wiring mistake.** It is extremely difficult to diagnose faults remotely, so if you are not sure of your ability to build a project - **don't**. All schematics where a PCB is available work - period! If yours does not, then the mistake is yours, not mine. See the troubleshooting guide before contacting me.

- Before asking questions, read the **FAQ** page, and check that the articles don't have the info you need. In many cases, I am asked questions that are fully explained on the pages. Visit the main index for access to all the information available on this site.

- I ***will not*** attempt to give answers to questions about stuff you find from links or elsewhere. Contact the owner of the site (or the manufacturer for commercial products) for more information.

- Consider posting your question on the ESP Forum rather than sending an e-mail. Others may be able to spend more time to help you with your questions.

- Do ***not*** ask me to endorse (or otherwise) 'Brand X' of anything - cables, amps, speakers etc, because I will not do so. Refer to the disclaimer and other comments relating to the naming, endorsing, or bagging of any product by name or model.

- I reply to most e-mails. If you do not get an answer, the e-mail address you (or your e-mail client) supplied was wrong, or your e-mail service may have problems. There may also be a spam blocker in place - be warned - I will only try to e-mail you **once**, if my attempt is blocked I will not try again.

- In some cases, your question or request was such that I will simply delete it. I regularly receive e-mails that are a blatant attempt to obtain something either free or by deception. If you send me an e-mail like that, I **will** delete it without a second thought.

- If your e-mail looks like spam, my spam filter(s) will delete it. Make sure that you include a sensible subject line, and if at all possible, avoid using free e-mail services (especially Yahoo! and its ilk).

- **Please make sure that the following are included ...**
    - Your name (it is extremely inconsiderate to send mail with no name, other than a "reply to" name that is often incorrect).

- Your e-mail address (one that **works!**).
- Proper English (no 'SMS speak' or other stupid abbreviations). *If u cnt b bothered typing yr req in full, I cnt b bothered trying 2 decode it*. If your primary language is other than English, just do your best. Most apologies from non-English speakers are redundant - their command of our language is better than some who speak nothing else! (true!)

Your computer thinks that the time and date is ...

Mon May 29 12:20:37 GMT-0400 (Eastern Standard Time) 2006

If this is not correct, please set at least the date correctly, as any e-mail that appears "old" may not get a reply in a timely manner (if at all).

Cheers,

Rod

The ESP SIM (Sound Impairment Monitor)

Rod Elliott (ESP)

Introduction

The ESP Sound Impairment Monitor is a method of determining just how much your amplifier modifies the original signal. The first version is designed to be built into an amplifier circuit, and although quite simple in concept will indicate if any modification is made to the signal by the amp, for any reason at all.

For example, many amplifiers have overload protection, and this may activate without you even realising it. The SIM will react immediately, since the input and output of the amp no longer match. The meerest hint of clipping - however brief - will turn on the LED, which is designed to stay on for long enough for you to see it.

The internal SIM is the simpler of the two variations, and is actually more accurate than the more complex external version, however it is not as versatile - it is built into the amp after all, so can't be used for anything else.

Description

Nearly all modern amplifiers use a differential input stage, based on the so-called "long-tailed pair". This type of amp will have the input signal applied to one input (the non-inverting input is almost universally used as input), and the feedback to the other. This configuration is identical to that used in an opamp, and just like an opamp, the power amp will attempt to make both inputs have the same voltage at any point in time.

When the amplifier protection circuits operate, or the amp starts to clip, the inputs will have very different voltages on them. Slew rate limiting will also cause the inputs to develop very different voltages, and indeed, any amplifier abberation will change the voltage differential between the inverting and non-inverting inputs of the amplifier.

The internal SIM uses an opamp to measure the signal at each of the amp inputs. This will normally be fairly low - perhaps in the order of about 2 to 5mV under normal operation at just under full power. The SIM has enough gain to allow an indication at voltage differentials down to 1mV between inputs, which means that the finest of amplifiers is easily monitored for any impairment.

Figure 1 shows the differential amp used by the SIM, and it is a completely conventional circuit. This is adjustable by using VR1 to null out any normal variations that the amp might show when there is no distortion or other nastiness in evidence. The second stage is a high gain amplifier, and will amplify the residual signal to a level suitable for the rectifier and indicator circuits.

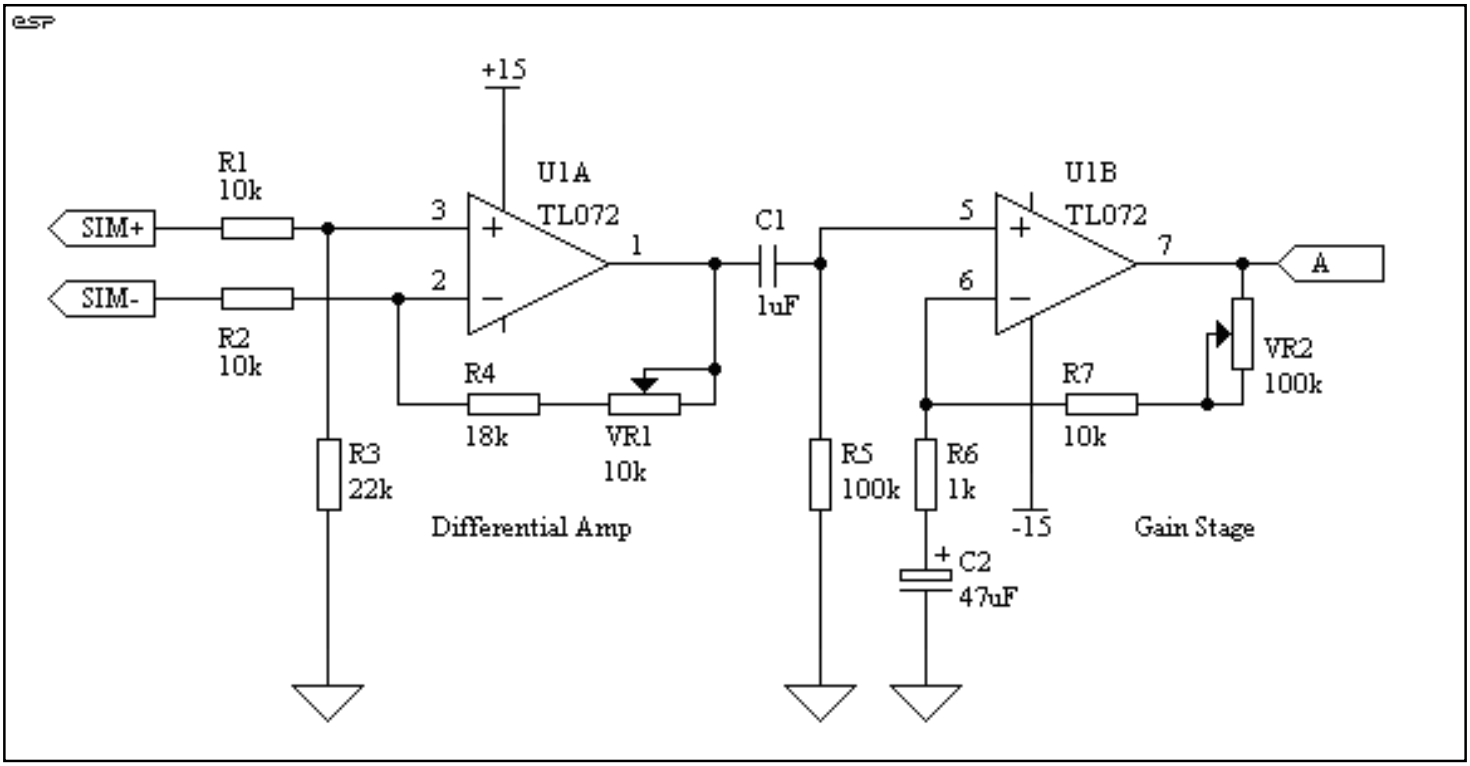

Figure 1 - The SIM Input Stage

The opamp shown is adequate for most applications, but the use of a premium device from Analog Devices or Burr-Brown will improve performance, especially at high frequencies. This is not strictly necessary, because the operation of any amplifier protection or clipping (or any other undesirable effect) will affect all frequencies, not just those that caused the original problem. This is why TIM (transient intermodulation distortion) is so objectionable if it occurs. The SIM will reliably detect any such problem, probably before you are even remotely aware that it is happening.

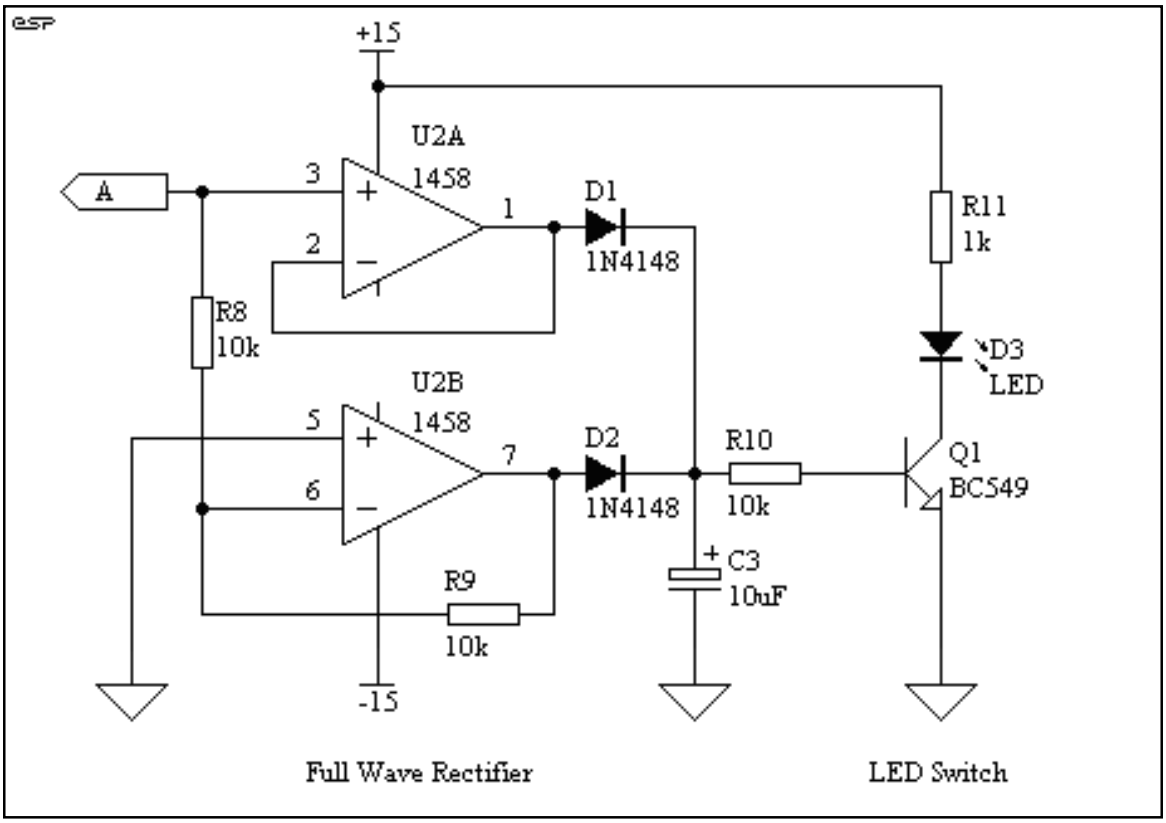

Figure 2 - SIM Detector and LED Switch

Figure 2 shows the detector, which is a simple full wave rectifier. The 1458 opamp specified is quite adequate for this, as the two sections function only as buffers, and accuracy is not important. When the error signal exceeds the detection threshold (about 1.2 Volts), the LED will light, and remain on for long enough to see, even with very short duration signals. The use of a full wave rectifier ensures that an error signal of either polarity will activate the LED.

Connection To An Amplifier

The circuit is designed to use 10k resistors at the amp inputs (as well as those on the SIM circuit itself). Figure 3 shows a typical amplifier (the 60W amp of Project 03) with the SIM connections added. This can be applied to almost any amplifier, with the only effect being that the input impedance will be a little lower than before because of the 42k SIM+ connection input impedance. If desired, the input impedance of the SIM can be increased, and the resistors R3, R4 and VR1 will need to be increased as well to maintain the same ratio.

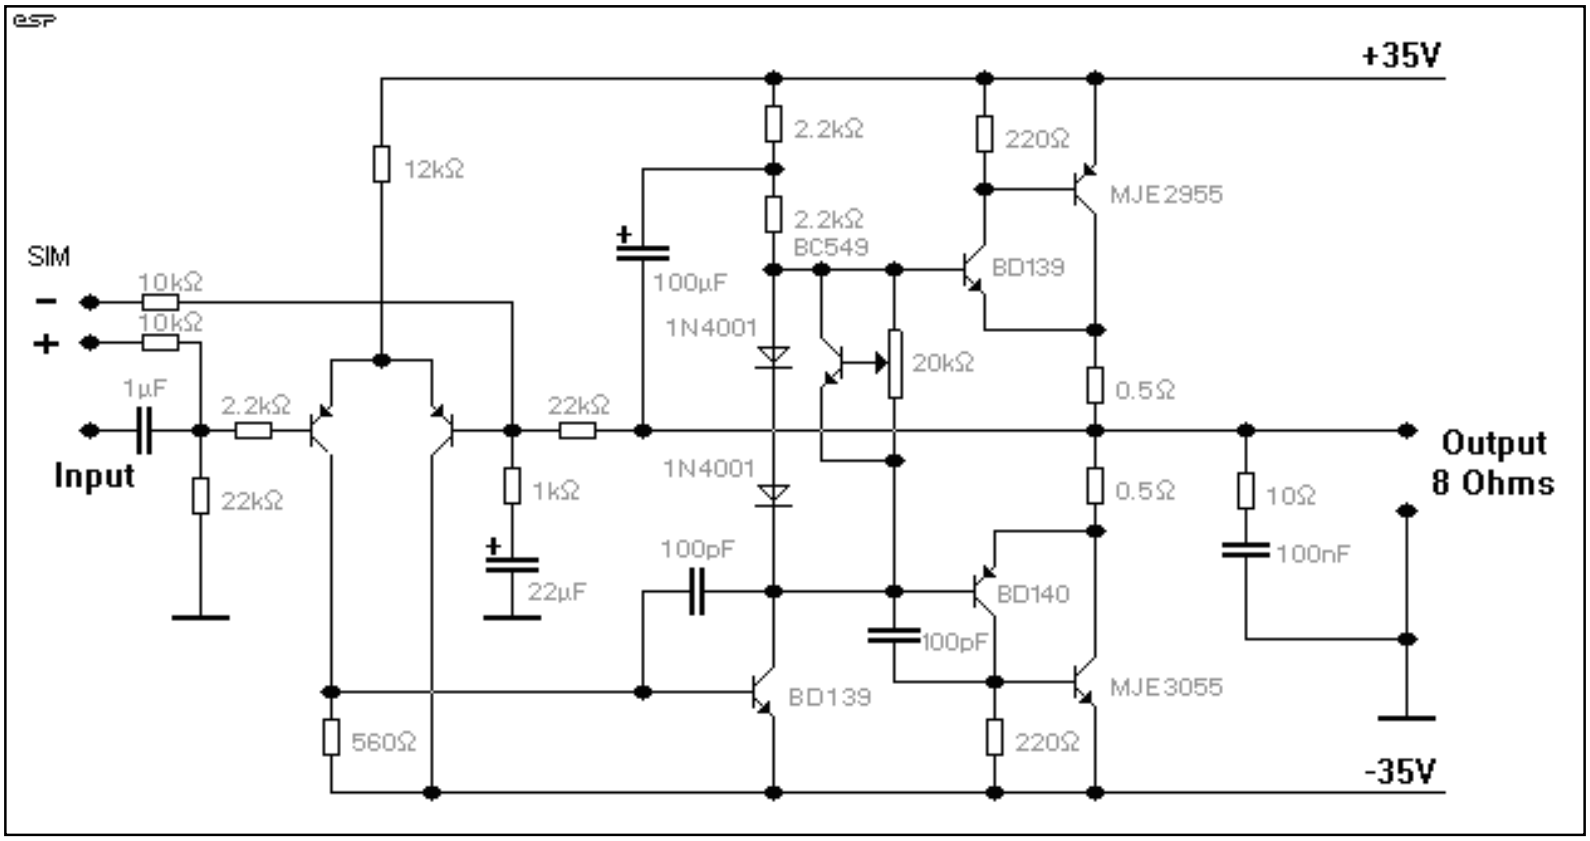

Figure 3 - Connecting The Internal SIM To An Amp

Make sure that all wiring is as short as possible, and the wires should be tightly twisted and preferably shielded as well. This will prevent noise from being picked up by the SIM or the amp. The 10k resistors at the amplifier are to ensure that the stability of the amplifier is not compromised by the capacitance of the cable, and to provide a buffer against noise pickup. These must not be omitted.

Setup And Operation

When the SIM is connected to a power amp, the unit must be calibrated. This will not be as easy for those without an oscilloscope, but a steady signal source is essential. This can be an audio oscillator or a test CD, and the idea is to adjust the circuit so that at all normal settings below clipping, the LED remains off.

First, advance the input level to the amp to a normal to quiet listening level. Disconnect the speaker. With VR2 advanced so that the LED is flickering or barely on, carefully adjust VR1 until the LED is extinguished. Advance VR2 again, and readjust VR1, and repeat this until no further improvement is posible.

If an oscilloscope is available, apply sufficient signal so that the amp is just below clipping. No clipping whatsoever is allowed, so give yourself enough margin to ensure that this is so. Adjust VR2 until the LED is barely visible, then reduce the setting very slightly so the LED is off. If you turn up the signal until the amp is almost clipping, the SIM will almost certainly show the vestiges of clipping well before it is visible on the oscilloscope.

If a 'scope is not available, then a certain amount of guesswork is needed. This will possibly reduce the sensitivity a little, but any audible distortion will still cause the LED to light. You will have to estimate the maximum level that you think is below clipping. If VR2 has to be reduced to near minimum resistance, there is almost certainly too much signal, so reduce it until VR2 can be advanced to close to the centre of rotation. The actual setting can be found by trial and error - at the point when the amp starts to clip, the SIM's LED will go from off to full brilliance (and vice versa) with the tinest change of input signal. Find this point, and reduce the level slightly. Adjust VR2 until the LED is just off.

The SIM is now set up properly, so the speakers may be reconnected and some music played through the system. It is possible that VR2 may have to be wound back a tiny bit if the LED operates at low listening levels, but if the amp is as good as the makers claim, there should be no indication until one of the "defined events" listed occurs - clipping, overload protection or slew rate limiting.

The SIM will indicate if any musical piece causes amplifier distress of any kind. As long as that LED remains off, all is well with your amp.

60-100W Hi-Fi Power Amplifier

Rod Elliott (ESP)

PCBs are available for this project. Click the image for details.

Introduction

Update - 24 Jul 2003. OnSemi has just released a new range of transistors, designed specifically for audio applications. These new transistors have been tested in the P3A, and give excellent results. As a result, all previous recommendations for output transistors are superseded, and the new transistors should be used.

The output devices are MJL4281A (NPN) and MJL4302A (PNP), and feature high bandwidth, excellent SOA (safe operating area), high linearity and high gain. Driver transistors are MJE15034 (NPN) and MJE15035 (PNP). All devices are rated at 350V, with the power transistors having a 230W dissipation and the drivers are 50W.

Having built a P3A using these transistors, I recommend them highly - the amplifier is most certainly at its very best with the high gain and linearity afforded by these devices. Note that there are a few minor changes to the circuit (shown below).

The basis for this amplifier was originally published as Project 03, and although the base design is over 20 years old, as an amplifier it remains "state of the art" - this is an extremely good amplifier. It is simple to build, uses commonly available parts and is stable and reliable. The design featured is a full update on the original project, and although it has many similarities, is really a new design.

This new amp (like the original) is based on an amp I originally designed many years ago, of which hundreds were built. Most were operated as small PA or instrument amps, but many also found their way into home hi-fi systems. The amp is perfectly capable of driving 4 Ohms, provided the supply voltage is maintained at no more than ±35V.

This amplifier, although very simple, is capable of superb performance. This is *not* an amp to be under estimated, as the sonics are very good indeed, and this is due (in part, at least) to the inherent simplicity of the design. The amp is exceptionally quiet, and is reasonably tolerant of difficult loads. It is an ideal amplifier for biamped systems, and may be operated in bridge mode (BTL) if you use the recommended output transistors (which have the necessary power ratings).

The design has had the benefit of many, many years of consistent use, and this version is the best of all - the

refinements ensure minimum "switch on" or "switch off" noise, and the availability of really good output devices has improved on a known and very stable design.

I have heard nothing but praise from those who have built this amplifier - the only feedback I have received has been very positive indeed. The sound quality is up there with the very best. Highly recommended !

A reader has constructed a site based on the assembly of the P3A amp, and he has some useful information that will be helpful for anyone else looking for equivalent transistors, design guides, etc. Tyler has put considerable effort into the site. See the Project 3A Construction Guide.

Description

Note that like the original, there is (still) no output short circuit protection, so if speaker leads are shorted while the amp is working with a signal, there is a very real risk of the transistors being destroyed. The specifications are very similar to those of the original project, but the use of a current sink in the differential pair input stage means that there is virtually no thump at turn on or off.

I have also added the ability to adjust the quiescent current, and with the transistors specified the amp will provide 100W into 8 ohms, at a **maximum** supply voltage of ±42V. This supply is easily obtained from a 30-0-30V transformer.

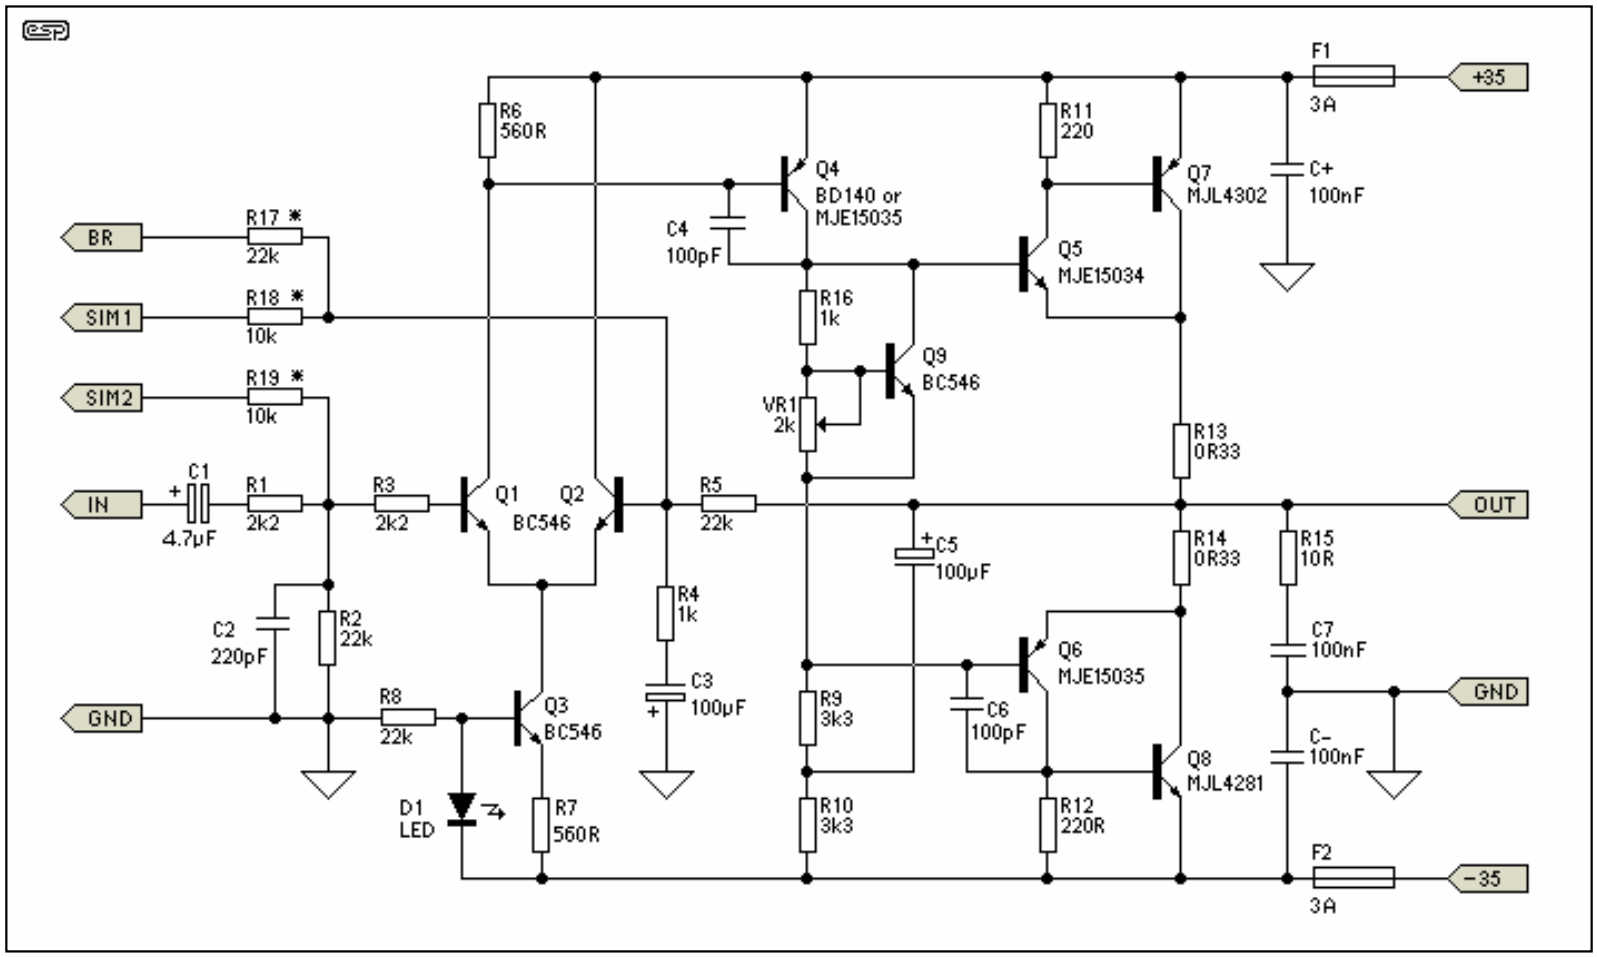

Figure 1 - Amplifier Schematic

As can be seen, it is not a complex amp, but the performance is excellent. Connections are provided for a

SIM (Sound Impairment Monitor), and there is also a resistor (R17) added to allow bridging. This resistor connects to the output of the other amplifier (the master). When used in this way, the input should be grounded - do not omit the capacitor, or DC offset will be too high. When used in bridge mode (also called BTL - Bridge Tied Load), the SIM should be taken from the master amplifier only.

* Components marked thus are optional - if you do not want to use the SIM or bridging, these may be omitted completely.

For use into 4 ohms (including bridging into 8 ohm loads), do **not** exceed ±35V (from a 25-0-25V transformer). Most applications will be satisfied with the lower voltage, and the reliability of the amp is assured with almost any load. In bridge mode, this amp will happily produce 200W into 8 ohms, and will do so reliably even for continuous high power levels. Never attempt to operate the amp in bridge mode into 4 ohms, as this represents an equivalent load to each amp of 2 ohms. The amp was not designed to handle this, and will fail. ±42V is the **absolute maximum** voltage, and should only be used where 4 ohm loads will never be applied.

D1 is a green LED, and should be a standard type. Don't use a high brightness LED, or change the colour. This is not for appearance (although the green LED looks pretty neat on the board), but for the voltage drop - different coloured LEDs have a slightly different voltage drop.

VR1 is used to set the quiescent current, and normally this will be about 50-100mA. The amp will work happily at lower current, but the distortion starts to be noticeable (on a distortion meter monitored by an oscilloscope) at less than around 40mA. The Class-A driver (Q4) has a constant current load by virtue of the bootstrap circuit R9, R10 and C5. Stability is determined by C4, and the value of this cap should not be reduced. With fast output transistors such as those specified, power bandwidth exceeds 30kHz.

With the suggested and recommended 35V supplies, Q4 and the output drivers (Q5 and Q6) will normally not require a heatsink. With 4 ohm loads, you may find that a heatsink for Q5 and Q6 is needed, but my experience is that these transistors should not get hot under most operating conditions.

If using the amp at ±42V, a small heatsink should be used for Q4, as the dissipation will be quite a bit higher and the device will get very warm.

Although I have shown MJL4281A and MJL4302A output transistors, these are very recent and may be hard to get for a time. The recommended alternatives are MJL21193 and MJL21194.

Note: It is no longer possible to recommend any Toshiba devices, since they are the most commonly faked transistors of all. The 2SA1302 and 2SC3281 are now obsolete, and if you do find them, they are almost certainly counterfeit, since Toshiba has not made these devices since around 1999~2000.

Before applying power, make sure that VR1 is set to maximum resistance to get minimum quiescent current. This is very important, as if set to minimum resistance, the quiescent current will be very high indeed (probably enough to blow the output transistors!).

Construction

Since I have boards available for this amp, I obviously suggest that these be used, as it makes

construction much easier, and ensures that the performance specifications will be met. Note that the layout of any power amplifier is quite critical, and great pains were taken to minimise problem areas - if you make your own PCB, it is unlikely that you will be able to match the published specifications.

All resistors should be 1/4W or 1/2W 1% metal film for lowest noise, with the exception of R9, R10 and R15 which should be 1/2W types, and R13, R14 must be 5W wirewound.

The bootstrap capacitor (C5) needs to be rated at at least 35V, but the other electrolytics can be any voltage you have available. The trimpot (VR1) should ideally be a multiturn, but an ordinary single turn pot can be used. Setting the current will be a little more difficult with a single turn pot, and they are not as reliable.

A pair of these amps will be quite happy with a 1°C/W heatsink for normal hi-fi use. Consider using a fan if you are going to push the amp hard. Remember - there is no such thing as a heatsink that is too big.

Basic Specifications

The following shows the basic measurement results ...

Gain	27dB
Input Impedance	24k
Input Sensitivity	1.22V for 100W (8 ohms)
Frequency response [1]	10Hz to 30kHz (-1dB) typical
Distortion (THD)	0.04% typical at 1W to 80W
Power (42V supplies, 8 ohm load) [2]	90W
Power (35V supplies, 8 ohm load) [3]	60W
Power (35V supplies, 4 ohm load)	100W
Hum and Noise	-73 dBV unweighted
DC Offset	< 100mV

Notes

1. The frequency response is dependent on the value for the input and feedback capacitors, and the above is typical of that when the specified values are used. The high frequency response is fixed by C4, and this should not be changed.
2. Operation into 4 ohm loads is ***not recommended*** with the 42V supplies. Peak dissipation will exceed 110W in each output transistor, leaving no safety margin with typical inductive loads. All supply voltages are nominal, at no load - your transformer may not be capable of maintaining regulation, so power may be slightly less than shown.
3. This figure is typical, and is dependent on the regulation of the power supply (as are 1 and 2, above). Worst case power with 8 ohm loads is about 50W, but the supply will be seriously inadequate if the power falls that far.

Four of these amps in a biamped arrangement will give you prodigious SPL, and is similar to the arrangement I am using. Coupled with a Linkwitz-Riley crossover, the amplifiers can be mounted in the back of the speaker box, so only signal and power are needed for a complete system that will leave most commercial offerings for dead.

Powering Up

If you do not have a dual output bench power supply - Before power is first applied, temporarily install 22 Ohm 5 W wirewound "safety" resistors in place of the fuses. Do not connect the load at this time! When power is applied, check that the DC voltage at the output is less than 1V, and measure each supply rail. They may be slightly different, but both should be no less than about 20V. If widely different from the above, check all transistors for heating - if any device is hot, turn off the power immediately, then correct the mistake.

If you do have a suitable bench supply - This is much easier! Slowly advance the voltage until you have about ±20V, watching the supply current. If current suddenly starts to climb rapidly, and voltage stops increasing then something is wrong, otherwise, continue with testing. (Note: as the supply voltage is increased, the output voltage will decrease - down to about 2V, then quickly drop to near 0V. This is normal.)

Once all appears to be well, connect a speaker load and signal source (still with the safety resistors installed), and check that suitable noises (such as music or tone) issue forth - keep the volume low, or the amp will distort badly with the resistors still there if you try to get too much power out of it.

If the amp has passed these tests, remove the safety resistors and re-install the fuses. Disconnect the speaker load, and turn the amp back on. Verify that the DC voltage at the speaker terminal does not exceed 100mV, and perform another "heat test" on all transistors and resistors.

When you are satisfied that all is well, set the bias current. Connect a multimeter between the collectors of Q7 and Q8 - you are measuring the voltage drop across the two 0.33 ohm resistors. The most desirable quiescent current is 75mA, so the voltage you measure across the resistors should be set to 50mV ±5mV. The setting is not overly critical, but at lower currents, there is less dissipation in the output transistors. Current is approximately 1.5mA / mV, so 50mV will represent 75mA quiescent current.

After the current is set, allow the amp to warm up (which it will), and readjust the bias when the temperature stabilises. This may need to be re-checked a couple of times, as the temperature and quiescent current are slightly interdependent. When you are happy with the bias setting, seal the trimpot with a dab of nail polish.

If the temperature continues to increase, the heatsink is too small. This condition will (not might - will) lead to the destruction of the amp. Remove power, and get a bigger heatsink before continuing. Note also that although the power transistors are mounted to the board, never operate the amp without a heatsink - even for testing, even for a short period. The output transistors will overheat and will be damaged.

When all tests are complete, turn off the power, and re-connect speaker and music source.

Power Supply

Before describing a power supply, I must issue this ...

WARNING: Mains wiring must be done using mains rated cable, which should be separated from all DC and signal wiring. All mains connections must be protected using heatshrink tubing to prevent accidental contact. Mains wiring must be performed by a qualified electrician - Do not attempt the power supply unless suitably qualified. Faulty or incorrect mains wiring may result in death or serious injury.

A simple supply using a 25-0-25 transformer will give a peak power of about 75W into 8 ohms, or 60W or so continuous. This is influenced by a great many things, such as the regulation of the transformer, amount of capacitance, etc. For a pair of amps, a 300VA transformer will be enough. Feel free to increase the capacitance, but anything above 10,000uF brings the law of diminishing returns down upon you. The performance gain is simply not worth the extra investment.

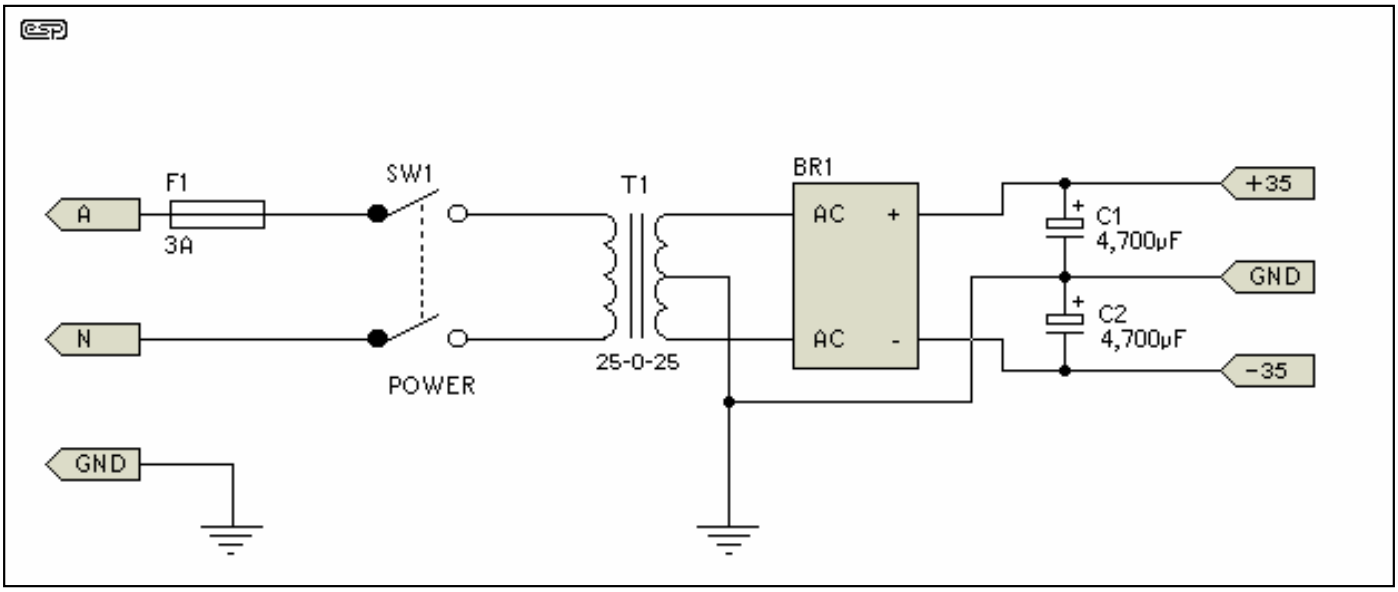

Figure 2 - Recommended Power Supply

For the standard power supply, as noted above I suggest a 300VA transformer. For 115V countries, the fuse should be 6A, and in all cases a slow blow fuse is required because of the inrush current of the transformer.

The supply voltage can be expected to be higher than that quoted at no load, and less at full load. This is entirely normal, and is due to the regulation of the transformer. In some cases, it will not be possible to obtain the rated power if the transformer is not adequately rated.

The bridge rectifier should be a 35A type, and filter capacitors must be rated at a minimum of 50V. Wiring needs to be heavy gauge, and the DC must be taken from the capacitors - not from the bridge rectifier.

Understanding Power Transistors Breakdown Parameters

APPLICATION NOTE

INTRODUCTION

Among the electrical parameters of a Bipolar power transistor, the breakdown related ones are the most critical to measure. As a matter of fact, as the breakdown voltage can be pretty high, the instantaneous power dissipated during the test must be accurately controlled to avoid a local hot spot on the chip. On the other hand, the breakdown mechanisms are prone to high frequency oscillations and care must be observed to accurately measure this parameter. This application note gives a definition of the breakdown parameters and the associated physics of semiconductor devices. A chapter describes the test techniques and methods recommended to perform this kind of measures.

Since most of the high voltage bipolar transistors are NPN type, all the analysis carried out in this note will be referenced to NPN devices. The PNP mechanisms are essentially the same, with reverse polarities of all biases.

BREAKDOWN MECHANISM

Let us first consider the Collector to Base junction. Like a $p-n$ diode, the avalanche process limits the collector−base voltage the transistor can sustain. When the voltage is large enough, the n−side depletion region will reach the n+ contact diffusion and, if the voltage increases further, the contact will supply electron to the $p-n$ junction. At this point, the Collector−Base junction is essentially shorted and the current is limited by the external resistances.

Basically, three mechanisms control the breakdown: thermal instability, tunneling effect and avalanche multiplication.

THERMAL INSTABILITY

The breakdown for thermal instability is the result of large increase of leakage current when the junction temperature increases. Germanium based devices are more sensitive to this mechanism compare to the Silicon. The process snowball as the leakage current increases, yielding higher junction temperature which can lead to the destruction of the chip if it extends above the melting point of the semiconductor material.

TUNNELING EFFECT

When the electrical field approaches 10^6 V/cm in Silicon, a significant current begins to flow by means of the band to band tunneling process. To get such a high field, the junction must have relatively high doping concentration on both side of the p−n junction. As a matter of fact, the field may be so high that it creates enough force on a covalently bounded electron to free it. This creates two carriers, a hole and an electron to contribute to the current. From an energy−band point of view, in this breakdown process an electron makes a transition from the valence band to the conduction band without the interaction of any other particles.

The breakdown mechanism for silicon device with breakdown voltage lower than 4Eg/q comes from the tunneling effect. For junctions having breakdown voltage in excess of 6Eg/q, the mechanism is generated by avalanche multiplication. At voltages between 4Eg/q and 6Eg/q, the breakdown is a combination of the two effects.

Since the energy band gap in silicon decreases with temperature, the breakdown voltage due to tunneling effect in these semiconductors has a negative temperature coefficient. This temperature effect can be used to differentiate the tunneling effect from the avalanche mechanism which has a positive temperature coefficient.

One must point out that the tunneling effect is dominant for zener voltage in the 5 V to 6 V range. This mechanism is not present for high voltage junctions since the doping concentration is too low to generate the tunneling effect.

AVALANCHE MULTIPLICATION

This mechanism, also named impact ionization, is the most important one in junction breakdown since the avalanche breakdown voltage imposes an upper limit on the reverse bias of the collector voltage. The value at which breakdown occurs depends on the structure of the junction and the dopant concentration used to manufacture the transistor. Both the structure and the epitaxy being controlled, the breakdown voltage of a given semiconductor is reasonably predictable at the design stage.

In this process, free carriers can gain enough energy from the field between collisions to break covalent bonds in the lattice when they collide with it. Consequently, every carrier interacting with the lattice creates two additional carriers and the mechanism snowballs as three carriers can also participate to the collisions. This leads to a sudden multiplication of carriers in the space−charge region when the electrical field becomes large enough to trigger the avalanche.

Let us consider an electron traveling in the space−charge region of a reverse biased pn junction. The electron travels, on average, a distance L (the mean free path) before losing energy by interacting with an atom in the lattice. The energy ΔE gained from the field *E* by the moving electron between collisions is:

$$\Delta E \sum q \int_0^L E.\,dx \qquad (1)$$

Assuming the electron has accumulated enough energy from the field prior colliding with an atom, the bond between the atom core and one of the bound electron can be broken during the collision. This creates three resulting carriers which are free to leave the region of the collision. A simplified schematic representation is given in Figure 1.

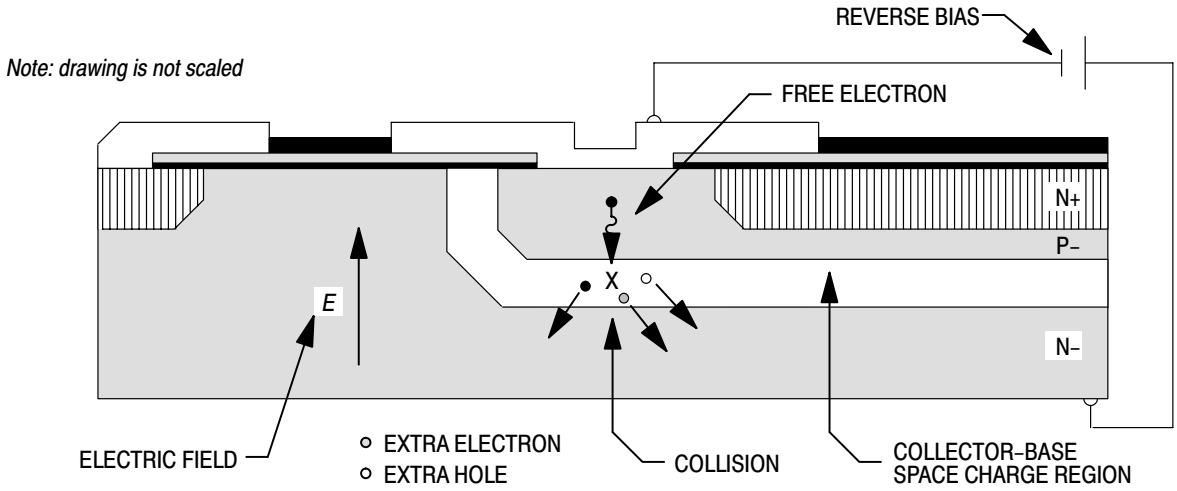

Figure 1. Simplified Representation of the Avalanche Process in a Junction

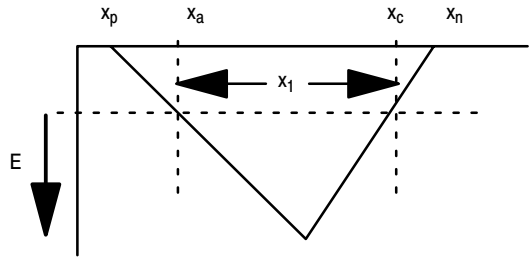
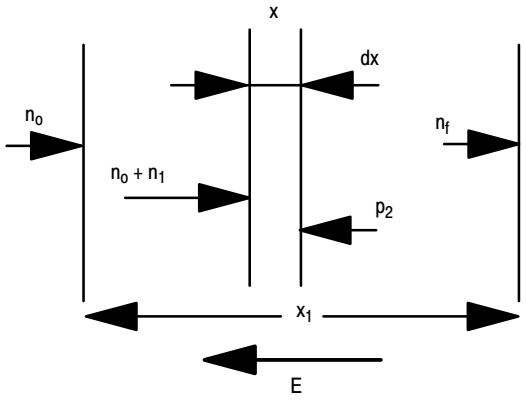
Near the edge of the space charge region, the electric field is low and practically no carriers can gain enough energy from the field to create a hole−electron pair before they lose their kinetic energy in a collision with the lattice. Consequently, the avalanche is confined to the central area of the space charge region where the field is sizable. This is represented in Figure 2, the central region being identified by x_1.



(a) Ionization occurs in the high field area x_1 of the space charge region



(b) Carriers pair are created in the region dx at x, by electrons flowing from the left and hole flowing from the right

Figure 2. Ionization Process Location for a Non Punch Trough Structure

Let us consider the number of carriers created by avalanche in a small volume of width dx located within x_1 at x (see Figure 2b). Let n_o = density of electrons entering x_1 from the left at x_a.The avalanche phenomenon will increase this density between x_a and x_c in a way that the electrons entering the volume Adx at x from the left have a density $n_o + n_1$. The probability that electrons create electron−hole pairs when travelling through dx is given by the product of the ionization coefficient α**n**, times the length dx. Since the electrons gain energy more rapidly when the field is higher, the ionization coefficient is a function of the electric field, hence of the position in the semiconductor.

In the same manner, the density of holes will increase as a consequence of the avalanche, and the $\alpha_{\mathbf{p}}$ factor represent the ionization coefficient for the holes.

Let n_f be the density of electrons that reaches x_c:

$$n_f \sum n_o + n_1 + n_2 \tag{2}$$

where n_2: density of electrons created between x and x_c.

Since electrons and holes are created in pair, $n_2 = p_2$, we may write:

$$\frac{dn}{dx} \sum (\alpha_n - \alpha_p)(n_o + n_1) + \alpha_p n_f \tag{3}$$

Assuming that $\alpha = \alpha_n = \alpha_p$, we can rewrite equation 3 as follows:

$$n_f - n_o \sum n_f \int_{xa}^{xc} \alpha \, dx \tag{4}$$

The ratio of the density of electrons n_f leaving the space−charge region to the density n_o entering is called the multiplication factor **M**:

$$\mathbf{M} \sum \frac{n_f}{n_o} \sum \frac{1}{1 - \int_{xa}^{xc} \alpha \, dx} \tag{5}$$

As the integral in the denominator of equation 5 approaches unity, the **M** factor increases to infinity. Therefore, the avalanche will occur when:

$$\int_{xa}^{xc} \alpha \, dx \sum 1 \tag{6}$$

The density of ionizing collisions at x is proportional to **n*** which represent the density of excited electrons arriving at x with enough energy to create the electron−hole pair. The density **n***, in turn, is the total electron density **n** times the probability that an electron has not collided in a distance **d** necessary to get the right energy:

$$\mathbf{n^*} \sum \mathbf{n} \exp\left(-\frac{\mathbf{d}}{L}\right) \tag{7}$$

The length **d** may be derived from equation 1 by letting E_1 being the minimum energy necessary to create the ionization process, and *E* being the average field that accelerates the electron:

$$d \sum \frac{E1}{qE} \tag{8}$$

Since the ionization coefficient depends strongly on the electric field, the multiplication factor also increases rapidly with field. Consequently, a small increase in field, as the voltage approaches breakdown, causes a sharp increase in current as observed on a curve tracer. Not only does the ionization coefficient vary with field, hence with the position, in the space charge region, but the width of the space charge region varies also with voltage. Therefore, the evaluation of **M** with equation 5 is difficult and a good approximation can be derived from the simplified equation 9:

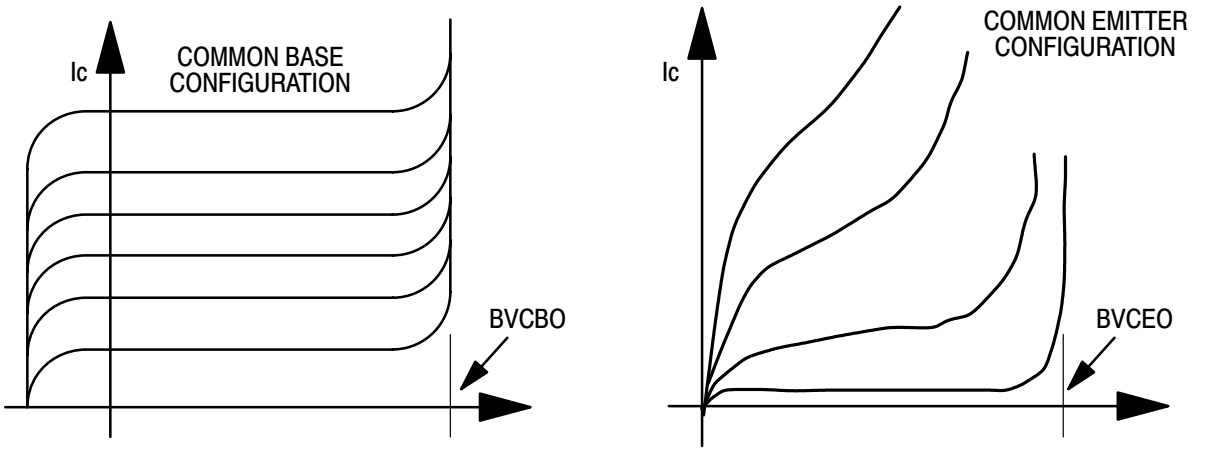
$$\mathbf{M} \sum \frac{1}{1 - \left(\frac{Vr}{Bv}\right)^n} \tag{9}$$

with $2 < n < 6$

Vr: the reverse voltage applied across the junction

Bv: the breakdown voltage.

In the common Base configuration, the breakdown due to the impact ionization (avalanching) gives a well defined voltage as depicted in Figure 3a, the effect of the current coming from the emitter having little effect on the breakdown.



(a) Under breakdown, the emitter current is not affected

(b) At low impact ionization rate, the base current starts to increase, yielding an emitter current increase and, eventually, a collector current runaway

Figure 3. Common Base and Common Emitter Breakdown Typical Curves

For the common Emitter configuration, the breakdown is not as sharply reflected in the transistor output characteristics as depicted in Figure 3b, and occurs at a lower voltage BVCEO. In this configuration, as soon as the impact ionization process starts, the secondary holes are injected into the base, yielding a base current which, in turns, leads to an increase in the emitter current and a current runaway may eventually occurs as the mechanism snowballs.

SECOND BREAKDOWN

The use of power transistor is limited by the second breakdown phenomenon which is an abrupt decrease of the device voltage capability with a simultaneous internal constriction of current. Figure 4 shows a typical Ic/Vc characteristic of a transistor under second breakdown. The avalanche breakdown (also named first breakdown) occurs when the voltage applied across the junction reaches the value specific for this device as discussed above. As the voltage is increased, the second avalanche occurs.

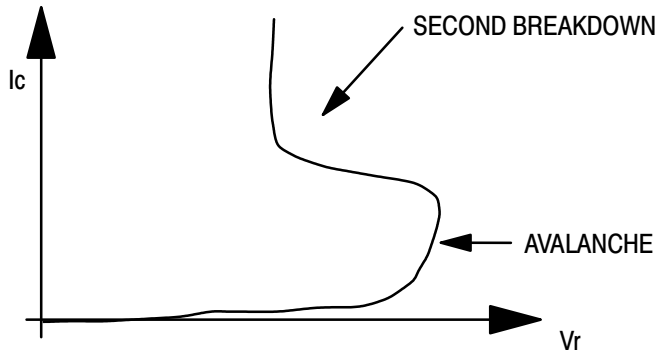


Figure 4. Typical Second Breakdown Characteristic

The initialization of this mechanism is essentially caused by the temperature effect. After a time delay following the power pulse P = Ic*BVCEO applied to the transistor, the device goes into the second avalanche area. During the time elapsed from avalanche to second breakdown, the junction is unstable and may be rapidly downgraded. In particular, the resistance of the breakdown spot becomes extremely low. During the third part of the curve, when the voltage is significantly reduced, the chip is at high temperature and the semiconductor is in the intrinsic mode near the breakdown spot location. If the current keeps increasing, the silicon melts and the transistor is permanently destroyed.

BASIC POWER TRANSISTOR GEOMETRY

The simplified cross section of a power transistor given in Figure 5 illustrates the main areas involved in the

breakdown process. When the voltage rises across the transistor, the electrical field is sustained by the N−epitaxy, the depletion region increasing accordingly. One must point out that, in reality, a modern transistor is not built with a single junction as depicted in Figure 5, but with several emitter stripes diffused into the base P−. Such technology is mandatory to get the expected static and dynamic characteristics requested in today's applications: the photo given in Figure 6 illustrates this concept.

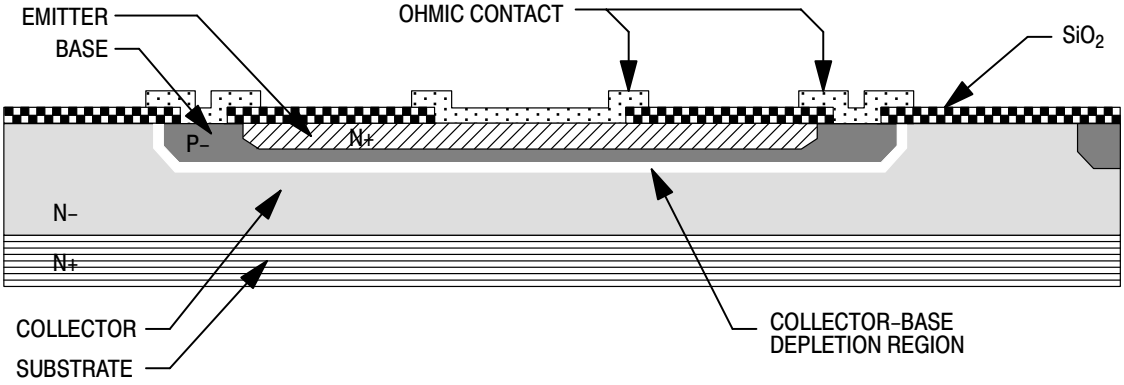

Figure 5. Simplified Cross Section of a Bipolar Power Transistor

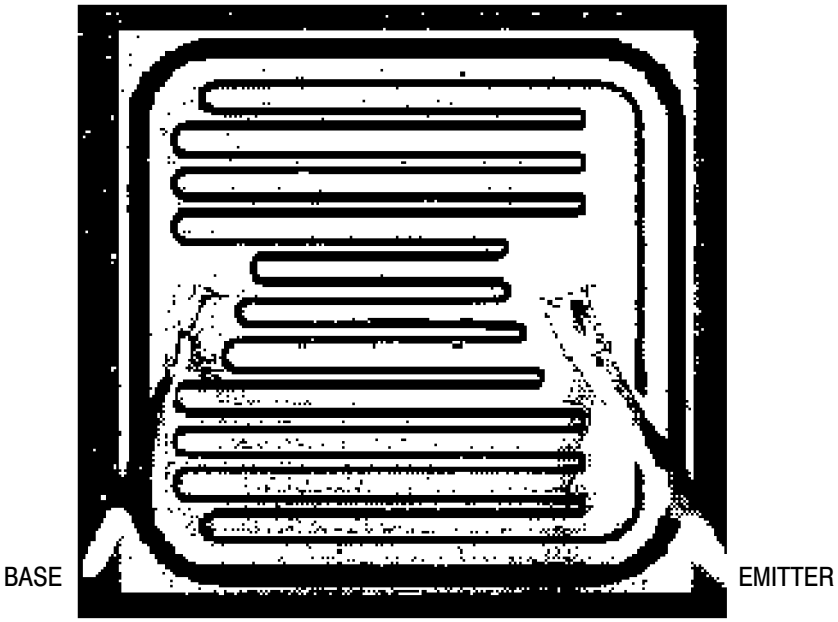

Figure 6. Photo of a Typical Power Transistor Using the PLANAR Termination

On top of that, the electrical field must not collapse at the edge of the chip, where the base diffusion no longer exists. To prevent this mode of failure, the transistors are designed with a junction termination suited for the kind of device under development. A junction termination example is given in Figure 7

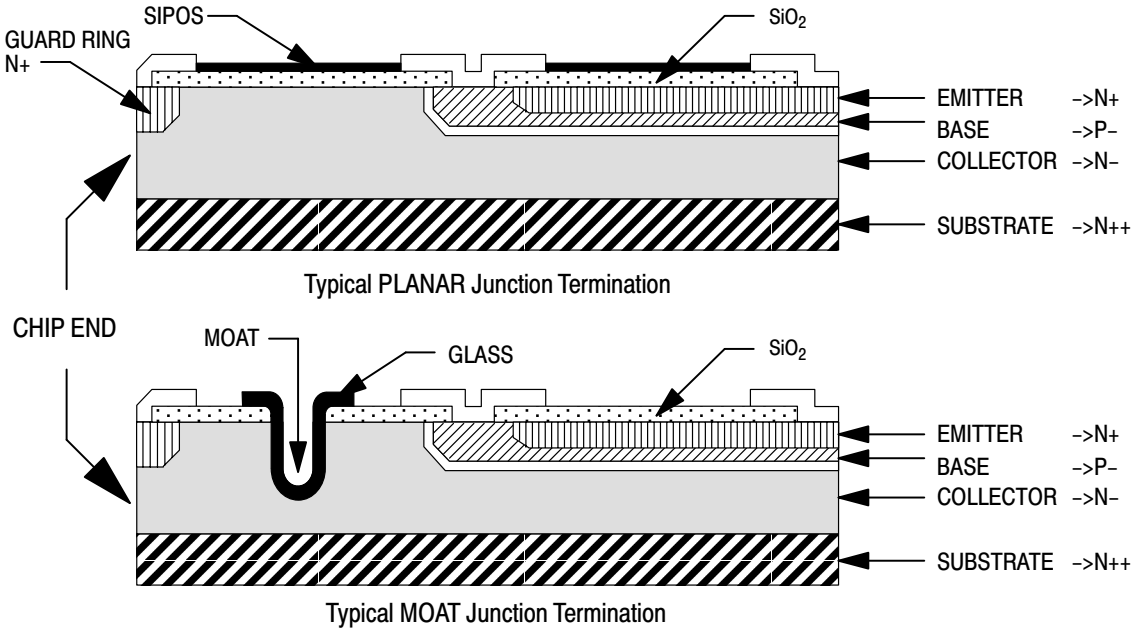

Figure 7. Typical Junction Terminations for a High Voltage Bipolar Transistor

At the time of printing this document, the PLANAR process is the most widely used technology to manufacture power transistors. However, the MOAT termination is still used for very high voltage device with BVCBO of 1500 V and above.

DYNAMIC BREAKDOWN CHARACTERISTICS

Although the static breakdown characteristics are valuable to define the performances of a semiconductor device, they do not provide all the informations needed to safely use a power transistor. Leaving aside the switching parameters, the dynamic behaviour of a power transistor is bounded by three main parameters:

FBSOA: Forward Bias Safe Operating Area

RBSOA: Reverse Bias Safe Operating Area

BVsus: Breakdown Sustaining

The designer of a given application must carefully check that, under no circumstances, the transistor will operate out of the curves provided in the data sheet: severe damage, or destruction, occurs if the operating point moves outside the specified limits.

FBSOA

The FBSOA curves are specified to define the maximum safe operating area for a given device. This parameter depends on the chip geometry and the process used to built the transistor. Particularly, the emitter fingers perimeter is extremely important since it highly influences the current spread across the silicon. As a matter of fact, at turn on, the current starts to flow from the periphery of the emitter finger, as depicted in Figure 8 The rbb' increases as we move toward the center of the emitter finger and the Base−Emitter junction is not fully forward biased during the first microseconds. Consequently, the current density is maximum at the edge of the junction and the emitter becomes prone to local hot spots.

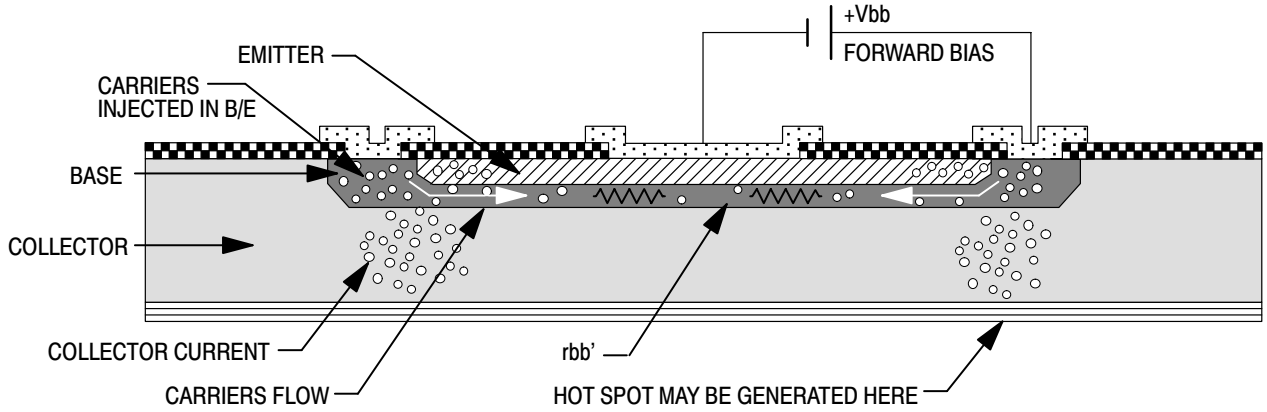

Figure 8. Turn on Mechanism for a Bipolar Power Transistor

The data provided for the FBSOA curve are based on a maximum junction temperature of +150°C and is bounded by four points as shown in Figure 9:

BVCEO: maximum allowable voltage
Icm: maximum allowable collector current
Second breakdown
Pm: maximum power dissipation
Pw: pulse width

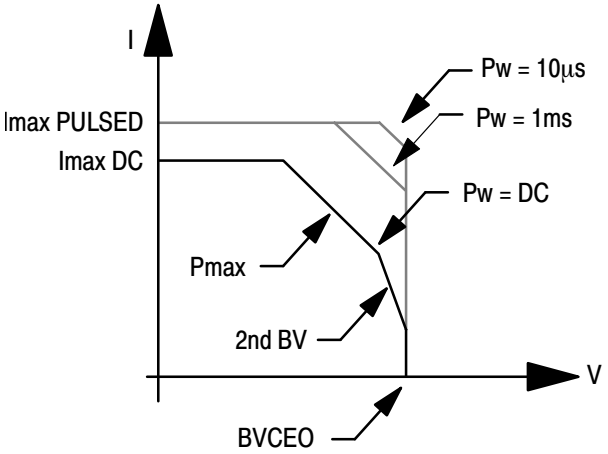

Figure 9. Typical FBSOA Curve

Since this parameter is temperature dependant, for a constant power, the FBSOA depends upon the pulse width. When the pulse is very short, below 1μs, the curves can be extended above the BVCEO limit for transistors specifically designed for switching applications.

The typical FBSOA test circuit is given in Figure 10 Cares must be observed to avoid overheating the silicon during the test. Of particular importance are the short pulses which have a high energy content since such pulses can generate a local hot spot within the silicon chip, even though the case temperature stays at ambient temperature.

Since the FBSOA test can damage the transistor, one must not re−use devices exposed to a characterization procedure. On the other hand, using conventional power supplies to bias the device under test is not recommended since they do not have the capability to accurately control either the pulse width or the current amplitude. It is preferable to use commercial equipment designed for that purpose, or to built a specific test jig, with appropriate dynamic performances, to evaluate a limited number of devices.

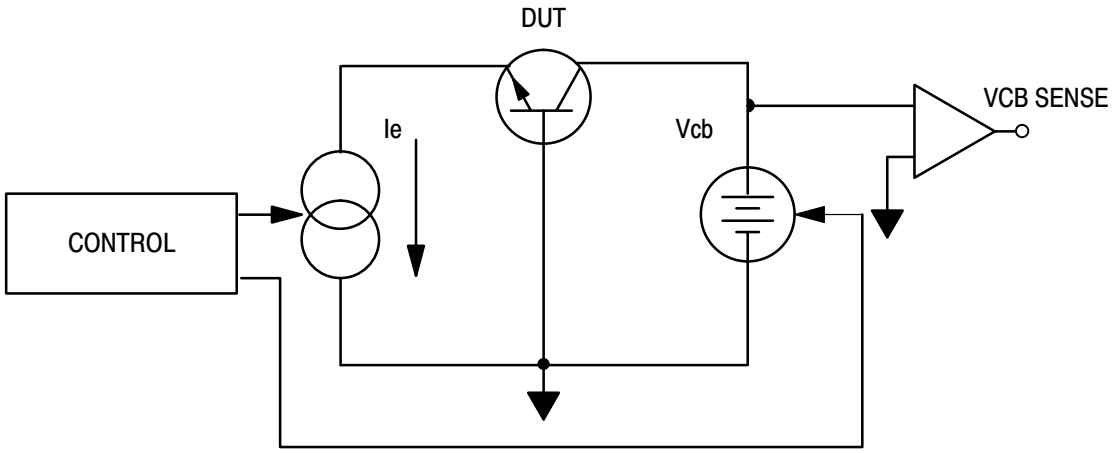

Figure 10. Typical Forward Bias Safe Operating Area Test Circuit

RBSOA

The RBSOA curves are used to define the maximum current/voltage a transistor can sustain under Base−Emitter reverse bias. As depicted by the typical test circuit given in Figure 11, this parameter is essentially an analysis of the breakdown, under dynamic condition, when the device is loaded by an inductor.

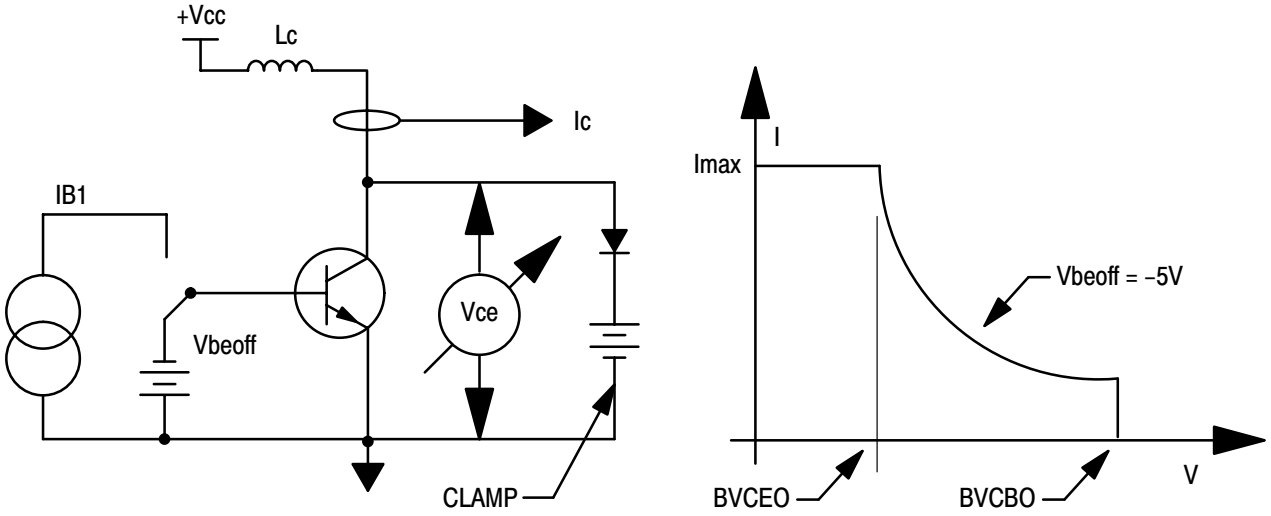

Figure 11. Typical Reverse Bias Safe Operating Area Test Circuit

The test is normally performed with a clamp connected across emitter−collector to limit the voltage within the BVCES/BVCEX of the device under test. In this case, the transistor is not avalanched and most of the energy stored into the inductor is dissipated in the clamp circuit. As a matter of fact, when a voltage clamp is used, the transistor sustains the current−voltage stress only during its collector current fall time.

The same parameter can be evaluated without providing a voltage clamp: in this case, the transistor will be forced in the avalanche region (assuming L*(dI/dt) > BVCES) and all the energy accumulated in the inductor will be dissipated into the device under test. This condition forces much more stress into the silicon as the current will flow during a longer time than the collector current fall time (all of the $1/2L*I^2$ energy must be dissipated) under avalanche condition. Extreme care must be observed when performing such a test since the transistor is very rapidly destroyed if the current is not carefully limited by the external circuit. As a standard rule, the test is carried out by slowly increasing the voltage clamp until the transistor goes into avalanche, the current being limited by the pulse width applied during the charging time of the inductor.

The RBSOA test is sometime named sustaining breakdown (BVCEsus) when it is performed unclamped, or inductive switching when the collector voltage is clamped below BVCES.

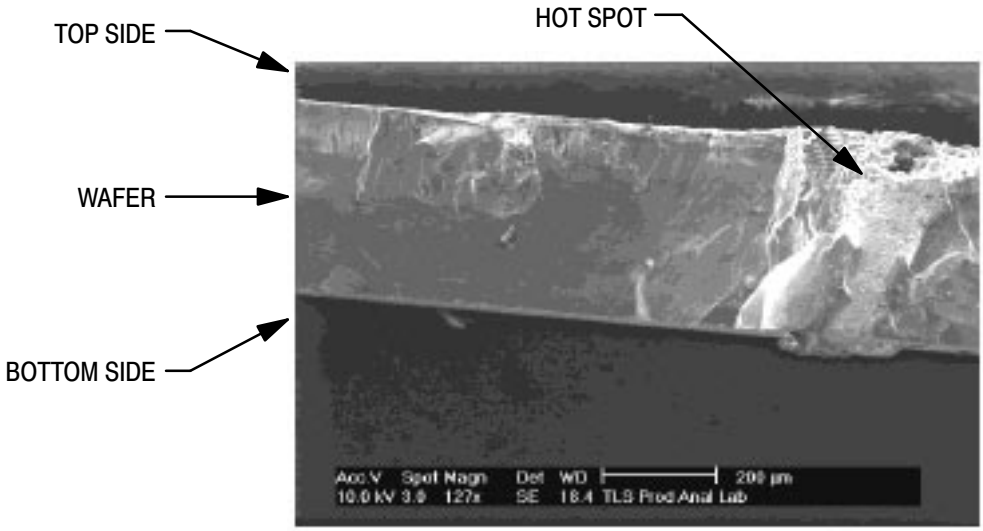

Figure 12.(b) Cross Section of the Damaged Chip (given Fig. 12a) Showing how the Silicon Melts.

POWER DEVICE BEHAVIOUR

The reverse bias characteristics of a power transistor are split into two families: the leakage current and the breakdown.

Generally speaking, the leakage current tests do not generate high stress into the chip, unless the transistor under test has a voltage capability well below the voltage bias. As a matter of fact, since the bias voltage is defined prior being forced across the junction, there is no snap back in the characteristic and the test circuit remains stable. On top of that, leakage currents are in the micro ampere range, for modern silicon power transistors, and the power generated during the test cannot damage the chip. As an example, let us assume an ICEO test performed at 400 V, the maximum current being 100 μA, yielding 40mW in the junction. This value is well within the power handling capability of the transistor and cannot damage the device.

However, although they provide reliable informations, the leakage tests characterize neither the breakdown voltage nor the avalanche mode of a bipolar transistor. These behaviour are analyzed by means of the safe operating area tests as discussed above.

When the transistor is tested in BVCEO, the current/voltage characteristic exhibit a snap back effect when the Collector/Emitter voltage jumps from the breakdown to the test point point defined at a higher current. This phenomenon, illustrated in Figure 13, is prone to heavy uncontrolled oscillation due to the negative impedance which is developed from point A to point B.

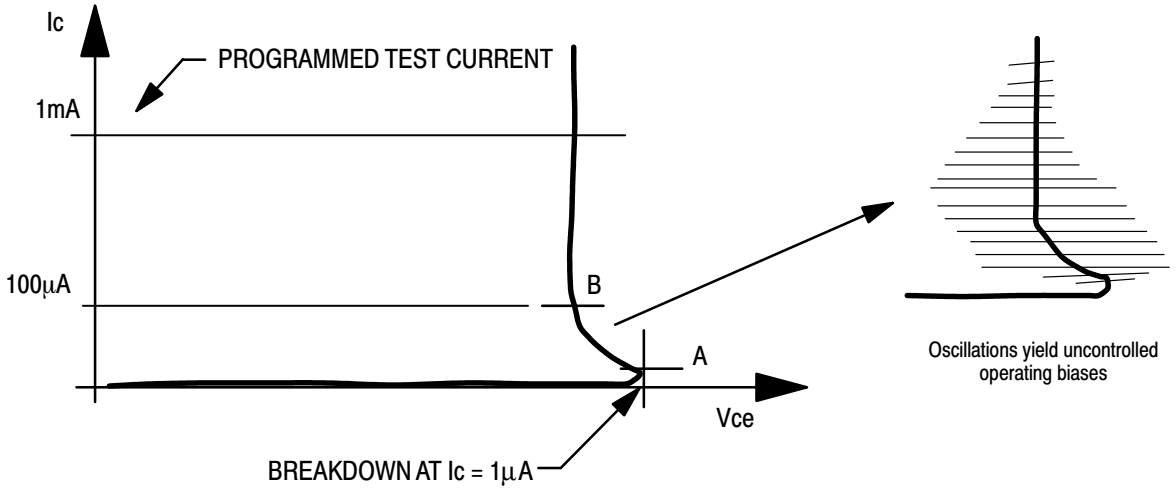

Figure 13. Typical BVCEO Characteristic

Such behaviour can be observed with a curve tracer by limiting the power dissipated into the transistor.

The power transistors are characterized, among others parameters, by a set of breakdown curves as depicted in Figure 14 Under no condition can the transistor be exposed to a voltage−current above the maximum rating provided in the data sheets.

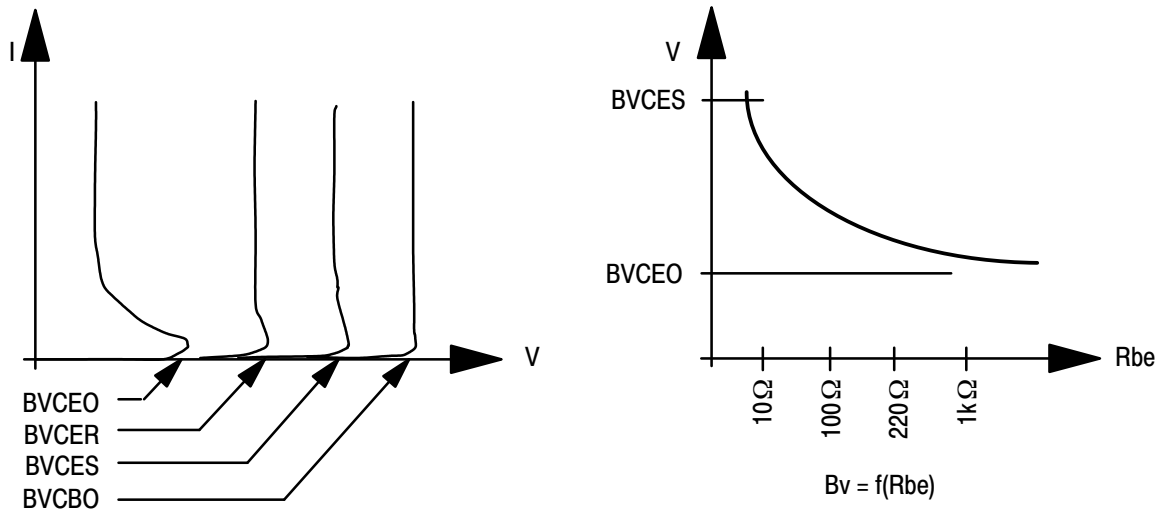

Figure 14. Typical Breakdown Curves (BVEBO not shown)

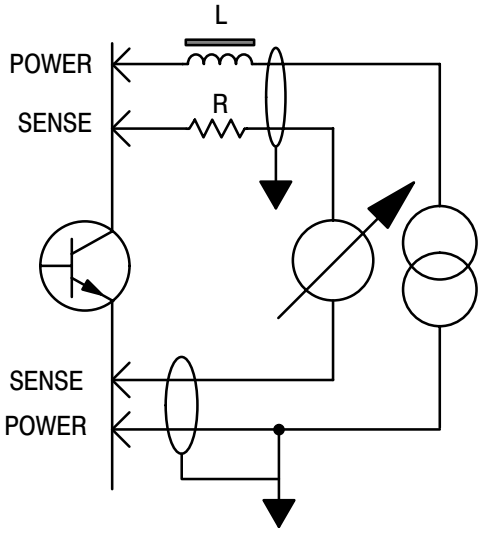
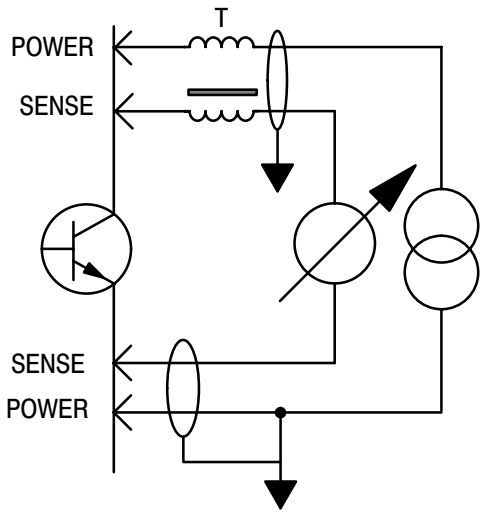
Because the current source used to perform the breakdown test has a high voltage compliance (in fact, the open load voltage must be higher than the maximum breakdown voltage one expects to characterize), it is not easy to make it oscillation free when the load is very variable. The problem can be cured by using anti oscillation networks right across the transistor electrodes (see Figure 15), but the device can be damaged or destroyed if the current rises above the maximum value allowable for a given chip.



The values of R and L are adjusted for a given transistor and test conditions. Typical values are R=470 Ω and L=100 μH. All the network must be located as close as possible to the transistor under test.
Kelvin contacts are mandatory. Shielding cables are recommended.

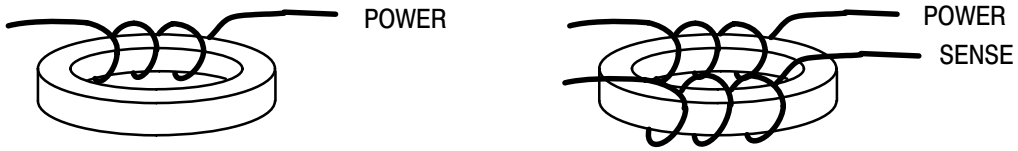


The transformer T1 provides an AC feedback to the current source and is adjusted for a given set of test conditions.
Typically, the primary inductance is 100 μH with Np/Ns=1.

Figure 15. Typical Anti Oscillation Networks

It is also possible to use a capacitor, connected across Collector−Base of the transistor under test, to generate a local AC feedback, although this is not recommended. Keeping in mind that the current source associated with the transistor is a high gain transconductance amplifier, any LC network connected across it generates high frequency oscillations that will make the BVCEO test impossible. Since one cannot define accurately the parasitic inductances and stray capacitances existing in the test circuit, it is preferable not to use a capacitive feedback across the transistor.

The inductor L and the transformer T can be built around a toroid using a high permeability ferrite material. A typical application is given in Figure 16



Toroid: 16x20
Ferrite: N27, B50, A4A
The transformer may require a larger core to accommodate the primary and secondary turns. Using a high permeability material limits the number of turns needed to get the expected inductance.

Figure 16. Typical Inductor Design

One must point out that the design of such an anti−oscillation network very much depends on the test system used to measure the breakdown. Consequently, it's not easy to modelize an accurate circuit and several attempts are usually necessary to tune the network for a given environment.

Another issue with the BVCEO test is the discharge of stray capacitances into the transistor. When the tests are carried out with an automatic instrument, the cables can be several meter in length and the stray capacitance becomes non negligible and are charged up to BVCEO when the current source is connected to the device. Since this source has a finite settling time (i.e., the current does not stabilize to the programmed value in less than a few tens of microseconds!), the current coming from the discharge of the stray capacitance cannot be controlled and may damage the chip within a few micro second. This is particularly true for the BVCEO test as depicted in Figure 17: during the negative going slope, the Collector/Emitter voltage collapses, discharging the

stray capacitance by the delta V from A to B, yielding a peak current above the programmed value.

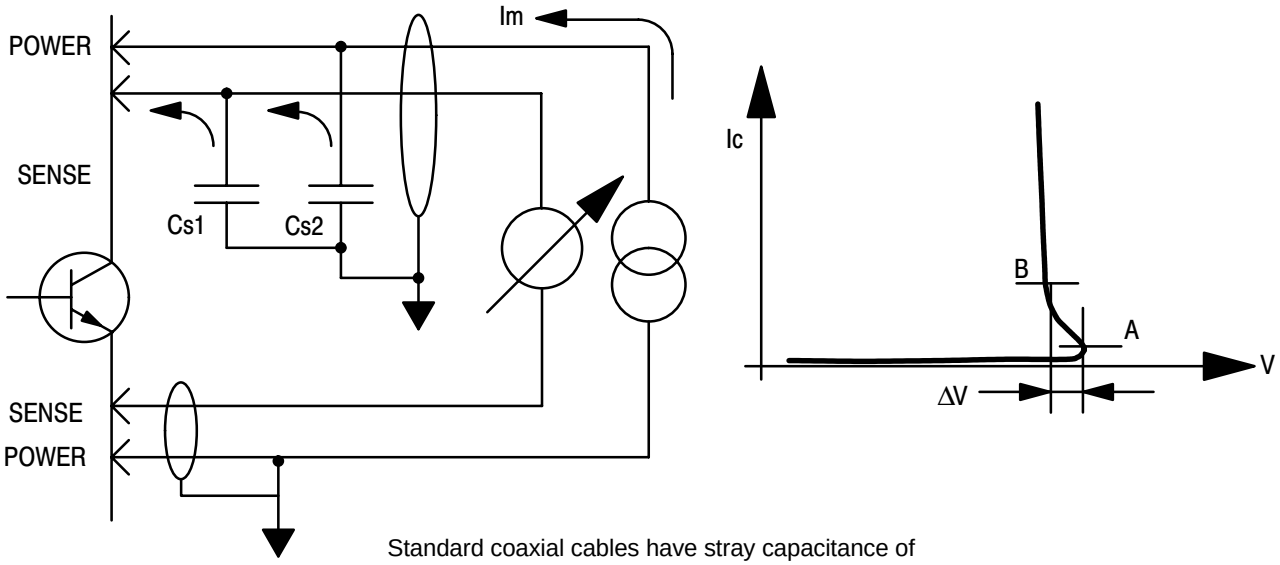


Figure 17. Stray Capacitances Effect

Assuming a $\Delta\beta V$ of 60 V and a total series resistance of 10 Ω, the peak current flowing from the stray capacitances Cs1/Cs2 as depicted in Figure 16, is 6 A. On the other hand, most of the automatic test handler are connected to the tester by coaxial cables up to five meters long. In this case, the total stray capacitance (combining Power and Sense) is 1000 pF, yielding a time constant of:

$Pw = 5*\Sigma Cs*\Sigma R$

$Pw = 5*1000*10^{-12}*10$

$Pw = 50ns$

During this amount of time, the transistor must dissipate the energy accumulated in Cs1 & Cs2:

$Ej = \Sigma Cs*\Delta V^2*0.5$

$Ej = 1000*10^{-12}*60*60*0.5$

$Ej = 1.8\mu J$

This value cannot damage the transistor but, if the circuit oscillates, the $\Delta\beta V$ can be much higher and, for a high voltage power transistor, the energy can rise to a value above the maximum capability of the junction. As an example, let us assume $\Delta\beta V$ = 500 V, then Ej = 125 μJ. Of course, a power transistor can easily handle such amount of energy, but the same transistor can be rapidly damaged when the energy is generated during the transient phase of the breakdown mechanism. As a matter of fact, during uncontrolled oscillation, most of the energy developed in the circuit will be dissipated in a very small area of the die, yielding a very high current density which, in turn, generates a hot spot in the silicon. Ultimately, the silicon may melt and the device is destroyed. This is a consequence of the multiplication factor **M** as discussed above.

Consequently, it's recommended to reserve the breakdown test for engineering and characterization purpose, using the leakage current test to perform, incoming inspection. However, the breakdown parameters are fully tested, under several biases and case temperatures, during the development of a new power transistor. Regular samplings also provide statistics, at production level, to make sure the devices are fully within the guaranteed limits published in the data sheet.

PARAMETERS DEFINITIONS

The off condition parameters are split into two families: the leakage currents and the breakdown voltages. Both are characterized during the development of a transistor and tested during the final test process. The voltage spans from a low 6.00 V for the Bvebo, to a high 1800 V for the Bvcbo, the leakage currents ranging from nano ampere to one milli ampere at room temperature.

Speaker Leads

Speaker leads have been discussed extensively in my article on impedance, but I shall repeat some of this here for the sake of completeness. For the full text, see Impedance [2] and Amp Sound, an article discussing the influences that affect the sound of amplifiers.

This was pointed out to me by a reader, and was originally published in the New York Times (on-line edition) a while ago ...

A Spat Among Audiophiles Over High-End Speaker Wire

By ROY FURCHGOTT

In the last year, Lewis Lipnick has tested high-end audio cables from 28 manufacturers. As a professional musician with the National Symphony Orchestra and as an audio consultant, he counts on his exacting ear to tell him if changing cables affects the accuracy of the sound from his $25,000 Krell amplifiers.

His personal choice is a pair of speaker wires that cost $13,000. "Anyone would have to have cloth ears not to tell the difference between cables," he said.

"In my professional opinion that's baloney," said Alan P. Kefauver, a classically trained musician and director of the Recording Arts and Sciences program at the Peabody Institute of Johns Hopkins University. "Has the wire been cryogenically frozen? Is it flat or round? It makes no difference, unless it makes you feel better." His choice for speaker wire? Good-quality 16-gauge zip wire.

The disagreement would be unnotable except for one thing: experts are in agreement that most cables that claim to improve the sound of audio equipment don't. Even cables costing thousands of dollars per foot are often little more than sonic snake oil, experts say. Consumers trying to purchase audio cables often find themselves buying high-end replacements because the only cables in the store are expensive ones.

A purchaser of an entry-level $550 stereo system might be sent home with $55 worth of the least expensive middle-quality audio cables. While experts agree that most cables make exaggerated and unfounded claims about improving sound, they cannot agree on which cables actually do improve sound and which do not.

The scientific record is unclear. So far no research paper contending to prove or disprove the value of fancy wires has been accepted by the leading industry publication, The Journal of the Audio Engineering Society, said Patricia M. MacDonald, its executive editor. She said there were dozens of reasons a research paper might not meet her journal's standards.

"I don't think anyone should infer anything from it," she said.

The manufacturers and sellers of audio goods like to stay above the fray. Cables are a highly lucrative item that may account for a modest percentage of sales but a greater percentage of profit. Even audio manufacturers not directly involved in the cable business like to steer clear of the debate.

[Related Articles: Do It Yourself: A Little Soldering Goes a Long Way; (December 23, 1999)]

Polk Audio, a well respected manufacturer of loudspeakers in Baltimore, no longer makes cables but declined an invitation to set up a listening test in its laboratories. One reason it gave was that the test could affect relationships with audio stores. "We would be hearing from every retailer in the country," said Paul Dicomo, communications director for Polk Audio. Kerry Moyer, staff director for the Consumer Electronics Association, which represents manufacturers, said accessories were usually the highest markup items, wires included. Sales of high-margin accessories have become critical in the current market, where prices of components like receivers, amplifiers and DVD players, have had profit margins squeezed by competition.

"It becomes a question of where are we going to make a little money?" he said. Mr. Moyer, whose $3,000 sound system uses about $300 worth of cables, said the technological superiority of a cable is not the issue -- it is the perceived value to the hobbyist.

"If someone feels good about buying it, whether it works or it doesn't, it makes them feel good," he said. "I don't think we should question."

John Dunlavy, who manufactures audiophile loudspeakers and wire to go with it, does think questioning is valid. A musician and engineer, Mr. Dunlavy said as an academic exercise he used principles of physics relating to transmission line and network theory to produce a high-end cable. "People ask if they will hear a difference, and I tell them no," he said.

Mr. Dunlavy has often gathered audio critics in his Colorado Springs lab for a demonstration.

"What we do is kind of dirty and stinky," he said. "We say we are starting with a 12 AWG zip cord, and we position a technician behind each speaker to change the cables out." The technicians hold up fancy-looking cables before they disappear behind the speakers. The critics debate the sound characteristics of each wire. "They describe huge changes and they say, 'Oh my God, John, tell me you can hear that difference,'" Mr. Dunlavy said. The trick is the technicians never actually change the cables, he said, adding, "It's the placebo effect."

This leads to disagreements based on competing science. Bruce Brisson, who owns Music Interface Technology, an ultrahigh-end wire manufacturer in Rockland, Calif., also wants to see cable charlatans revealed and may use his extensive laboratory to do it.

"I am getting ready to expose this in the year 2000," he said. "People are paying a lot of money and getting nothing for it." But he disagrees with Mr. Dunlavy on the effectiveness of wires, saying that the theory Mr. Dunlavy uses to design his cables is not the right theory and that is why listeners cannot hear a difference. **

Some scientists say it would be difficult to prove one way or another. Changing cables leaves a time lapse that makes comparison difficult. Putting several stereos side by side with the different wires would mean that the speakers would be different distances from the ear, which could have an effect. And while a switch could be made that would send a signal through each of several cables to a speaker from a single sound system, cable makers say the switch itself might spoil the advantages of their wires.

Part of the difficulty is that there are still unexplained acoustic phenomena. William Morris Hartmann, a professor of physics at Michigan State University in East Lansing, works on psycho-acoustic projects, which investigate the way sound is perceived, rather than the way it is produced. There are examples, he said, of sounds that measure beyond the range of human hearing, and yet some people seem to perceive them. That means the market is left open to wild claims and psuedoscience. "It's annoying, but it's hard to disprove," Professor Hartmann said.

Perhaps the closest thing to middle ground is the position taken by Russ Hamm, an electrical engineer whose New York company G Prime Ltd. installs digital processing

equipment for studios. Mr. Hamm said that indeed, wires do make a perceivable difference, but very little, and then only to professionals, like the engineers at BMG Music. He
lent them new high-grade cables for use on roughly $250,000 of equipment. On his system, Mr. Hamm uses a specialty cable manufactured in Vienna that costs $2 a foot.

"We are talking subtle differences, but that is what the high end is all about," he said.

It is a subtlety he describes as a 2 percent difference on a high-end system. "If you had a fine Bordeaux wine, how much does it matter if it's in a nice wineglass or a Riedel crystal glass?"

His advice to audiophiles: "I would say that you want to put the first $10,000 into your equipment."

The above is reproduced verbatim, and I hope that this information is helpful to your understanding of the topics to follow. Remember that the purpose of this article is *not* to try to sell you something, but to inform and rationalise the many myths that abound regarding the audibility (or otherwise) of different cables.

** It is worth noting that the year 2000 has come and gone, and to my knowledge, neither Bruce Brisson nor anyone else has produced a scientifically sound explanation for the alledged superiority of any one cable over another. There is simply little or no validation available for the vast majority of the outlandish claims made.

We hear so much about damping factor, the effect of speaker leads (and how much better this lead sounds compared to an "ordinary" lead), and how amplifiers should have output impedances of micro-Ohms to prevent "flabby" bass and so on. But what does it all really mean?

Before an informed judgement can be made, we need to look at some of the real factors involved. There are a multitude of impedances involved in a typical amplifier to loudspeaker connection, most of them having a vastly more profound effect than the impedance of the speaker lead alone.

For example, my own (tri-amped) hi-fi uses separate amps for the bass and mid with a

designed output impedance of about 2 Ohms. This provides a useful extension of the bottom end (I'm using sealed enclosures), without excessive peaking at resonance. Much the same effect is found with most valve amplifiers, which typically have an output impedance of 1 to 6 Ohms.

Ignoring the losses in the speaker lead (which are usually very small), the impedance of the cable is very low compared to that of loudspeaker crossover networks and the like. While there is no denying that some speaker leads do sound different, the important thing is "different" rather than "better"

A double-blind test carried out by an Australian electronics magazine many years ago found that most listeners thought that the really thin figure-8 type speaker cable had better bass than all the more expensive ones. Treble response was generally thought better using a heavy duty 3-core mains cable. No-one thought that any of the high priced cables sounded better than anything else.

Other workers in the field, such as Douglas Self [1], have determined much the same, so even in the light of some convincing evidence to the contrary, we have reviewers still extolling the virtues of cables costing more than a decent set of loudspeakers.

Generally, resistance and inductance in the speaker lead can (and does) cause minor variations in level, especially with difficult loads. These deviations are likely to be less than 0.1dB for reasonable cable constructions, with inductance less than 4uH. The resistance of a typical cable (perhaps 0.1 Ohm) causes response variations across the band, following the loudspeaker impedance curve, but these are usually even less at around 0.05 dB. Neither variation is audible.

You will even find references in some cases to the cable's characteristic impedance - a value that is only useful if cables are used for radio frequencies, or are many kilometres in length. These are uncommon in audio listening rooms in my experience. The characteristic impedance of a cable has no effect whatsoever on signal frequencies that are low compared to cable length. At the worst (using coaxial cable) a signal travels at 0.8 of the speed of light (3x10^8 m/s).

Assume that for an adequate safety margin we want to be able to pass up to 100kHz through the speaker cable. The wavelength at this frequency is 3000 metres, or in coax, 3750 metres. A typical listening room may require up to 10 metres of cable, so at the very worst case, the cable is 1/300 to 1/375 times the wavelength of the signal. The effect is utterly insignificant in all respects. The signal will be delayed by an amount that is less than that experienced if the listener were to move his/her head by 1mm towards

or away from the loudspeaker. This is of course a common occurrence, and often by several millimetres, even while asleep.

Difficult Loads

While it is true that reasonable quality twin cables (figure eight or zip cord) are adequate for nominal 8 ohm loads over short distances, there are a number of popular loudspeakers that are anything but nominal at high frequencies.

Two that a reader advised me about are the AR11 and the Quad ESL (old model). Both of these drop below 2 ohms in the treble frequencies. The AR bottoming out at 5kHz and the Quad at 18Khz (although anything from 15kHz to 18kHz is common). The dips are fairly sharp and so the load impedance is highly capacitive on the way down and inductive on the way up. The frequencies are high enough to not worry good amplifiers but what about the response at these dip frequencies?

Twin wire cables all have significant inductance which increases in proportion to length. With 10 amp rated twin flex over only 5 metres the response was down by 2.5 dB into one Quad ESL at 18 Khz, and 3.5 dB into the other speaker which had 8 metres. This was audible and unacceptable.

The only way to reduce cable linear inductance is to make the two wires talk to each other. Running in close parallel is a start, tight twisting is better but only by using multiple wires for each and interweaving can you really get the inductance down. Several cable makers have done this and sell them as low impedance cables, which is exactly what they are. There are several different cables that use this method, and twin coaxial cable is also used to achieve a similar result.

One construction uses two groups of 72 strands of enamelled wire plaited around a solid plastic core. Using these cables with difficult loads, the droop at either 5 or 18 kHz disappeared and the sound was distinctly better. There would be virtually no other way to solve the problem short of mono amplifiers sited next to each loudspeaker.

One (potentially major) drawback ocurs if you own certain amplifiers that are unstable with capacitive loads. Typical multiple twisted pair cable has about 9nF per metre of capacitance with little resistance or inductance, which causes many amplifiers to go into parasitic oscillation. The fix is simple, wind twelve turns of wire around a pen and put it in series with the beginning of the cable. This tiny coil has far less inductance than even one metre of twin flex.

This description of the possible issues with speaker cables is the first I have seen that

makes some sense from a technical perspective. There is sufficient evidence from my own measurements and those of many writers that there are indeed some detectable (and measurable) differences. With this in mind, and wanting to provide all the information I can, I have included this information - and this is the one area where properly sized and well made cables really does make a difference. If you own speakers that present a highly capacitive load, or have deep "notches" in the impedance curve, I would take this information seriously.

Summary

Essentially, the main offenders in speaker leads are resistance and inductance. Of these, inductance is the hardest to minimise, and although usually small, it may still cause problems with some loads (see update, below). Many construction methods have been used, from multiple CAT-5 data cables, with the wires interconnected (usually all the coloured leads are deemed the +ve conductor, and all the white wires - the "mates" - are used as the negative). Because of the tight twist, the inductance is minimised, but at the expense of capacitance. In some cases, the capacitance may be high enough to cause instability in the amplifier, which not only does awful things to the sound, but can damage the amp.

Another popular method of minimising inductance is to use a pair of coaxial leads (e. g.75 Ohm TV/video coax or similar). The inner conductor of one and the outer conductor of the other are joined to make the +ve lead, and vice-versa for the negative. A good quality coax has a relatively low capacitance, and by interconnecting in this way, inductance is also reduced by a very worthwhile margin.

It is widely held that with difficult loudspeaker loads - as presented by many modern speaker systems with complex crossover networks - that reducing inductance can be very beneficial. This is especially true where the crossover causes significant drops in impedance at some frequencies. This also places unusually high demands on the amplifier - one of the reasons that some amplifiers just don't "cut it" with some speakers.

These problems can be reduced or even eliminated entirely by biamping or triamping [3], allowing the use of good quality but not extravagant speaker leads.

Resistance, which is easy to eliminate, reduces the damping factor and wastes power. With even reasonably robust leads, this should not be an issue

Bottom Line on Speaker Leads

Use quality cable, but extravagance will buy no more genuine performance. You will be able to obtain far greater benefits by biamping the system [3] than spending the same

amount on esoteric (read "expensive") speaker leads.

Be willing to experiment, using 3-core mains cable (not the types described above, either), and paralleling two of the conductors for the speaker negative connection (or the positive - the speaker will not care either way). Save yourself a fortune, so you can buy more music instead.

I have seen several references on the web regarding the use of Cat-5 network cable and specially wired coaxial cable for speakers. The idea with network cable is to parallel the wires (these cables are usually 4-pair), and it is claimed that the sonic performance is excellent. I haven't tried it, but Cat-5 is relatively inexpensive, and might work quite well. Try it if you want to. Wiring coaxial cables for speaker use is also not too hard, and it is claimed that this can beat most of the really expensive cables.

Before one even considers the alleged benefits of one cable over another, here is something to think about ...

> "What does "veiled" mean (in reference to high frequency reproduction), and how is it determined that the veiling effect is caused by anything specific, as opposed to everything in general? This includes state of mind (i.e. good day, kids acting up, wife annoyed about something), health (cold or flu, hay fever), position of listening chair (was it moved to vacuum the floor?), etc."

And, no, these are not trivial questions. They are every bit as important as anything else, and all the more so if we have only a subjective interpretation of the sound, without measured results that show the effect. Have a look at the article "Amplifier Sound" for more info.

Interconnects

All well designed interconnects will sound the same. This is a contentious claim, but is regrettably true - regrettable for those who have paid vast sums of money for theirs, at least. I will now explain this claim more fully.

The range (and the associated claims) of interconnects is enormous. We have cables available that are directional - the signal passes with less intrusion, impedance or modification in one direction versus the other. I find this curious, since an audio signal is AC, which means that electrons simply rush back and forth in sympathy with the applied signal. A directional device is a semiconductor, and will act as a rectifier, so if these claims are even a tiny bit correct, I certainly don't want any of them between my preamp and amp, because I don't want my audio rectified by a directional cable.

Oxygen free copper (or OFC) supposedly means that there is no oxygen and therefore no copper oxide (which is a rectifier) in the cable, forming a myriad of micro-diodes that affect sound quality. The use of OFC cable is therefore supposed to improve the sound.

Try as I might (and many others before me), I have never been able to measure any distortion in any wire or cable. Even a length of solder (an alloy of tin and lead) introduces no distortion, despite the resin flux in the centre (and I do realise that this has nothing to do with anything - I just thought I'd include it :-). How about fencing wire - no, no distortion there either. The concept of degradation caused by micro-diodes in metallic contacts has been bandied about for years, without a shred of evidence to support the claim that it is audible.

At most, a signal lead will have to carry a peak current of perhaps 200uA with a voltage of maybe 2V or so. With any lead, this current, combined with the lead's resistance, will never allow enough signal difference between conductors to allow the copper oxide rectifiers (assuming they exist at all) to conduct, so rectification cannot (and does not) happen.

What about frequency response? I have equipment that happily goes to several MHz, and at low power, no appreciable attenuation can be measured. Again, characteristic impedance has rated a mention, and just as with speaker cables it is utterly unimportant at audio frequencies. Preamps normally have a very low (typically about 100 Ohms) output impedance, and power amps will normally have an input impedance of 10k Ohms or more. Any cable is therefore mismatched, since it is not sensible (nor is it desirable) to match the impedance of the preamp, cable and power amp for audio frequencies.

Note: There is one application for interconnects where the sound *can* change radically. This is when connecting between a turntable and associated phono cartridge and your preamp. Use of the lowest possible capacitance you can find is very important, because the inductance of the cartridge coupled with the capacitance of the cable can cause a resonant circuit within the audio band.

Should you end up with just the right (or wrong) capacitance, you may find that an otherwise respected cartridge sounds dreadful, with grossly accentuated high frequency performance. The only way to minimise this is to ensure that the interconnects have very low capacitance, and they **must** be shielded to prevent hum and noise from being picked up.

At radio frequencies, Litz wire is often used to eliminate the skin effect. This occurs because of the tendency for RF to try to escape from the wire, so it concentrates on the outside (or skin) of the wire. The effect actually occurs as soon as the frequency is above DC, but becomes noticeable only at higher frequencies. Litz wire will not affect your hi-fi, unless you can hear signals above 100kHz or so (assuming of course that you can find music with harmonics that go that high, and a recording medium that will deliver them to you). Even then, the difference will be minimal.

In areas where there is significant electromagnetic pollution (interference), the use of esoteric cables may have an effect, since they will (if carefully designed) provide excellent shielding at very high radio frequencies. This does not affect the audio per se, but prevents unwanted signals from getting into the inputs or outputs of amps and preamps.

Cable capacitance can have a dramatic effect on sound quality, and more so if you have long interconnects. Generally speaking, most preamps will have no problem with small amounts of capacitance (less than 1nF is desirable and achievable). With high output impedance equipment (such as valve preamps), cable capacitance becomes more of an issue.

For example, 1nF of cable capacitance with a preamp with an output impedance of 1k

will be -3dB at 160kHz, which should be acceptable to most. Should the preamp have an output impedance of 10k, the -3dB frequency is now only 16kHz - this is unacceptable.

I tested a couple of cable samples, and (normalised to a 1 metre length) this is what I found

	Single Core	**Twin - One Lead**	**Twin- Both Leads**	**Twin - Between Leads**
Capacitance	77pF	191pF	377pF	92pF
Inductance	0.7uH	1.2uH	0.6uH	NT
Resistance	0.12 Ohm	0.38 Ohm	0.25 Ohm	NT

NT - Not Tested

These cables are representative of medium quality general purpose shielded (co-axial) cables, of the type that you might use for making interconnects. The resistance and inductance may be considered negligible at audio frequencies, leaving capacitance as the dominant influence. The single core cable is obviously better in this respect, with only 77pF per metre. Even with a 10k output impedance, this will be 3dB down at 207kHz for a 1 metre length.

Even the highest inductance I measured (1.2uH) will introduce an additional 0.75 Ohm impedance at 100kHz - this may be completely ignored, as it is insignificant.

The only other thing that is important is that the cables are properly terminated so they don't become noisy, and that the shield is of good quality and provides complete protection from external interfering signals. Terminations will normally be either soldered or crimped, and either is fine as long as it is well made. For the constructor, soldering is usually better, since proper crimping tools are expensive.

The use of silver wire is a complete waste, since the only benefit of silver is its lower resistance. Since this will make a few micro-ohms difference for a typical 1m length, the difference in signal amplitude is immeasurably small with typical pre and power amp impedances. On the down side, silver tarnishes easily (especially in areas where there is hydrogen sulphide pollution in the atmosphere), and this can become an insulator if thick enough. I have heard of some audiophiles who don't like the sound of silver wire,

and others who claim that solid conductors sound better than stranded. Make of this what you will :-D

The use of gold plated connectors is common, and provides one significant benefit - gold does not tarnish readily, and the connections are less likely to become noisy. Gold is also a better conductor that the nickel plating normally used on "standard" interconnects. The difference is negligible in sonic terms.

There is no reason at all to pay exorbitant amounts of hard earned cash for the "Audiophile" interconnects. These manufacturers are ripping people off, making outlandish claims as to how much better these cables will make your system sound - rubbish! Buy some good quality audio coaxial cable and connectors from your local electronics parts retailer, and make your own interconnects. Not only will you save a bundle, but they can be made to the exact length you want.

Using the cheap shielded figure-8 cable (which generally has terrible shields) is not recommended, because crosstalk is noticeably increased, especially at high frequencies. That notwithstanding, for a signal from an FM tuner even these cheapies will be fine (provided they manage to stay together - most of them fall to bits when used more than a few times), since the crosstalk in the tuner is already worse than the cable. With typical preamp and tuner combinations, you might get some interference using these cheap and nasty interconnects, but the frequency response exceeds anything that we can hear, and distortion is not measurable.

Digital / Optical Interconnects

Recently I have seen adverts and reviews on fibre optic digital interconnects. Some are supposedly far superior to others, despite the fact that 1s and 0s (light present, light not present) are all that is passed. IMHO, it would take truly monumental incompetence to design any digital interconnect that was incapable of passing a digital signal without corruption. Since fibre optics (non-audiophile grade) are used to carry phone calls and data all 'round the world, with very low error rates and over huge distances, it is ludicrous to assume that any commercial digital interconnect will make any difference over a distance of a metre or so.

Bear in mind that the receiver reconstitutes the signal wave shape, it is usually buffered, and will use some form of error correction as well. As for claims that the difference is audible ....

Summary

Aside from interference pickup, capacitance and crosstalk are the only real potential

problem with interconnects. Capacitance can be minimised by selection of the cable. In some cases, even though the impedance of the preamp may be low enough, use of a highly capacitive cable may cause RF instability in the output stages - this will definitely ruin the sound.

Crosstalk is all but eliminated by the use of good quality shielding, which will generally also reduce interference. Keeping lead lengths to the minimum needed will also help reduce any possible negative influences.

Bottom Line on Interconnects

Use home made ones, or buy cables that are well made and reasonably priced. The expensive ones that will "make your system sound better" won't - you are just making some idiot richer, and yourself poorer.

I know that this is heresy to some, but I really don't care. This is factual, and I can prove my claims, while the makers of these fancy cables can't.

I have seen home-made cables, braided from multiple strands of wire-wrap wire. The shielding on some of these can be mediocre (at best), so experiment, but don't expect miracles.

Power Leads

The power lead (cord or cable if you prefer) is how mains power at 220V, 240V, 110V at 50 or 60Hz gets to your system. The specifics of the voltage and frequency are determined by where you live, and the available household mains provided by your electricity company.

There are mains cables (power cords) available that defy belief. Would you spend US $3000 for a 2 metre mains lead? You can buy a very nice amplifier indeed for this sort of money, but they are there, and someone must be buying the stupid things.

What possible effect 2 metres of flexible cable can have to counteract the kilometres of power company's wiring is a simple question to answer. None. Or, to more precise, none whatsoever. I am not referring to cables with inbuilt filters or other esoterica here, just perfectly ordinary mains leads.

I have measured the distortion on the mains at my workshop test bench. Last time I did this it was 5.6%, and there is absolutely nothing that a cable can do to change this, regardless of cost. The distortion is caused by a multitude of things completely outside our control, with power supplies for computers and other equipment being only one group of offenders.

These draw power at the peak of the AC waveform, causing it to become flattened (similar to clipping in a power amplifier). The various power company transformers along the way will also introduce some degree of distortion, and there are inductive and capacitive losses within the distribution system. As well, there are large motors being controlled by various speed controllers (most use large solid-state switches), used in industry and commercial centres. Lifts, air compressors, machinery, the list is endless.

Because of the resistance of the supply authority's cabling and transformers (there are

some massive cost considerations they must address), when a high power appliance is turned on, the mains voltage falls. This resistance (actually it is impedance) will cause the voltage to vary from one second to the next, with significant drops at the times when meals are being prepared (electric stoves switched on all over the place), and at other periods. I have measured the impedance at my house at 0.8 Ohms (we use 240V in Australia), so an appliance that draws 10 Amps (such as a heater) will cause the voltage to fall by 8 Volts. This could be reduced by increasing the size of my internal wiring, but the gains would be few and the cost high. In 110V countries such as the US, the wiring impedance must be made lower, since all currents are higher for the same power. It is likely that this causes even greater compromise due to the larger wire sizes that must be used (larger wire means greater cost).

So, given that the mains is distorted, and varies in amplitude from minute to minute throughout the day, and has significant impedance, what can be done to fix this? One method would be to use an Uninterruptable Power Supply (UPS), which (if you get the right type) uses the incoming mains to charge batteries, then uses an inverter to supply power to your equipment. You can buy one of these for $3000, and the emerging mains supply will be as clean as the UPS can make it. No cable can do this, regardless of price.

Using a UPS will ensure that your 100W amplifier can provide 100W, despite the variations in the supply voltage. Whether you can hear any difference is doubtful, because even given that the mains can (and does) vary by up to 10%, your equipment should have a reserve power rating that can accommodate such variance.

I have been advised by a reader (in the US) who reminded me that unless the UPS is specifically designed for sinewave output (and the distortion is quoted), it will probably have greater distortion than the mains anyway. The voltage will be stable, but the switching noise of the UPS may actually make matters worse.

A 100W amp (at nominal supply voltage) should give at least 100W. At 10% low supply, this drops to about 80W, a difference of less than 2dB. If you are operating power amps at close to clipping all the time, you will hear the difference, but this is not the way Hi-Fi gear is meant to be used.

> **Q:**Having a nice clean sinewave from the UPS or power conditioner should make a difference though, shouldn't it?
> **Q:**Why would it not make any difference to the sound from the amp?

The answers are simple and complex, but the result is the same. At the very best,

transformer dissipation might be slightly lower, but the AC from the secondary of the transformer is rectified and filtered, making it into DC, since the amp cannot operate from AC power supplies. The amount of DC "ripple", or superimposed AC signal is determined by the design of the amplifier's power supply, and is completely independent of outside influences other than the mains supply impedance. Even this has a very minor effect in the greater scheme of things.

If I really wanted to be able to supply 100 Amps to my speakers for brief moments, my power supply can already do this. If I wanted to be able to do it all the time for extended periods, my speakers would catch on fire. No mains lead will give my power supply this ability, nor take it away. The limitations are in the supply itself, and include the transformer, rectifier and filter capacitors.

One useful observation is that the mains in the US seems to be basically pretty nasty, and not at all what we are used to in Australia. Interference seems to be a major problem, and if this is the case, it will find its way through the power supply and into the amplifier (or other equipment) if the power supply is not well designed.

Also, because of the lower mains voltage in the US (nominally 120V), the current drawn by power amplifiers in particular can cause real problems with cheap light duty cables. I have already made this point, but it is worth making again. Use of a heavy duty lead (possibly shielded if interference is a problem) will make a difference. Whether the power difference is audible or not is debatable, but elimination (or even reduction) of mains borne interference is likely to result in a worthwhile improvement in sound quality.

Normally I would expect that any interference would be audible all the time, and it seems very unlikely that it only manifests itself when there is music playing. Electricity is not that cunning, and is not by nature vindictive. Having said that, it must be noted that when an amplifier is producing a lot of power, the current spikes on the mains will be much greater, and may have an influence that would normally be un-noticed. The easy way to determine this is to move the leads about to find out if this changes the background noise level. If it does, then re-locating the leads will provide far greater benefit than spending a king's ransom on power leads.

Use of a proper power conditioner (or a "pure" sinewave UPS) will completely eliminate mains interference, and this will naturally be beneficial. This is not something I have encountered, but if there is a problem, then this is probably the best way to fix it.

In some cases, all that may be needed is interference suppressors ("spike arrestors"), to get rid of clicks and pops that get into the system via the mains. These are readily

available and fairly cheap, and might be a good place to start.

I have examined several mains leads I have, and upon inspection I saw that the pins of the US plugs are of thin sheet metal (brass). This is folded over for the flat pins (active and neutral) and rolled into a tube for the earth pin. In contrast, our (Australian) plugs have solid brass pins, and are altogether much more substantial than the US ones (the US lead I have is rated at 13A, and is a very solid cable - but the pins are a weakness IMHO). The standard 13A fused UK plug is even more solid than ours - the pins are probably capable of at least 50A based on their size. One style of European style plug I have is also nice and solid. Elsewhere, I do not have samples, and can't comment.

To give you an idea. Listed below are the pin sizes and materials for 4 mains plugs I have

	Australia	10A	**US**	13A	**UK**	13A	**Europe**	10A - 15A
Active	6.4 x 1.5	Brass	6.2 x 1.1	F-Brass	6.3x 4	Brass	4.8 Dia	NP Brass
Neutral	6.4 x 1.5	Brass	6.2 x 1.1	F-Brass	6.3x 4	Brass	4.8 Dia	NP Brass
Earth	6.4 x 1.5	NP Brass	4.7 dia	T-Brass	8x 4	Brass	NA	

- F-Brass - Folded thin sheet brass
- T-Brass - Tubular thin sheet brass
- NP Brass - Nickel Plated Brass
- NA - Not Applicable (This connector uses a recessed socket, and has two plates for the earth contact, and a socket for the earth pin which is in the wall outlet)

As you can see, even though the US lead has a higher current rating and requirement, the pins are smaller and capable of less current. Where the others use solid brass pins, the US lead has thin sheet brass folded over to give a thicker overall pin - which is still thinner than the others. It is also wibbly - you can quite easily bend the flat pins with your fingers - I did ! Bent them right over at the base, *and* bent them in the middle. This is impossible with any of the others. From what I recall of US wall outlets, they are also fairly wimpy affairs, with relatively poor contact surfaces.

Another point mentioned was that by using a high current shielded cable for the mains may prevent the current spikes caused by the amplifier's rectifier from injecting spurious

noise into interconnects and other equipment. There may be some truth in this, and the effects are certainly measurable - this is why professional audio gear uses balanced connections, to eliminate exactly this sort of problem. Use proper "lead dress" - keep all power leads as far as possible from signal interconnects, and if they must cross, then cross them at right angles.

It also seems that the regulations in the US as to what you may (or may not) use as a power cable are somewhat lax (by Australian standards, anyway), allowing sub-standard connectors at both ends of the cable, and with seemingly minimal control over what may legally be sold as a mains lead.

Many (most?) of the high-end cables that I have seen referred to would not be legal in Australia, and in many other countries. No mains lead is allowed to be sold here without electrical authority approval - this is quite expensive to obtain, and involves voltage drop testing (the lead's resistance) and electrical insulation tests, along with various others. Shielded mains lead is uncommon, but I am sure that it would be available.

I have been taken to task seriously by some for not having tested any of the mains cables - well I can't, because I (like everyone else) have no criteria to base tests on. I know from experience that long (or light duty) leads will reduce the power available, but have no way to create interference of the type that could cause severe sonic degradation so I can verify that a cable eliminates it.

As to blanket claims that "the power cord has more influence than anything else in the chain other than room positioning of the speakers" (and yes, someone did make that claim), what can I say?

One of the respondents is apparently a distributor of high end power leads (so I discovered from someone else's posting), and he had no proof to offer, and nor did anyone else, so I am still left with the same conclusion as before (with some modification based on interference problems).

Other (Cheap) Things You Can Do

I had an e-mail from one of my regular readers, who was telling me that his apartment is wired using aluminium cable. This is (apparently) no longer acceptable in the US, but the fact that it was ever allowed at all is quite amazing. He discovered that he was having mains problems, so rather than "invest" in high-end power cables, he simply decided to replace the wall outlets with new ones, and re-terminate the aluminium house wiring. This in itself is not easy, because aluminium forms an oxide (*very* quickly) which is an insulator, and terminations need to be airtight - literally - to stop this from happening.

Aluminium also "flows" under pressure, so to terminate it properly needs a connector that applies constant pressure over a prolonged time - either that, or the terminations need to be tightened every couple of years. This can even happen with copper - many is the time I have found wall outlets where the connector screws were loose enough to allow the cable to move, this was not through negligence but simply the passage of time.

I quote (verbatim) from the e-mail -

> About the power lead, it's a sad world. Actually, my apartment has aluminum wiring. It is deemed fire-hazard these days, but it's an old building and they're not going to re-do the wiring. I had to replace three receptacles because the contact points of the aluminum wires slowly burnt away and left the sockets unusable. Whenever I plugged in a high-power equipment, it'd crackle, lose power and cause even more contact point to burn away.
>
> In that sense, buying a new $3 socket and getting it freshly connected to the mains wire helps HECK of a lot more than buying a $650 mains cable. As an added bonus, I get fresh copper socket holes. I'd think that helps a lot more than replacing a standard cable with a silver super-duper cable.

I couldn't agree more. This is a sensible approach, and does not cost a great deal. In addition, his apartment is (marginally!) less of a fire hazard than before, and the use of an expensive mains lead would not have fixed the underlying problem. Perhaps a few more people could adopt this sensible attitude and actually get some real (as opposed to imaginary or just "cover-up") improvements.

Bottom Line on Power Cables

I am still waiting for a "high-end" power lead manufacturer to supply me with some scientific proof of the advantages of their cable, and how they improve the sound. I have asked, and have not received the information. Nor do I expect to, since they cannot provide any sort of proof because they don't have any.

The last paragraphs of the above tell more of the truth of the matter than any high-end power lead maker ever will. The same (but to a lesser degree outside the US) benefits can be had from anyone who has old wiring and wall outlets regardless of where they live. Even in my own home, I have completely rewired the mains, because the old wiring had perished insulation, and all the sockets were worn out. The difference was not audible, but at least I know that an electrical fault is unlikely.

Audiophile Capacitors

Here we have another bunch of lies - or perhaps half truths is a better description. There are differences between capacitors, but they are not (generally) audible - despite the claims. I have seen reference to dielectric losses, the "sound" of polyester is supposedly inferior to that of polystyrene, and on and on. The stupid part is that all these are true - at radio frequencies - at audible frequencies it is very hard or impossible to measure any difference (or hear a difference, using even a simple blind test).

At the frequencies you and I can hear, there is no audible or measurable difference between most capacitors, unless the equipment builder has done something monumentally idiotic, such as reverse bias an electrolytic. This is (fortunately) rare.

There are some capacitors that are inferior in some regards (but superior in others). For example, many ceramic capacitors have a temperature coefficient that causes the capacitance to vary with temperature (usually negative - N750 or N500 capacitors). NPO ceramic caps have a "negative/positive/zero" temperature coefficient - i.e. close to zero). There are many claims that these should not be used in audio, but they are useful in audio and RF designs for decoupling (bypassing). The values are generally too low to be useful in most audio circuits (although ceramics are made in higher values, but not always easy to get), but otherwise they would almost certainly be fine - after all, the dielectric is a ceramic and not plastic, so they have low loss and very low self inductance. Having said that, ceramic caps usually have poor stability (they should never be used in filter circuits other than for RF suppression), and non-linearities are well documented at high AC voltages. I would not use a ceramic cap in the audio path for this reason.

Many other high stability or low loss/high power RF circuits (but not those using inductors - N500 or N750 ceramics counteract the temperature coefficient of the coils) will use silvered mica or the like - this is great at 400MHz, but quite unnecessary at 20kHz. Mind you, they are far and away the best low value caps you can buy, and if you can tolerate the expense, fine. Just don't expect to hear a difference.

Many modern opamps have such a wide bandwidth that ceramic caps (usually in conjunction with electrolytics) should be the only choice for bypassing, despite the negative comments of some audiophiles.

Then there are electrolytic capacitors. Claim upon claim has been made about their distortion and poor frequency response, particularly at high frequencies. I recently saw an article (which I would give reference to if I could remember where I saw it) where a standard electrolytic and an audiophile grade unit were tested in the same circuit. The standard electrolytic was actually better, having a distortion component at mid and high frequencies that was only marginally worse than the "high end" unit, but was much better at low frequencies.

The audibility of an electrolytic cap is (to my mind) still highly contentious. At low frequencies, all electrolytics will start to introduce some distortion. The levels are quite low, but as the capacitor's reactance becomes significant, distortion rises.

The reactance of any capacitor is determined with the formula

$$\mathbf{Xc = 1 / (2 * \pi * f * C)}$$

where **Xc** is capacitance reactance, **f** is frequency and **C** is capacitance (in Farads)

If Xc is maintained at 1/10 (or 0.1) of the supplied load impedance, then this low frequency distortion will not be an issue, but in any case is far lower than that of a loudspeaker.

High frequency performance is affected by the capacitor's internal inductance and dielectric losses, which causes a rise in impedance as frequency increases. It is very common to see electrolytics bypassed with polyester or similar caps, and for RF this is essential. It is also needed when bypassing the power supply rails of an amp, since at the frequencies that amps like to oscillate at (typically above 1MHz), the electrolytic simply has too much impedance. For audio frequencies a bypass is not needed, but will do no harm.

The combined effects of internal resistance and inductance contribute to the electrolytics' equivalent series resistance, or ESR. This can be measured (I have an ESR tester), and is a good indication that a cap is failing. As electrolytics age, their ESR will rise until a point is reached where the component will be unserviceable.

As a test, I checked a few caps in my workshop. I could not measure any distortion created by an electrolytic passing signal current (as opposed to speaker current, which I did not test at this stage). I also checked the frequency response of a couple of electros, and found zero degradation at 100kHz - even a square wave was passed with no visible deterioriation in rise time (which would indicate frequency limitation).

I then tested the ESR and capacitance of a 220uF and 10uF electrolytic, and a 1uF polyester capacitor.

Type	Value	Meas Val.	ESR
Electro	220uF	207uF	0.17
Electro	10uF	10.1 uF	1.2
Polyester	1.0uF	1.02uF	1.5

I thought that this was quite interesting, personally. If we use 10uF electros where we might have otherwise used a 1uF polyester, the ESR is better. Will it make any difference whatsoever to the sound? Of course not. None of these devices introduced any measurable distortion or anything else that I could see. One thing I know for sure is that if I can't see any change on my distortion meter residual, then there is no change. A complex waveform does not affect the validity of this testing, since I can test distortion at any frequency I like, and the appearance of multiple frequencies at once does not affect any passive device.

Considering that I use the averaging facility on my oscilloscope to eliminate noise completely, I can see the most minute change in a signal waveform. If nothing can be seen here, then no-one, regardless of how good they think their ears are, will be able to hear the difference in a properly conducted test.

I was recently taken to task for not mentioning tantalum capacitors. I hate them! They are unreliable, and many tests have shown that their linearity is highly suspect. The only intermittent short circuit I have ever found in a cap was with a tantalum in a power supply circuit. It would fail for long enough to blow the fuse, and then work again. I strongly suggest that you don't use tantalum caps in anything more advanced than a dustbin.

Bottom Line on Capacitors

Various people have advocated passing pulse signals through two different sorts of

capacitor, and subtracting the result, claiming that the non-zero residue proves that capacitors can introduce audible errors. In fact such tests expose only well-known capacitor shortcomings such as dielectric absorption and series resistance, and perhaps the vulnerability of the dielectric film in electrolytics to reverse biasing.

No-one has been able to show how these imperfections could cause capacitor audibility in an amplifier,and my own tests confirm this.

I must confess though, that perhaps we don't know how to perform the "audibility" tests. I do not believe that there is a significant difference, but many do ... who knows?

Non-polarised electrolytics are a different matter, especially when used in crossover networks. These have a tendency to lose capacitance as they age, shifting the crossover frequency with disasterous results (sonically speaking). Because the loss is gradual, you may possibly not even hear it until the tweeter has almost stopped working, as you get used to the sound over a period of time. Unless all bi-polars age at the same rate (unlikely), you *will* start to notice a difference between the two speakers. This is your cue to head off to the electronics shop and buy some replacements (non electrolytic, preferably). There are (supposedly) some major audible differences between bipolar electrolytics and film dielectric (plastic) types. This is your chance to test the theory.

A reader wrote telling me I was wrong about capacitors, and that the differences are audible. The specifics of this audibility were not discussed, and no measurements were offered, except for the following observation:

> There is an audible and measurable difference between different dielectrics. It's less to do with dissipation factor, and more to do with dielectric absorption. There is no black magic about it - its very well documented throughout the entire range of electronics industries. Here's how to convince yourself that this is possibly the most insidious source of distortion in audio. Get a largish value electrolytic reservoir cap and charge it up to (say) 50 volts for a minute or so. Then, with a DVM attached to the terminals, discharge the cap so the voltage reads zero.
>
> After removing the discharge resistor, watch the voltmeter reading climb back up as the cap miraculously charges itself back up from nowhere. In a signal coupling capacitor this would be bizarre enough behaviour to be a worry, but can you imagine what the effect must be if the cap is in a feedback loop? Give it some thought, and think about how much damage would have to be done to a signal to loose the ambience surrounding a quiet instrument buried in a large ensemble. Think of reverb at -60dB, or lower.

> Dielectric absorption is significant, and ceramic caps suffer from it badly, as do electrolytics. Do some measuring, but more importantly, do some listening.

Fair comment, and it deserves an answer. I also know the "stored charge" phenomenon of electrolytics (I actually demonstrated it to my son recently), and although this is absolutely real, it does not reflect the behaviour of the cap in a real world amplifier.

Most capacitors normally don't charge and discharge in this manner, but remain charged to some DC potential at all times. The charge recovery mechanism should never come into play in a properly designed circuit, regardless of programme material. There are exceptions! A capacitor used as the "dominant pole" or Miller capacitance in the Class-A amplifier section of a power amp is charged and discharged fully with each cycle of the input waveform. Ceramic capacitors are commonly used in this role, but I suggest that polystyrene is probably much better. Will you be able to hear the difference? My own experience is that you should not hear the slightest change in the sound, but it is conceivable that with some amplifiers this may in fact be audible in extreme cases.

The dielectric absorbtion process is present to some degree in all capacitors, and although some are definitely worse than others in this respect, I have conducted some tests with my Sound Impairment Monitor (SIM), which has never been able to detect any degradation of the type you might think should happen.

The claim that there will be an effect similar to reverberation at -60dB is complete nonsense. No such effect is measurable or audible. I do think that after all these years, someone would have worked out a way to prove this effect if it existed at all. No such proof has been offered, but I have seen "proof" that a ceramic capacitor (pushed way beyond its voltage rating if I recall correctly) can introduce some measurable distortion. The solution is easy - don't run any capacitor at above its voltage rating, and all will be well.

Feel free to test the theory. Make sure there is no DC in the signal line, and connect a bipolar cap (say 10uF) in series with the interconnect between preamp and power amp. Wire a switch across the cap, and have someone operate the switch while you are listening. You have to be able to hear a difference at least 75% of the time (and accurately identify whether the cap is in or out of circuit). If you can do this, then the probability is that the capacitor is audible (unless you do something nasty with the switch wiring that gives audible clues - this is cheating :-)

High Current Amplifiers

There are some who insist that the instantaneous current output needs to infinite (or at worst, half this value), and that amplifiers with limited current sound terrible. This is another piece of nonsense.

Let's assume that a nominal 8 Ohm loudspeaker load has an impedance minimum of 1 Ohm at some frequency. This is a bad design, but a valid assumption. This means that the amplifier must be able to supply a maximum of 8 times the normal current. A 100W amplifier would then supply a normal peak current of a little over 3.5 Amps. At the frequency where impedance falls to 1 Ohm, this becomes just over 28A.

So let's have a look at the very worst case possible, where the load is fully reactive and returns all supplied energy 180 degrees out of phase (at this point, the load is performing no work, so if a loudspeaker, is making no sound). The amplifier now has to deal with two lots of current - that supplied to the load, and that returned from the load. Even it it were possible, the worst case above would require a current capacity of 56A, however a loudspeaker that presented such a load to any amplifier will not last long in the market, since it will blow up nearly every amplifier that is attached to it.

There is no audible benefit whatsoever in creating an amp that can supply 100 or 200A, since the load will never need this current and is incapable under any circumstance of drawing more than the applied voltage and minimum impedance will allow (allowing for the reactive component of the load).

Bottom Line on High Current Amps

Most quality amps will be able to supply sufficient current to drive the loudspeaker load. Any more capability than this is a waste of money, since it will never be used. To achieve these extravagant currents, the output stage and power supply must be far larger than will ever be needed in real life.

Class-A amplifiers are generally capable of a very modest current, usually barely above that theoretically needed to drive the speaker. I have not heard anyone claim they are rubbish, because of the low current capability.

The one exception is with extreme crossover networks or other speaker configurations that create a difficult impedance load. It will often be found that some amplifiers cannot drive these speakers well, and others have no problem. An amplifier capable of high current may sound better with these loads, but I suggest that the speaker design is flawed if the designer is incapable of creating a crossover that cannot maintain a respectable impedance.

Monoblock Power Amps (And Preamps)

Someone has managed to convince a sizable segment of the audiophile fraternity that to achieve acceptable channel separation, completely separate amplifiers must be used. Considering that it has been shown [5] that 20dB channel separation is quite sufficient for a full stereo image to be appreciated, it is nonsense to claim that infinite separation is needed or desirable.

It is not at all difficult to design an amplifier with better than 50dB separation, even using valves, and any more than this is of no audible benefit. The "cross-modulation" effect that a shared power supply supposedly introduces is drivel. If an amp is so heroically ill-conceived as to suffer from cross-modulation, then simply sticking it into its own case with a separate power supply certainly won't fix it. I might suggest that it is most ideally suited as a boat anchor, since the design is so seriously flawed that it is beyond salvation.

A common power supply is a sensible (and far cheaper) alternative, and will cause no crosstalk in itself. Most amps have a very high ripple rejection, and if they reject ripple, they will also reject any signal frequencies that happen to get onto the supply line.

In fact, the conventional power supply capacitors will filter out all but the lowest frequencies anyway, and since bass is almost invariably recorded onto disc as mono, a minor amount of crosstalk at low frequencies is of no consequence - even if it *were* possible by this means, which it generally is not.

Bottom Line on Monoblocks

Unless you only need a single channel amp (for a subwoofer, for example), they are a waste of money, and serve no useful purpose. You will get a slight improvement in output power, but the real difference will be inaudible in the majority of cases.

Alternatively, they are useful if you want to have the shortest possible speaker leads. The amp can be installed next to the speaker, and a very short lead used to connect the two. Then we create a problem with the low level interconnects, which will be of significant length. There is far more chance of interference and high frequency loss in long interconnects than in speaker cables, so ideally the interconnects should be low impedance balanced circuits. Sadly, most monoblocks do not offer this essential option.

Power Supplies

I have seen reviews, and claims by amplifier designers, that for this amp to sound good, it must have a fast power supply. A power supply does not have speed - high, low or otherwise ... unless it is regulated.

> **Anecdote:** A regulated supply will have a finite ability to maintain its output voltage as the load varies - this is well known in engineering circles, and can cause problems if it is not fast enough.
>
> I have worked on power supplies (many years ago) that were used to power the head positioning amplifiers in the old washing machine sized computer disk drives. One of the tests that we needed to run was a switched load - varying the load from about 0.1 of the rated current to full current repeatedly.
>
> Detectors were used to measure how far the output voltage dropped when the full load was applied, and I designed the circuit to do this. It was fairly fast, and would latch a "Fail" LED if the output fell below a predetermined limit for more than about 1us. BTW, the low voltage limit was set at only about 1V below the rated output voltage, which was 24V if I remember correctly.

Bear in mind that there is no audio signal that can cause an amplifier to go from quiescent current to full output in anything *near* 1us. A 20kHz signal has a period of 50us, and full power at 20kHz will fry your tweeters in seconds.

So, speed is valid for a regulated supply for a critical application, but is completely meaningless for a power amplifier with an unregulated supply - which is 99.9% of them. There is no audio signal that is so fast that it will demand power from perfectly ordinary electrolytic capacitors faster than they can supply it. It is not necessary (other than for radio frequency bypassing) to use polyester caps in parallel with the main electrolytic filter caps, and nor is there any valid reason to specify that 100,000uF (or any other outlandishly expensive number) is needed to power an amp so the supply will be "fast".

A standard electrolytic (say, 10,000uF) will have an equivalent series resistance (ESR) of perhaps 0.01 Ohm, which means that it has an internal time constant of about 100us. More significant is the fact that discharge current is limited by ESR, so if charged to 50V, the maximum current available is 5,000A peak - this is a lot of current! In fact it is so high that it can destroy the cap itself - this is a very good reason not to use a screwdriver to discharge a power supply, well apart from the fact that a decent amount of

capacitance will take the end off a small screwdriver.

If this 50V supply is connected to a 8 Ohm speaker via an amplifier, the maximum current the speaker will draw is 6.25A (although some speakers will demand more at certain frequencies). In reality it will be far less than this most of the time. I can make a power supply "slow", simply by placing some resistance in series - the caps will no longer be able to discharge at their maximum rate. Will this affect an amplifier? Only in that the maximum power will no longer be achieved, but this will also happen if the AC mains supply is 10% low. Does this somehow degrade the sound of an amplifier? I think not.

Bottom Line on Power Supplies

Fast power supplies are a myth, as all power supplies are inherently "fast" in this context. Regulated supplies are generally only used with Class-A amps to reduce ripple. These do not have to be fast, because the current variations are much lower with the Class-A topology. Most will have a fair sized electrolytic at the regulator output anyway, so they are "fast" again.

Massive capacitance and "audiophile" grade caps are not going to improve the sound of the DC from your supply, regardless of cost or claim. The power supply is a passive part of the amplifier, and has little or no influence on the sound, unless grossly and ingeniously poorly designed. I say "ingeniously", because it would take spectacular incompetence to so badly design a power supply that it audibly affected the sound at any signal level below clipping. From some of the posings I have seen on various bulletin boards, such incompetance may well be rife, since just changing a power lead makes them audibly better :-)

"Special" Designs

The editorial page has a pair of prime examples of "Special Designs", including a more detailed examination of the sample below. See I am as Mad as Hell for more info.

I recently saw information on the web about an amp whose claims to fame (infamy, more like it) were along the following lines (this is taken from the site)

- World's smallest number of parts - 9 parts per channel (excluding attenuators)
- World's shortest signal pass length - 32 m/m (including the length of parts)
- World's shortest NFB loop length - 9 m/m (including the length of the resistor)
- World's smallest filter/condenser - 1000µF

- Powerful voltage regulation with high capacity transformer - 170 VA cut-core transformer +- individual coils
- Dual mono construction with each channel in a separate chassis.
- Rigid and compact aluminum chassis construction to release vibrations smoothly.
- Separate 12-position attenuators for each channel.
- Can be up-graded into a pair of complete mono amplifiers by adding another Model X Stupid Name

Oh, wow, and ... I mean ... like ... who gives a toss! This amplifier sold for some astronomical sum, and as near as I could tell from the advertising blurb, seems to use a couple of power opamps as the entire circuit. The power supply was separate.

So the amp has few components and a short signal path. What about the several hundred metres of standard professional class cable and very long signal paths that are common in the mixers that were used in the recording studio? Is this "magical" short signal path going to somehow make that all go away - somehow I doubt it. Since this amp does use a power opamp, the manufacturer obviously does not count the 30 or so transistors inside the device - why not? They are real, whether you acknowledge them or not.

As for the "world's shortest negative feedback path". So what? The claim was made that by doing this, power supply bypass capacitors that by some mystical process ruin the sound were not needed. What rubbish. My 60W power amp has a negative feedback path that is about 50mm long - in other words, typical. Because of its design, it will operate perfectly happily with no power supply bypass capacitors too - the result is greatly reduced power because of the resistance of the power leads. Do you want that? Does this sound like a good idea? No, I didn't think so either.

The one I liked best (or least, depending on how you think I read this nonsense) was the "world's smallest filter capacitors". What possible benefit - other than profit maximisation - does this infer? I honestly have no idea. I could run my amp with 1000uF caps too. Anyone can. The immediate result is a dramatic reduction in power, as ripple voltage is very high at any reasonable power level, and you start to get clipping as the ripple voltage encroaches on the audio signal. Ah, but we also have "powerful voltage regulation" and a high capacity transformer. Big deal. I can run my amp off a 10kVA transformer if I want to, and it won't change the sound one iota. Anyone can make a voltage regulator (assuming that one is actually used, which I doubt), but why? Extra heatsinks, more stuff to fail, and zero sonic benefit.

I won't even bother discussing the "dual mono construction", but I am intrigued by the "rigid and compact aluminium chassis to release vibrations smoothly". Quite apart from

the fact that being rigid and compact in no way ensures that vibrations will be released smoothly or otherwise, I am at a complete loss as to why anyone might think for an instant that this was important. This is an amplifier, not a speaker cabinet. Left to their own devices, amplifiers don't normally vibrate - this is not one of their characteristics. Are we supposed to believe that a power amp is in some way microphonic?

Try this (if you dare). Place your ear as close as possible to the speaker, and have someone drop the power amp a short distance while powered on and connected. What do you think is the chance that you will hear anything from the speaker (other than if the amp destroys itself when it is dropped)? I will tell you, to save the embarassment of having to explain to the service guy what happened to the amp. Nothing, that's what. If these clowns *have* managed to make an amp that is microphonic, then I definitely don't want one.

Bottom Line on Special Designs

Most are rubbish, but genuinely overpriced, while others are just trying to do something different (which they're not) and desperately attempting to convince (confuse?) us that it makes a difference. It doesn't.

I thought about this one for a while, and it finally made it into my "Hall of Infamy" - the editorial. You can read more about it there (see above).

Opamps

Many is the claim that opamps have a distinctive sound, and can readily be heard in audio equipment. Discrete designs supposedly sound superior, regardless of the fact that in many cases they will measure worse than even a cheap opamp.

I have never been able to measure an opamp's distortion, because it is so far below my equipment's limits that it cannot be detected. Devices are available with distortion as low as 0.00008% - this is close as you can get to the ideal "straight wire with gain". The bandwidth of the better devices is so wide that significant gain is available at 100kHz, so phase irregularities and response problems are non-existent in sensible designs.

Considering the fact (and in the vast majority of cases, it is fact) that the final mixed down signal you get from a CD has passed through up to 100 opamps at various stages of production before you even get to listen to it, it is ludicrous to assume that *not* using opamps in the last 1% of the audio chain will have any audible effect.

Bottom Line on Opamps

Opamps are great. They simplify design, have low distortion and excellent power supply rejection, and good ones are very quiet indeed. There are few areas where a discrete design will be better. This naturally assumes the use of good quality units - the venerable uA741 might be OK in a thermal controller, but you don't want them in audio gear (although you might be surprised at some of the opamps that you might find - some are little better than the 741, but they are still used).

Valves (Tubes)

Valve amplifiers are back, with units in all sorts of configurations selling for astounding sums.

The valve sound is one phenomenon that is real. It has been known for a long time that listeners sometimes prefer to have a certain amount of second-harmonic distortion added in, and most valve amplifiers provide just that, due to huge difficulties in providing good linearity with modest feedback factors.

While this may well sound nice, hi-fi is supposedly about accuracy, and if the sound is to be modified in this manner, it should be set from the preamp front panel by a control (Douglas Self suggests a 'niceness' knob).

Valves offer some advantages - their overload characteristics are smoother than solid state designs, so even when clipping the sound is less harsh. While this is most desirable for a guitar amplifier that will be operating into clipping for much of the time, it is unhelpful for hi-fi, where clipping should be avoided altogether.

Valve amps also have much higher output impedance than transistor amps, and this makes some speakers sound better. It also makes other speaker sound worse, so the results are unpredictable.

There are few modern transistor amps that will measure worse than any valve amp, regardless of cost. Indeed, the vast majority are so superior in all respects that it is difficult to justify using valves in anything other than guitar amps, where, despite much advertising hype, no transistor amp has ever been able to sound exactly the same as a valve unit. Close - but not the same.

The rash of single-ended directly heated triode monoblock amplifiers of late is something that astonishes me. These will typically have a distortion of 1 to 3%, are of low power -

typically less than 10W, and have no redeeming features (IMHO).

Such an amplifier generates large amounts of second-harmonic distortion, due to the asymmetry of single-ended operation, and needs a very large output transformer because the primary carries the full DC anode current, and core saturation must be avoided. The inherent distortion of an iron cored inductor or transformer is ever-present, and only global feedback can remove it.

High values of feedback around a transformer are extremely difficult, because the phase irregularities generally cause the amplifier to oscillate. This may have been the state of the art 50 years ago, but there is no sensible reason to go back. Next we will hear someone extolling the virtues of the wax cylinder as having superior sonics to vinyl or CD (needless to say these superior sonics will be "very subtle" and "only audible with the finest (i.e. most expensive) single ended triode monoblock amplifier").

In one review, a single ended triode amplifier yielded 3% THD at 9 Watts, at a cost of $3400 [4]. This is an appalling result for a very expensive single channel amp. The amplifiers in powered computer speakers are better than that!

Despite all of the above, I have no doubt that many of these amps sound delightful. Not exactly my cup of tea, but having used valve amps of many types over the years (including those I designed and built myself), I still like the sound of them. They also don't blow up with difficult loads - they may stress out a little and give less power than normal, but they survive. The majority of valve amps are far less forgiving of open circuits (no speakers connected), and some will fail if pushed hard into an open circuit. The typical failure mode is a high voltage flashover, which either carbonises the valve socket or base (or both), or causes the insulation in the output transformer to fail.

Bottom Line on Valves

This is one area I shall leave open-ended. There are some valve amps that do sound very good indeed, but are generally very expensive. Valves are also fragile, generate copious amounts of heat, and have a limited life. Correct biasing is essential, and few valve amps provide a simple method of doing this.

The trend towards having these hot "bottles" out in full view, and able to be touched (and / or broken) by age challenged persons (the rug-rats) is a definite safety hazard. I would not like anyone's kids to be able to burn and then electrocute themselves in one small mishap.

.... However - I do (or did until recently) use a valve preamp in my own system, and I

have no idea what that says about me. It does sound nice, but I am probably deluding myself in thinking that it is better than my solid-state preamp. That's fine for me, because I designed and built it, so it didn't cost me a king's ransom.

Speakers

There are many very fine loudspeakers available, and interestingly, although these have a far greater effect on the sound that you hear than the amplifier, there is nowhere near the controversy with loudspeakers as seems to be evident with the rest of the audio chain.

Certainly there are proponents of various crossover alignments, the benefits or otherwise of vented boxes versus sealed, but otherwise this seems to be a reasonably sensible (even if intimidatingly expensive) field of endeavour.

Most audiophiles have their favourite speaker system(s), and these will all have some undesirable characteristics, for such is the state of the art. The perfect loudspeaker does not exist, because of the physics of making electro-mechanical objects with finite mass react in a completely predictable manner at all frequencies. This (of course) is something that speakers cannot do.

A flat frequency response is desirable, and rapid decay of internal resonances means that the loudspeaker contributes a minimum of its own sound to that from the source. Good quality drivers and well braced, non resonant cabinets, combined with high quality components in crossover networks and a sensible approach to ensure that phase irregularities at the crossover frequencies do not cause response or impedance peaks and dips are common in most quality systems.

The listening room and the recorded material has a very great influence on the final sound you hear, vastly more than a few interconnects or a mains lead. No-one is going to make the listening room anechoic, and nor would you want to. The positioning of speakers is one thing that can have a profound effect on the sound, but this is so often completely ignored.

One problem is that the optimum placement of speakers for sound quality will often be completely inappropriate to the layout of the room, meaning that a liveable area is no longer available, and causing much friction between the listener and s/he who must be obeyed.

Bottom Line on Speakers

Buy what sounds good, build your own and experiment, whatever. This is too complex an area to try to offer suggestions or advice (although there are many who will do just that, with no knowledge of your listening room, its furnishings or anything else).

Bear in mind that building a speaker system without measurements is futile. The ear (and attached brain) is easily fooled, and has a very short memory for what you hear. Speakers can have huge anomalies in response, and within a few minutes the brain has made the necessary adjustments, and everything will seem to sound as it should.

Try this experiment. If you have a graphic or parametric equaliser, reduce a band somewhere in the midrange area (say, between 500Hz and 1kHz). Listen to the system for about 15 minutes, then restore the missing frequency range. Suddenly, the system will sound as if it has a hugh peak in the midrange, and for a time will sound awful. Within another 15 minutes or so, everything will have settled back to normal.

Conclusion

On the one hand, we have respected designers who simulate, build, measure and modify until they are satisfied that the performance is as expected. Then, and only then, the amplifier (or whatever it might be) is auditioned in a proper listening test (as opposed to a lab speaker), and perhaps only the designer listens to it in the first instance. If the sound is as expected, then others will usually be invited to listen as well. Comments are made, and if it is felt that they are valid (a sufficient number of listeners made the same remarks, for example), then further modifications will be made, more tests, more listening, until everyone is satisfied that the measured and audible performance is in agreement. The measurements are available on the colour glossies, and are considered a part of the equipment - this is the specification, against which others can be compared.

Compare this to the snake oil vendors. As an example, they buy perfectly ordinary cable from an established manufacturer, clad it in some fancy heatshrink tubing, write their sales pitch, and sell it. They might actually bother to listen to it as well, but there isn't much point, since it is the same wire as used by others anyway. Do you see specifications, measurements, or other factual data? No! What you see on the colour glossies is a sales pitch, aimed directly at your emotional responses. There are no means for direct comparison, not a mention of anything that will help you to make a reasonable and informed decision as to which "thing" is (or might be) better than the other.

Non blind listening tests are flawed - and especially so when conducted by a dealer. Don't expect that the levels will be precisely matched, but *absolutely* expect the salesthing to tell you *what to hear* - not exactly a fair comparison.

When only emotions are allowed to make the decision on technical equipment, we can be fairly certain that we will make the wrong choice, other than by chance. Having spent all that money, no-one, and I mean no-one, will be willing to admit that they were defrauded, robbed or deceived. The survival instinct takes over, and we hear exactly what we expect to - whether it exists ot not.

In the long term, the subjectivist approach will cost you a lot of money, and possibly yield a system that is less hi-fi than something from a department store. A review without technical tests is without substance or meaning, and nearly all descriptions about amplifier sound should be taken with a large dose of salt (possibly epsom).

Claims that power leads and interconnects will magically transform the sound of your system are false and misleading in the extreme. The various system components may be influenced by some combinations, but a well designed system should not care.

The current impasse between the scientific and subjectivist camps is unlikely to be resolved in the near future, because as politics and religion have shown over the centuries, people will believe what they want to, despite any evidence that may be offered to show that they are misguided or just plain wrong.

There is great difficulty defining the quality of an audio experience - you can't draw a picture to show what something sounded like. In addition, our acoustical memory is far more fleeting and more readily fooled than visual memory. It is much easier to visualise what the Sydney Harbour Bridge looks like than to recall all but the basic details of a musical performance.

> From Douglas Self -
>
> It has been universally recognised for many years in experimental psychology, particularly in experiments about perception, that people tend to perceive what they want to perceive. This is often called the 'experimenter expectancy' effect; it is more subtle and insidious than it sounds, and the history of science is littered with the wrecked careers of those who failed to guard against it. Such self-deception has most often occurred in fields like biology, where although the raw data may be numerical, there is no real mathematical theory to check it against.
>
> When the only 'results' are vague subjective impressions, the danger is clearly much greater, no matter how absolute the integrity of the experimenter. Thus in psychological work great care is necessary in the use of impartial observers, double-blind techniques, and rigorous statistical tests for significance. The vast majority of Subjectivist writings wholly ignore these precautions, with predictable results. In a few cases properly controlled listening tests been done, and at the time of writing all have resulted in different amplifiers sounding indistinguishable. I believe the conclusion is inescapable that experimenter expectancy has played a dominant role in the growth of Subjectivism.
>
> It is notable that in Subjectivist audio the 'correct' answer is always the more expensive or inconvenient one. Electronics is rarely as simple as that. A major improvement is

more likely to be linked with a new circuit topology or new type of semiconductor, than with mindlessly specifying more expensive components of the same type; cars do not go faster with platinum pistons.

All the above notwithstanding, most audio designers will still tend to accept (however reluctantly) some of the subjectivist propaganda, if only to be able to extract some of the obviously serious money that would otherwise go elsewhere. There is nothing wrong with this in principle, but where this happens, you will almost invariably get what you pay for, and the equipment's performance will be (hopefully) satisfying to both camps.

Just as likely is that the subjectivists will determine that this same piece of equipment is hopelessly inadequate in all respects, despite the fact that it has zero distortion of any kind, and a frequency response from DC to daylight. (A good quality standard interconnect comes to mind!)

These were the first three audio double blind tests ever done.

* The Swartz 40 is a 20 Watt per channel power amplifier with quasi-complementary ouputs built exactly to the five transistor per channel design in the RCA Transistor Manual. By the espoused standards of subjectivists, nothing should sound worse than this amplifier.

DIFFERENT ≠ DIFFERENT	The different symbol means it is unlikely the percent correct score occurred by chance and thus the null hypothesis was disproven, which substantiates a real difference in sound quality.

The same symbol means that it is likely the correct score occurred by chance, the null hypothesis is not rejected, which means no difference was found. It does remain possible a difference may be substantianted with further testing.

The Belief Engine

Our brains and nervous systems constitute a belief-generating machine, a system that evolved to assure not truth, logic, and reason, but survival. The belief engine has seven major components.

James Alcock

The following beliefs are strongly held by large numbers of people. Each of them has been hotly disputed by others:

- Through hypnosis, one can access past lives.
- Horoscopes provide useful information about the future.
- Spiritual healing sometimes succeeds where conventional medicine fails.
- A widespread, transgenerational Satanic conspiracy is afoot in society.
- Certain gifted people have been able to use their psychic powers to help police solve crimes.
- We can sometimes communicate with others via mental telepathy.
- Some people have been abducted by UFOs and then returned to earth.
- Elvis lives.
- Vitamin C can ward off or cure the common cold.
- Immigrants are stealing our jobs.
- Certain racial groups are intellectually inferior.
- Certain racial groups are athletically superior, at least in some specific sports.
- Crime and violence are linked to the breakdown of the traditional family.
- North Korea's developing nuclear capability poses a threat to world peace.

Despite high confidence on the part of both believers and disbelievers, in most instances, neither side has much -- if any -- objective evidence to back its position. Some of these beliefs, such as telepathy and astrology, stand in

contradiction to the current scientific worldview and are therefore considered by many scientists to be "irrational." Others are not at all inconsistent with science, and whether or not they are based in fact, no one would consider them to be irrational.

Nineteenth-century rationalists predicted that superstition and irrationality would be defeated by universal education. However, this has not happened. High literacy rates and universal education have done little to decrease such belief, and poll after poll indicates that a large majority of the public believe in the reality of "occult" or "paranormal" or "supernatural" phenomena. Why should this be so? Why is it that in this highly scientific and technological age superstition and irrationality abound?

It is because our brains and nervous systems constitute a belief-generating machine, an engine that produces beliefs without any particular respect for what is real or true and what is not. This belief engine selects information from the environment, shapes it, combines it with information from memory, and produces beliefs that are generally consistent with beliefs already held. This system is as capable of generating fallacious beliefs as it is of generating beliefs that are in line with truth. These beliefs guide future actions and, whether correct or erroneous, they may prove functional for the individual who holds them. Whether or not there is really a Heaven for worthy souls does nothing to detract from the usefulness of such a belief for people who are searching for meaning in life.

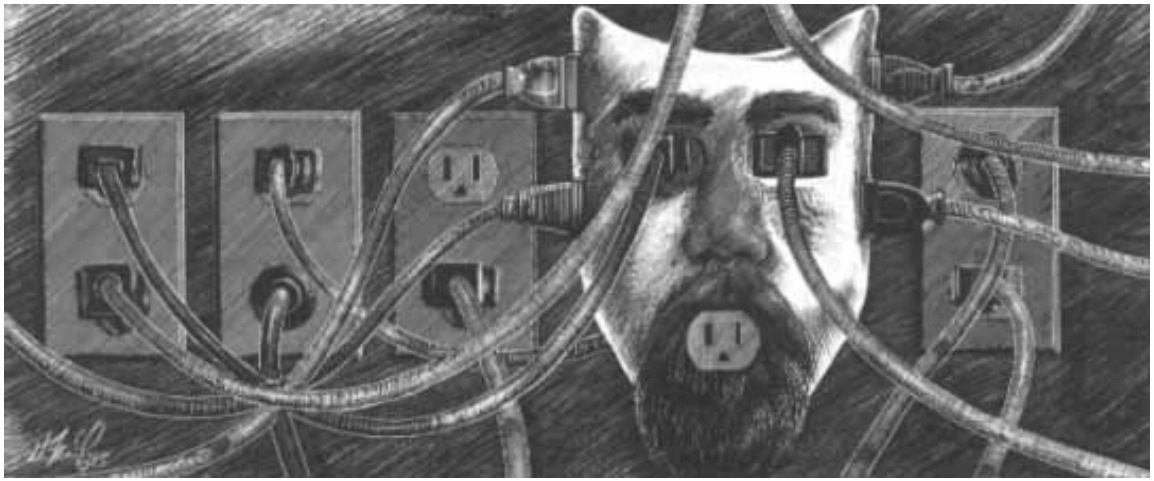
Nothing is fundamentally different about what we might think of as "irrational" beliefs -- they are generated in the same manner as are other beliefs. We may not have an evidential basis for belief in irrational concepts, but neither do we have such a basis for most of our beliefs. For example, you probably believe that brushing your teeth is good for you, but it is unlikely that you have any evidence to back up this belief, unless you are a dentist. You have been taught this, it makes some sense, and you have never been led to question it.

If we were to conceptualize the brain and nervous system as a belief engine, it would need to comprise several components, each reflecting some basic aspect of belief generation. Among the components, the following units figure importantly:

1. The learning unit
2. The critical thinking unit
3. The yearning unit

Network of Skeptical Organizations
- Links

4. The input unit
5. The emotional response unit
6. The memory unit
7. The environmental feedback unit.



The Learning Unit

The learning unit is the key to understanding the belief engine. It is tied to the physical architecture of the brain and nervous system; and by its very nature, we are condemned to a virtually automatic process of magical thinking. "Magical thinking" is the interpreting of two closely occurring events as though one caused the other, without any concern for the causal link. For example, if you believe that crossing your fingers brought you good fortune, you have associated the act of finger-crossing with the subsequent welcome event and imputed a causal link between the two.

Our brain and nervous system have evolved over millions of years. It is important to recognize that natural selection does not select directly on the basis of reason or truth; it selects for reproductive success. Nothing in our cerebral apparatus gives any particular status to truth. Consider a rabbit in the tall grass, and grant for a moment a modicum of conscious and logical intellect to it. It detects a rustling in the tall grass, and having in the past learned that this occasionally signals the presence of a hungry fox, the rabbit wonders if there really is a fox this time or if a gust of wind caused the grass to rustle. It awaits more conclusive evidence. Although motivated by a search for truth, that rabbit does not live long. Compare the late rabbit to the rabbit that responds to the rustle with a strong autonomic nervous-system reaction

and runs away as fast as it can. It is more likely to live and reproduce. So, seeking truth does not always promote survival, and fleeing on the basis of erroneous belief is not always such a bad thing to do. However, while this avoidance strategy may succeed in the forest, it may be quite dangerous to pursue in the nuclear age.

The learning unit is set up in such a way as to learn very quickly from the association of two significant events -- such as touching a hot stove and feeling pain. It is set up so that significant pairings produce a lasting effect, while nonpairings of the same two events are not nearly so influential. If a child were to touch a stove once and be burned, then if the child were to touch it again without being burned, the association between pain and stove would not automatically be unlearned. This basic asymmetry -- pairing of two stimuli has an important effect, while presenting the stimuli unpaired (that is, individually) has a much lesser effect -- is important for survival.

This asymmetry in learning also underlies much of the error that colors our thinking about events that occur together from time to time. Humans are very poor at accurately judging the relationship between events that only sometimes co-occur. For example, if we think of Uncle Harry, and then he telephones us a few minutes later, this might seem to demand some explanation in terms of telepathy or precognition. However, we can only properly evaluate the co-occurrence of these two events if we also consider the number of times that we thought of Harry and he did not call, or we did not think of him but he called anyway. These latter circumstances -- these nonpairings -- have little impact on our learning system. Because we are overly influenced by pairings of significant events, we can come to infer an association, and even a causal one, between two events even if there is none. Thus, dreams may correspond with subsequent events only every so often by chance, and yet this pairing may have a dramatic effect on belief. Or we feel a cold coming on, take vitamin C, and then when the cold does not get to be too bad we infer a causal link. The world around us abounds with coincidental occurrences, some of which are meaningful but the vast majority of which are not. This provides a fertile ground for the growth of fallacious beliefs. We readily learn that associations exist between events, even when they do not. We are often led by co-occurring events to infer that the one that occurred first somehow caused the one that succeeded it.

We are all even more prone to error when rare or emotionally laden events are involved. We are always looking for causal explanations, and we tend to infer causality even when none exists. You might be puzzled or even distressed if you heard a loud noise in your living room but could find no

source for it.

The Critical-Thinking Unit

The critical-thinking unit is the second component of the belief engine, and it is acquired -- acquired through experience and explicit education. Because of the nervous-system architecture that I have described, we are born to magical thinking. The infant who smiles just before a breeze causes a mobile above her head to move will smile again and again, as though the smile had magically caused the desired motion of the mobile. We have to labor to overcome such magical predisposition, and we never do so entirely. It is through experience and direct teaching that we come to understand the limits of our immediate magical intuitive interpretations. We are taught common logic by parents and teachers, and since it often serves us well, we use it where it seems appropriate. Indeed, the cultural parallel of this developmental process is the development of the formal method of logic and scientific inquiry. We come to realize that we cannot trust our automatic inferences about co-occurrence and causality.

We learn to use simple tests of reason to evaluate events around us, but we also learn that certain classes of events are not to be subjected to reason but should be accepted on faith. Every society teaches about transcendental things -- ghosts, gods, bogeymen, and so on; and here we are often explicitly taught to ignore logic and accept such things on faith or on the basis of other people's experiences. By the time we are adults, we can respond to an event in either a logical, critical mode or in an experiential, intuitive mode. The events themselves often determine which way we will respond. If I were to tell you that I went home last night and found a cow in my living room, you would be more likely to laugh than to believe me, even though there is certainly nothing impossible about such an event. If, on the other hand, I were to tell you that I went into my living room and was startled by an eerie glow over my late grandfather's armchair, and that the room went cold, you may be less likely to disbelieve and more likely to perk up your ears and listen to the details, possibly suspending the critical acumen that you would bring to the cow story. Sometimes strong emotion interferes with the application of critical thought. Other times we are cleverly gulled.

Rationality is often at a disadvantage to intuitive thought. The late psychologist Graham Reed spoke of the example of the gambler's fallacy: Suppose you are observing a roulette wheel. It has come up black ten times in a row, and a powerful intuitive feeling is growing in you that it must soon come up red. It cannot keep coming up black forever. Yet your rational mind

tells you that the wheel has no memory, that each outcome is independent of those that preceded. In such a case, the struggle between intuition and rationality is not always won by rationality.

Note that we can switch this critical thinking unit on or off. As I noted earlier, we may switch it off entirely if dealing with religious or other transcendental matters. Sometimes, we deliberately switch it on: "Hold it a minute, let me think this out," we might say to ourselves when someone tries to extract money from us for an apparently worthy cause.

The Yearning Unit

Learning does not occur in a vacuum. We are not passive receivers of information. We actively seek out information to satisfy our many needs. We may yearn to find meaning in life. We may yearn for a sense of identity. We may yearn for recovery from disease. We may yearn to be in touch with deceased loved ones.

In general we yearn to reduce anxiety. Beliefs, be they correct or false, can assuage these yearnings. Often beliefs that might be categorized as irrational by scientists are the most efficient at reducing these yearnings. Rationality and scientific truth have little to offer for most people as remedies for existential anxiety. However, belief in reincarnation, supernatural intervention, and everlasting life can overcome such anxiety to some extent.

When we are yearning most, when we are in the greatest need, we are even more vulnerable to fallacious beliefs that can serve to satisfy those yearnings.

The Input Unit

Information enters the belief engine sometimes in the form of raw sensory experience and other times in the form of organized, codified information presented through word of mouth, books, or films. We are wonderful pattern detectors, but not all the patterns we detect are meaningful ones. Our perceptual processes work in such a way as to make sense of the environment around us, but they do make sense -- perception is not a passive gathering of information but, rather, an active construction of a representation of what is going on in our sensory world. Our perceptual apparatus selects and organizes information from the environment, and this process is subject to many well-known biases that can lead to distorted beliefs. Indeed, we are less likely to be influenced by incoming information if it does not already correspond to

deeply held beliefs. Thus, the very spiritual Christian may be quite prepared to see the Virgin Mary; information or perceptual experience that suggests that she has appeared may be more easily accepted without critical scrutiny than it would be by someone who is an atheist. It is similar with regard to experiences that might be considered paranormal in nature.

The Emotional Response Unit

Experiences accompanied by strong emotion may leave an unshakable belief in whatever explanation appealed to the individual at the time. If one is overwhelmed by an apparent case of telepathy, or an ostensible UFO, then later thinking may well be dominated by the awareness that the emotional reaction was intense, leading to the conclusion that something unusual really did happen. And emotion in turn may directly influence both perception and learning. Something may be interpreted as bizarre or unusual because of the emotional responses triggered.

Evidence is accumulating that our emotional responses may be triggered by information from the outside world even before we are consciously aware that something has happened. Take this example, provided by LeDoux (1994) in his recent article in Scientific American (1994, 270, pp. 50-57):

> An individual is walking through the woods when she picks up information -- either auditory, such as rustling leaves, or visual, such as the sight of a slender curved object on the ground -- which triggers a fear response. This information, even before it reaches the cortex, is processed in the amygdala, which arouses the body to an alarm footing. Somewhat later, when the cortex has had enough time to decide whether or not the object really is a snake, this cognitive information processing will either augment the fear response and corresponding evasive behaviour, or will serve to bring that response to a halt.

This is relevant to our understanding of paranormal experience, for very often an emotional experience accompanies the putatively paranormal. A strong coincidence may produce an emotional "zing" that points us toward a paranormal explanation, because normal events would not be expected to produce such emotion.

Our brains are also capable of generating wonderful and fantastic perceptual experiences for which we are rarely prepared. Out-of-body experiences (OBEs), hallucinations, near-death experiences (NDEs), peak experiences -- these are all likely to be based, not in some external transcendental reality, but rather in the brain itself. We are not always able to distinguish material

originating in the brain from material from the outside world, and thus we can falsely attribute to the external world perceptions and experiences that are created within the brain. We have little training with regard to such experience. As children, we do learn to distrust, for the most part, dreams and nightmares. Our parents and our culture tell us that they are products of our own brains. We are not prepared for more arcane experiences, such as OBEs or hallucinations or NDEs or peak experiences, and may be so unprepared that we are overwhelmed by the emotion and come to see such experience as deeply significant and "real" whether or not it is.

Ray Hyman has always cautioned skeptics not to be surprised should they one day have a very strong emotional experience that seems to cry out for paranormal explanation. Given the ways our brains work, we would expect such experiences from time to time. Unprepared for them, they could become conversion experiences that lead to strong belief. When I was a graduate student, another graduate student who shared my office, and who was equally as skeptical as I was about the paranormal, came to school one day overwhelmed by the realism and clarity of a dream he had had the night before. In it, his uncle in Connecticut had died. It had been a very emotional dream, and was so striking that Jack told me that if his uncle died anytime soon, he would no longer be able to maintain his skepticism about precognition -- the dream experience was that powerful. Ten years later, his uncle was still alive, and Jack's skepticism had survived intact.

The Memory Unit

Through our own experience, we come to believe in the reliability of our memories and in our ability to judge whether a given memory is reliable or not. However, memory is a constructive process rather than a literal rendering of past experience, and memories are subject to serious biases and distortions.

Not only does memory involve itself in the processing of incoming information and the shaping of beliefs; it is itself influenced strongly by current perceptions and beliefs. Yet it is very difficult for an individual to reject the products of his or her own memory process, for memory can seem to be so "real."

The Environmental Feedback Unit

Beliefs help us to function. They guide our actions and increase or reduce our

anxieties. If we operate on the basis of a belief, and if it "works" for us, even though faulty, why would we be inclined to change it? Feedback from the external world reinforces or weakens our beliefs, but since the beliefs themselves influence how that feedback is perceived, beliefs can become very resistant to contrary information and experience. If you really believe that alien abductions occur, then any evidence against that belief can be rationalized away -- in terms of conspiracy theories, other people's ignorance, or whatever.

As mentioned earlier, fallacious beliefs can often be even more functional than those based in truth. For example, Shelley Taylor, in her book Positive Illusions, reports research showing that mildly depressed people are often more realistic about the world than are happy people. Emotionally healthy people live to some extent by erecting false beliefs -- illusions -- that reduce anxiety and aid well-being, whereas depressed individuals to some degree see the world more accurately. Happy people may underestimate the likelihood of getting cancer or being killed, and may avoid thinking about the ultimate reality of death, while depressed people may be much more accurate with regard to such concerns.

An important way in which to run reality checks on our perceptions and beliefs is to compare them with those of others. If I am the only one who interpreted a strange glow as an apparition, I am more likely to reconsider this interpretation than if several others share the same view. We often seek out people who agree with us, or selectively choose literature supporting our belief. If the majority doubts us, then even if only part of a minority we can collectively work to dispel doubt and find certainty. We can invoke conspiracies and coverups to explain an absence of confirmatory evidence. We may work to inculcate our beliefs in others, especially children. Shared beliefs can promote social solidarity and even a sense of importance for the individual and group.

In Conclusion

Beliefs are generated by the belief engine without any automatic concern for truth. Concern for truth is a higher order acquired cognitive orientation that reflects an underlying philosophy which presupposes an objective reality that is not always perceived by our senses.

The belief engine chugs away, strengthening old beliefs, spewing out new ones, rarely discarding any. We can sometimes see the error or foolishness in other people's beliefs. It is very difficult to see the same in our own. We

believe in all sorts of things, abstract and concrete -- in the existence of the solar system, atoms, pizza, and five-star restaurants in Paris. Such beliefs are no different in principle from beliefs in fairies at the end of the garden, in ghosts in some deserted abbey, in werewolves, in satanic conspiracies, in miraculous cures, and so on. Such beliefs are all similar in form, all products of the same process, even though they vary widely in content. They may, however, involve greater or lesser involvement of the critical-thinking and emotional-response units.

Critical thinking, logic, reason, science -- these are all terms that apply in one way or another to the deliberate attempt to ferret out truth from the tangle of intuition, distorted perception, and fallible memory. The true critical thinker accepts what few people ever accept -- that one cannot routinely trust perceptions and memories. Figments of our imagination and reflections of our emotional needs can often interfere with or supplant the perception of truth and reality. Through teaching and encouraging critical thought our society will move away from irrationality, but we will never succeed in completely abandoning irrational tendencies, again because of the basic nature of the belief engine.

Experience is often a poor guide to reality. Skepticism helps us to question our experience and to avoid being too readily led to believe what is not so. We should try to remember the words of the late P. J. Bailey (in *Festus: A Country Town*): "Where doubt, there truth is -- 'tis her shadow."

PRINCIPLES OF TRANSMISSION LINES

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to:

- State what a transmission line is and how transmission lines are used.
- Explain the operating principles of transmission lines.
- Describe the five types of transmission lines.
- State the length of a transmission line.
- Explain the theory of the transmission line.
- Define the term LUMPED CONSTANTS in relation to a transmission line.
- Define the term DISTRIBUTED CONSTANTS in relation to a transmission line.
- Define LEAKAGE CURRENT.
- Describe how the electromagnetic lines of force around a transmission line are affected by the distributed constants.
- Define the term CHARACTERISTIC IMPEDANCE and explain how it affects the transfer of energy along a transmission line.
- State how the energy transfer along a transmission line is affected by characteristic impedance and the infinite line.
- Identify the cause of and describe the characteristics of reflections on a transmission line.
- Define the term STANDING WAVES as applied to a transmission line.
- Describe how standing waves are produced on a transmission line and identify the types of terminations.
- Describe the types of standing-wave ratios.

INTRODUCTION TO TRANSMISSION LINES

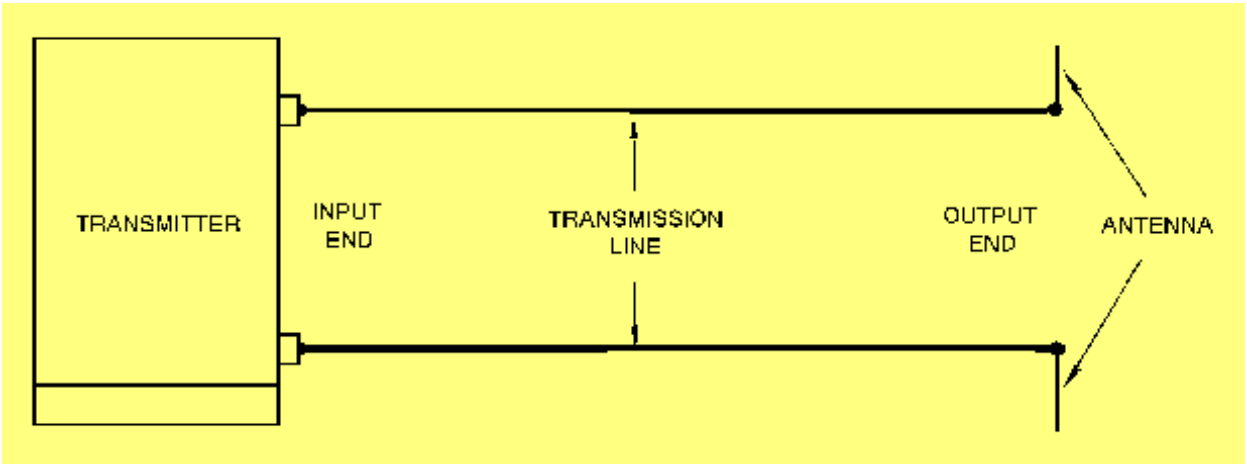
A TRANSMISSION LINE is a device designed to guide electrical energy from one point to another. It is used, for example, to transfer the output rf energy of a transmitter to an antenna. This energy will not travel through normal electrical wire without great losses. Although the antenna can be connected directly to the transmitter, the antenna is usually located some distance away from the transmitter. On board ship, the transmitter is located inside a radio room and its associated antenna is mounted on a mast. A transmission line is used to connect the transmitter and the antenna.

The transmission line has a single purpose for both the transmitter and the antenna. This purpose is to transfer the energy output of the transmitter to the antenna with the least possible power loss. How well this is done depends on the special physical and electrical characteristics (impedance and resistance) of the transmission line.

TERMINOLOGY

All transmission lines have two ends (see figure 3-1). The end of a two-wire transmission line connected to a source is ordinarily called the INPUT END or the GENERATOR END. Other names given to this end are TRANSMITTER END, SENDING END, and SOURCE. The other end of the line is called the OUTPUT END or RECEIVING END. Other names given to the output end are LOAD END and SINK.

Figure 3-1. - Basic transmission line.



You can describe a transmission line in terms of its impedance. The ratio of voltage to current (E_{in}/I_{in}) at the input end is known as the INPUT IMPEDANCE (Z_{in}). This is the impedance presented to the transmitter by the transmission line and its load, the antenna. The ratio of voltage to current at the output (E_{out}/I_{out}) end is known as the OUTPUT IMPEDANCE (Z_{out}). This is the impedance presented to the load by the transmission line and its source. If an infinitely long transmission line could be used, the ratio of voltage to current at any point on that transmission line would be some particular value of impedance. This impedance is known as the CHARACTERISTIC IMPEDANCE.

Editorial: Reaping What You Sow

Posted Monday, May 29 2006, by tom

Being a fairly sarcastic person (and by fairly I mean very), one has to be aware of the karmic toll one's actions are sure to elicit. You can only go around saying whatever you want in the form of a "joke" for so long before it catches up with you. I've spent my life watching words come out of my mouth thinking, I shouldn't have said that, while the retribution begins to crush me under its imposing and fully justified wrath. Examples? How 'bout the time I told a girlfriend that her "signature" dish that she worked on all day tasted just like that taste you get in your mouth after throwing up. Or the time some friends came over with a guy from another country and after a few hours of saying nothing to anyone, I looked over at him and said, "So why are you here anyways?"

Radiient Elara Theater Speaker Package Review

What do you say about speakers at this price range ($499 for a set of five)? They sound pretty darn good to my ears and I think that many would be pleased as punch to own them. The aesthetics are way above average though a bit higher quality veneer would have been appreciated. I can definitely see these working in a bachelor pad where you'd like to impress your friends without breaking the bank and you don't have to share the sweet spot with anyone.

Jeff Lorber: Worth Waiting For (!993) CD Review

Posted Wednesday, May 24 2006, by gds

Fans of the 1970's group Jeff Lorber Fusion (like me) were thrilled when, after a seven year hiatus from solo recordings, he returned to his fusion jazz roots with this release that was, well, *Worth Waiting For*. Sure, he was busy writing and producing for other (mostly vocal) artists during the late 1980's and early 1990's, but even his own break-through commercial success *Private Passion* (with female vocalist Karyn White) I think belied HIS true passion: fusion jazz.

The Lowest Inductance In The Business

The patented Goertz MI cable, invented by Ole Goertz, a Danish electronics and audio engineer, eliminates distortion between amplifier and loudspeakers. Patented in 20 countries, Goertz wire is flat by design. It's form follows function, in the best design tradition. We set out to create an electrically correct pathway between amplifier and loudspeaker, which required replacing typical cable psuedo-science with solid physics. Research showed that the perfectly flat shape, with minimum space between conductors, was the best way to achieve this.

But developing such a wire is a different proposition. Many audio companies do not even manufacture their own wire; packaging and marketing the products of others instead. As a primary maker of high-tech laminated conductors for industrial electronics applications, Alpha-Core was uniquely suited to transform the promising Goertz design into reality. Using the dielectrics Polyester Terapthalate and Teflon applied around each solid rectangular conductor, we achieved an extraordinarily thin profile between the two stacked wires. To provide maximum protection while maintaining thinness, the cable sandwich is then sheathed in tough, high grade polymer.

The result is a wire with a characteristic impedance that closely matches the impedance of loudspeakers. Alpha-Core's Goertz MI wire presents 2 to 4 ohms characteristic impedance as opposed to the 50 to 200 ohms presented by even the most expensive speaker cables. This correct electrical matching results in improved stereo imaging, better clarity, less high-frequency roll off and better low frequency definition.

Goertz Improves all Frequency Ranges:
LOW . . . MIDRANGE . . . HIGH
The degree of distortion along a loudspeaker cable depends on its resistance (**R**), inductance (**L**) and capacitance (**C**). Resistance is dependent on length and conductor cross section. A low resistance provides superior damping between the amplifier and the speaker diaphragm, governing its ability to convey a true, powerful bass and lower mid-range. A high cable inductance causes loss of signal strength towards the high end of the audible range (roll-off). It also causes frequency dependent phase-shift which disturbs true stereo imaging. The square root of the ratio L/C is termed Characteristic Impedance, and is a quality inherent in a cable, dependent on its geometry and materials, but not dependent on its length.

Goertz Virtually Eliminates Mismatch
The characteristic impedance of the Goertz MI cables in the order of 2 to 4 ohms closely matches the impedance of loudspeakers. Almost all other speaker cables have characteristic

impedance ranging from 50 to 200 ohms, a mismatch which causes distortion due to signal reflections. Impedance matching primarily improves the clarity of the highs and upper mid-range, but many users have also experienced improvements in the lower mid-range. The cause seems to be that signal reflections caused by impedance mismatch enter the feedback loop of many amplifiers and disturb their ability to reproduce faithfully even lower frequency signals.

Thick on Benefits, Thin as a Penny
The low inductance and characteristic impedance of Goertz cables are due to their flat construction and the nature of their insulation and jacketing material. The configuration places the heavy, solid conductors only 0.003 inches apart. The cables are 0.4 or 0.8 inches wide, and only 0.04 inches thick. As thin as a penny.

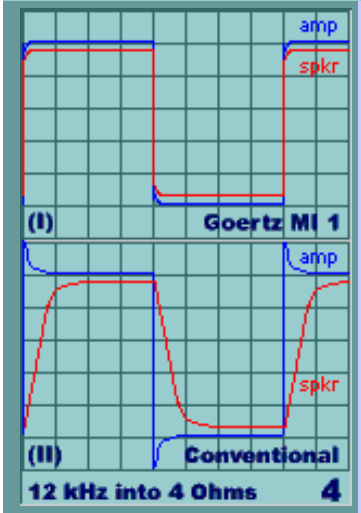
Perfect for Home Theater
Goertz MI speaker cable and interconnects are perfect for home theater applications. Due to the low inductance characteristics, Goertz audio products are ideal for long runs. No more positioning your equipment based on the limitations of your cable system. Dolby Digital home theater design requires full range audio frequencies be sent to rear speakers; Goertz cable allows extreme accuracy at any length. The space ratio, the relationship between conductor cross section, is about 50% in Goertz MI cables versus 5-20% in most other speaker cables. In other words, Goertz cables pack heavy conductor cross sections into an extremely slim package yielding greatly improved highs and mid-range, plus a truly powerful bass. Thanks to the flat construction and extreme compactness, they can be drawn anywhere and routed under thin carpets and wallpaper. If desired, paint with oil or water based paint.

What makes them Special?

Figure 1 is Goertz MI 1 (MI 2 is almost the same thickness, but twice as wide). Each conductor is a 0.375 by 0.010 inch solid band of high purity oxygen free copper (OFC) surrounded by a 0.0051 inch thick sheath of the space age insulation polyester terapthalate. The conductors are placed in close mutual contact within a 0.005 inch thick clear jacket. The mutual distance between the conductors is 0.003 inches and the overall dimensions of the cable are approximately 0.4 by 0.040 inches. The space ratio is close to 50%. The conductor cross section approximates 13 AWG, shown approximately twice actual size.

Figure 2 is a section through a competitor's cable extruded from clear PVC, having two stranded conductors of many fine copper wires. The space ratio of this style cable varies between 10% and 20%.

Figure 3 is a so called "multiple bandwidth" or "time compensated" cable with two larger and two smaller conductors twisted together inside a common jacket. The two differently sized conductors are used in parallel. The manufacturer claims that the treble components will travel along the lighter conductor, and the bass frequencies along the heavier conductors. The space ratio is 5% to 10%.



The Proof: Oscilloscope readings comparing the performance of a Goertz cable with conventional designs.

Figure 4 illustrates comparative measurements using a 12 kHz square wave transmitted via (I) a 25 foot Goertz cable, and (II) a 25 foot speaker cable of conventional bi-wire construction, both driving a 4 ohms loudspeaker. The characteristic impedance of the two cables are (I) 4 ohms and (II) 100 ohms. (A) is the signal at the amplifier, and (S) is the signal at the speaker.

Time Base = 10µS
Channel 1 V/DIV = 0.5 V
Channel 2 V/DIV = 0.5 V

It is evident that (I) is entirely distortion free, showing only the unavoidable power loss due to cable resistance. (II) in contrast indicates a clear leading edge spike at the amplifier, and significant distortion or roll off at the speaker terminals.

Goertz MI 1(Copper)/AG1 (Solid Silver)
The original Goertz cable, MI 1 in 13 gauge (AWG) *solid Oxygen Free Copper* (OFC) or 12 gauge *AG 1 in solid High Purity Silver*. The heavy, high purity Oxygen Free Copper (OFC) or solid high purity silver ribbons are sandwiched together, separated only by micro-thin layers of film insulation. The minute amount of active dielectric also provides rapid break-in; now audiophiles don't have to wait tens of hours to break in their cables, Goertz cables produce immediate results!

Goertz MI 2(Copper)/AG2 (Solid Silver)
MI 2 Heavy 10 gauge OFC copper or 9 gauge AG 2 solid silver cabling for improved bass and power handling over the remarkable Goertz MI 1. Great reviews confirm that this remarkable cable really delivers; superb bass control, vivid mid-range, and excellent high frequency extension combine with rejection of interference and no break-in period. Simply great value.

Goertz MI 3 (Cooper)/AG3 (Solid Silver)
Alpha-Core's "Big Boy" 7 gauge speaker cable; the answer for powerful audiophile systems. MI 3 was designed for high power amplifiers driving full range speakers. Perhaps the best speaker cable made today, the MI 3 delivers sublime clarity, dynamics, and definition throughout the audio spectrum. The extreme low DC resistance ensures diaphragm control for tight, powerful bass and mid-range, and the low inductance carries distortion free highs frequencies and crucial harmonics for outstanding imaging and depth perception.

Goertz 7 gauge MI 3 cables were developed at the request of Dan D'Agostino of Krell Industries and other customers who were seeking a speaker cable to complement today's powerful amplifiers. Double the cross section of Goertz MI 2 and AG 2, this newcomer features two solid conductors each measuring 1.25" by 0.012". As in Goertz MI 1 and MI 2, the micro-thin film dielectric means minimum break-in time.

The 7 AWG cable is available in two versions: The MI 3 'Divinity' in OFC copper, and the AG 3 'Divinity' in solid fine silver. Both are supplied with four inch user-friendly pigtails, and both feature Alpha-Core's unique solid fine silver spade connectors to fit all high-end binding posts. Goertz AG 3 is arguably the heaviest solid fine silver cable ever made. An eight foot pair contains more than a pound of 99.99% pure silver. So, for that extra muscle to drive the really powerful systems, Goertz MI 3 or MI AG 3 is the answer, The Alpha-Core "Big Boys" deliver punch in the bass and a sound so revealing that we maybe ought to mark them "Adults Only".

Class-A Part 1

Introduction

As discussed in Part 1, there has been a resurgence of two "ancient" technologies - vacuum tube (valve) amplifiers and Class-A systems. The big question is .... is there a difference? This part of the discussion looks at the differences in the output stages only - no feedback is used in any of the following, so the performance of the final stage can be assessed.

Class Comparison

The Class-AB output stage is essentially the same as that used in Project 3A), and this is compared with a Class-A emitter follower circuit using exactly the same circuitry. Both were operated with zero feedback, and the Class-AB stage was run at a quiescent current of 14mA vs. 2A for the Class-A circuit.

The Class-A version was operated using an ideal current source - a real current source will not be quite as good, however the difference in practical terms is very small (this was verified in a simulation).

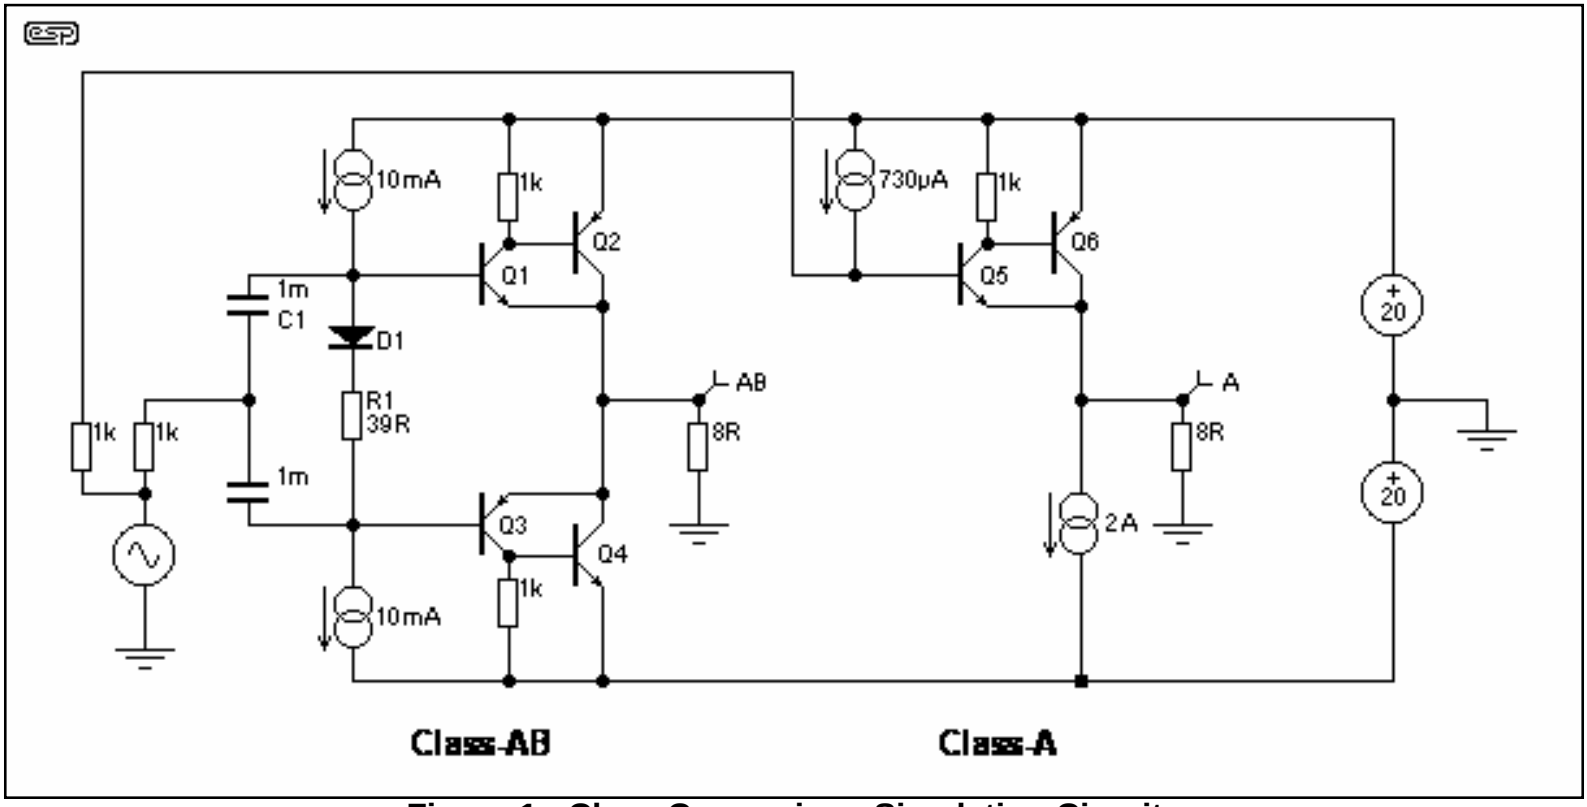

Figure 1 - Class Comparison Simulation Circuits

A description of the circuits is in order before we continue. The Class-AB output stage uses current sources to bias the bases, and 1,000uF coupling caps to the signal source. This is simply to allow the circuit to be biased correctly for the simulation, and has no effect on distortion. Because there is a small difference between the positive and negative halves of the circuit, the current sources were actually very slightly unbalanced to get less than 10mV DC offset at the output.

Quiescent current is set by the diode and 39 Ohm resistor, and was just over 14mA for the simulations used in this article.

The Class-A amp uses the same transistor configuration, but the bias is supplied by a much smaller current source - again, to obtain less than 10mV DC offset. I used a 2A current source rather than semiconductors to ensure that the results were not adversely affected by an imperfect current sink. Naturally, this choice is removed for a real amplifier.

Different results would be obtained using a Darlington emitter follower, however the difference in real terms is far less than will be caused by actual (as opposed to simulated) transistors. A quick check indicates that the Darlington configuration has slightly less second harmonic distortion, and less distortion overall. This will not necessarily be the same in a real amplifier.

It is worth noting that although the Class-A amp performs better with a Darlington, the

Class-AB circuit is significantly worse - even with higher quiescent current - this has been known for quite some time, but is still ignored by many designers.

Test Results

The first test was at close to full power - 15V peak (30V P-P) was used to ensure that both circuits were well away from clipping, as this would affect the results making a proper comparison impossible.

Logically, one would expect the Class-A emitter follower to be better (have lower distortion) but it doesn't! Distortion is 0.41% for the Class-A version, and 0.098% for the Class-AB. Spectral content shows that the Class-A circuit has higher harmonic levels than the Class-AB circuit up to about 6kHz, and it is only after this frequency that the Class-A amp shows an advantage. Even in this form (widely believed to have predominantly second harmonic distortion), there is considerable third harmonic distortion, as well as 4th, 5th, etc. Distortion falls to very low levels (-100dB) at 6kHz (6th harmonic).

By contrast, the Class-AB circuit has lower distortion overall, with low order harmonics almost an order of magnitude lower than Class-A. However, the spectral graphs show that high order harmonics are at a much greater level. Where the eighth harmonic was 100dB down in the Class-A circuit, the 31st harmonic was 100dB down in Class-AB. Which is preferable? I shall leave that up to the individual reader. I know for a fact that I can't hear distortion that is -100dB ... perhaps some people can, but I've not met any.

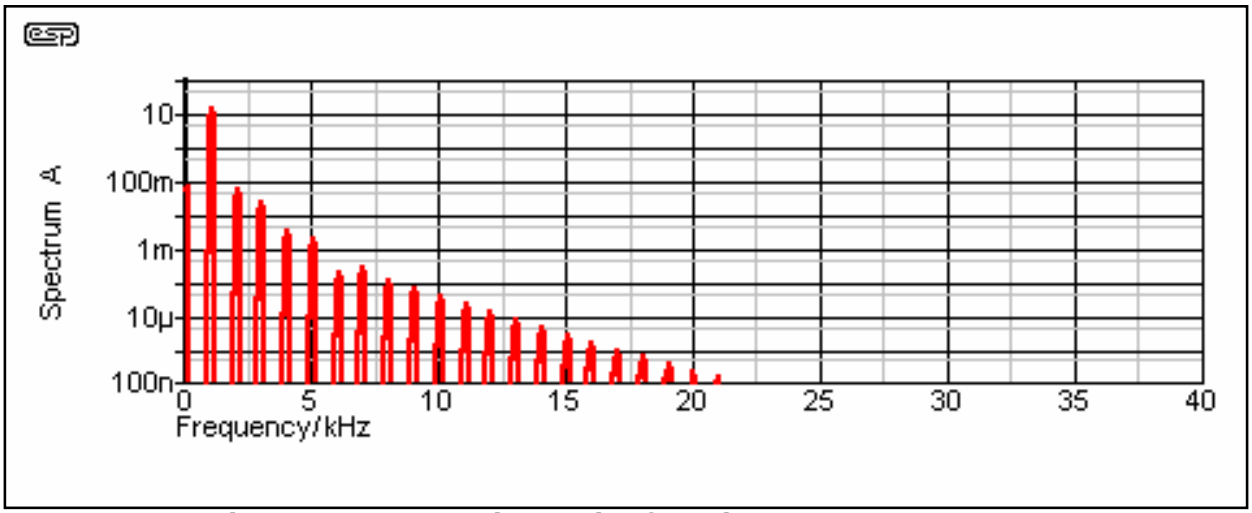

Figure 2 - Spectral Results for Class-A Output Stage

As you can see, the second harmonic (2kHz) is about 48dB below the fundamental, and the remaining harmonics are below the -100dB level by 8kHz (the 8th harmonic). The level at 8kHz is actually -102dB referred to the fundamental. This cannot be considered a bad

result. With the addition of feedback, these components will be reduced further, but it is also to be expected that any 'real-world' semiconductors will perform worse than their simulated counterparts.

Note that this is a single-ended Class-A stage, and it is this very configuration that is said to have predominantly even order harmonics (second, fourth, etc.). Instead of what is normally expected, we have an even progression of harmonics, with both odd and even represented in an orderly progression. To obtain predominantly even order harmonics, common 'wisdom' claims that the output stage should be operated as a common emitter amplifier (an emitter follower as shown is common collector). This is analogous to a common cathode stage as used in most single-ended triode (SET) amps.

Use of a common emitter stage will increase the levels of distortion dramatically - a quick test indicates that using the same topology for the stage but operating it as common emitter increases distortion to 8.56% at 30V P-P output, and it is still 1.61% at 2V P-P (these are the same levels used for all tests described in this article). This is hardly an encouraging result, but it does match the typical distortion levels of a SET Class-A amp. Adding some emitter feedback will reduce this very high distortion to something more tolerable at low levels (I measured 0.23%), and will also reduce distortion at higher voltages/ powers. At a little under 30V P-P, distortion was 3.8% - hardly awe inspiring. There is still a significant number of odd order harmonics at all power levels, and it is probably fair to say that very few (if any) amplifiers actually produce *only* even order harmonics.

It is easy to eliminate even order harmonics, but very difficult to eliminate odd ordered ones. This is despite any advertising material that claims the contrary.

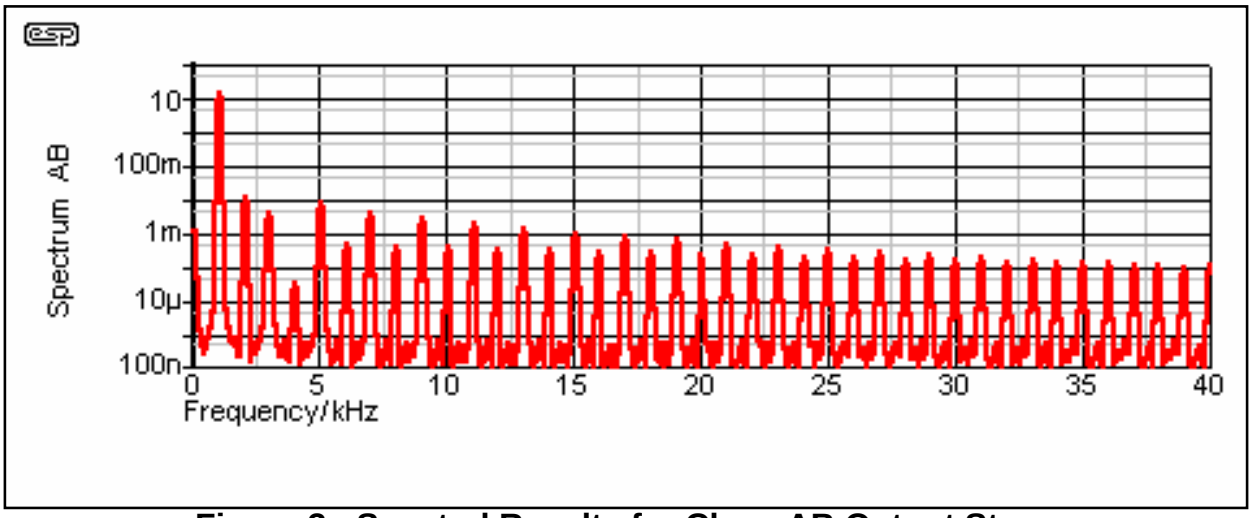

Figure 3 - Spectral Results for Class-AB Output Stage

For Class-AB, the second harmonic is 63dB below the fundamental, but there are higher order harmonics present at ever diminishing levels. Although it is unlikely that any of these would be audible, it is just this effect that some people claim ruins the sound. Again, feedback will reduce these levels, and in both cases shown, the system noise will help to mask any distortion products. Do not expect real power transistors to equal these results,

because it is almost a certainty that they won't (as with the Class-A example above).

Bear in mind that the 1mV level shown represents -83dB, and the 100nV minimum level equates to -163dB referred to the 15V peak level at 1kHz. A great many of the harmonics displayed are so far below the noise floor that no affordable test instrument would be capable of resolving them (and this includes the ears of the vast majority of people).

Low Power Operation

It is at low levels that we see some differences, and the performance differences are more like we might expect. For the Class-AB circuit, it is important to ensure that the test level is high enough to ensure that the transistors will turn off completely - at very low levels the circuit will operate in Class-A, and this would give us an unrealistic distortion level.

With 1V peak output (707mV RMS, or 2V P-P), this ensures that the Class-AB circuit is working as Class-AB. Now we see the effects of crossover distortion - even though it is not visible on a waveform graph. Total Harmonic Distortion (THD) is now 0.245% for Class-AB, but a minuscule 0.0195% for Class-A.

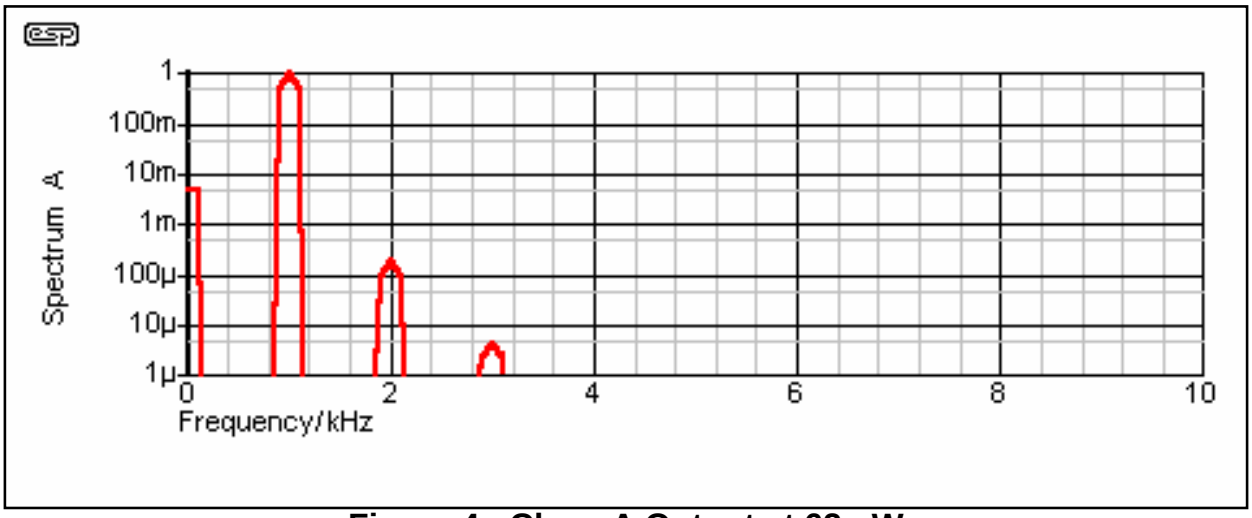

Figure 4 - Class-A Output at 62mW

Here we see the harmonic content at 62mW output level. There are only a couple of low order harmonics present, with everything beyond 4kHz well below audibility. The minimum level of 1uV is 120dB below the signal level, and can be considered so far below audibility that it is not worth considering.

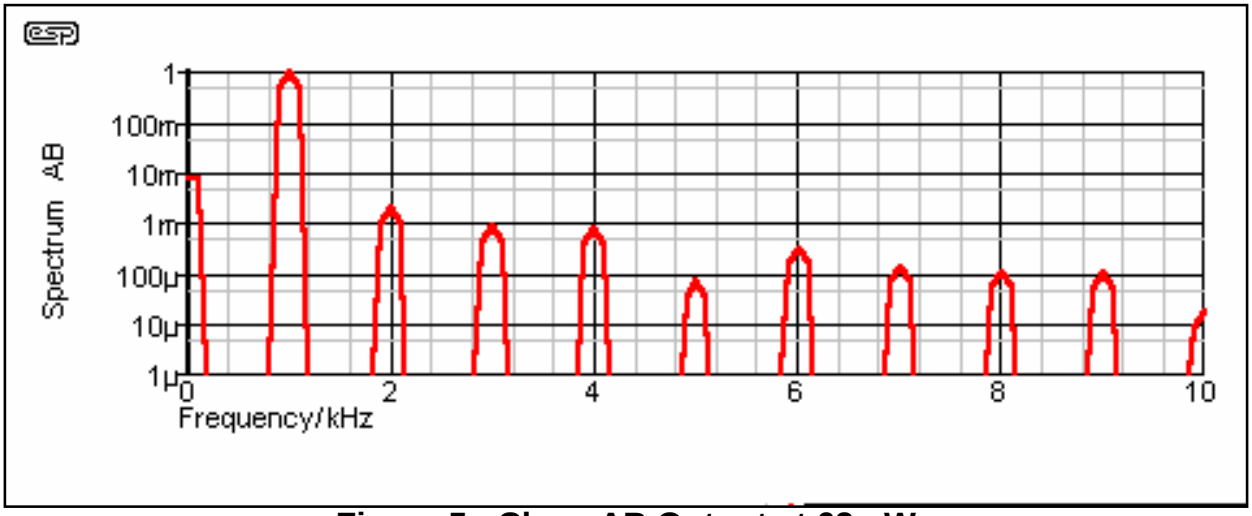

Figure 5 - Class-AB Output at 62mW

Things are not quite so rosy here. However, with an overall THD of 0.245% it still cannot be considered a bad result. Everything beyond 4kHz is more than 60dB below the signal level, and that will be close to the amplifier noise floor, and well below the listening room noise.

To explain that last point, assume a typical high-efficiency loudspeaker, with 100dB/W/m (very high efficiency by today's standards). 62mW is 12dB below 1W (close enough), so the peak level at 1 metre in the room is 88dB SPL. Since the upper harmonics are all more than 60dB below the fundamental, that makes them less than 28dB SPL. A very quiet room indeed would be needed to be able to hear a signal at only 28dB SPL, and it would probably be impossible in the presence of the fundamental.

Conclusion

As shown above, Class-A will give vanishingly low levels of distortion at low levels. Based on many amplifier tests over the years, I also know that a Class-AB amp can do exactly the same, but at all levels below clipping (not just low levels). Whether the overall advantages and disadvantages of a Class-A amp are worth the effort is entirely up to you - if having one makes you feel better (and especially so if you build it yourself), then there is no reason to avoid having one.

Of course you will need sensitive speakers, otherwise the available power at any sensible dissipation is just too low to be useful. In a biamped or triamped system, Class-A is ideal for tweeters. Will you hear a difference? I don't know - it depends on the amp, your hearing, and whether you perform a true blind test so you are completely unaware which amplifier you are listening to at any time during the test.

High Power, High Fidelity MOSFET Power Amplifier

Rod Elliott (ESP)

Updated 01 Feb 2004

PCBs are available for this project. Click the PCB image for details.

Introduction

In various parts of The Audio Pages, I have said that I am not a fan of MOSFET power amplifiers. Well, this amp has changed my views, and I consider this to be a "reference" system in all respects. The performance is extremely good, with vanishingly low distortion levels, plenty of power, very wide full power bandwidth, and the "self protecting" nature of the MOSFETs themselves.

This is not to suggest that the amp is indestructible (no amplifier can make that claim successfully), but it is much more tolerant of faults than a bipolar transistor amp, and requires nothing more than a pair of zener diodes to limit the current. Having said that, I would still recommend that you avoid shorted output leads and the like - i.e. Don't push your luck ;-)

One thing that has emerged that is absolutely critical is the PCB layout. The layout of this new amplifier is similar to that used for the P68 Subwoofer amplifier, and this has some major benefits. P68 has no right to sound as good as it does, and although designed for subwoofer use, it has proven during listening and testing to be a very low distortion design - despite the Class-B output stages. All PCB tracks in the input and driver section are as short as possible, minimising the chance of noise pickup from other sections of the circuit.

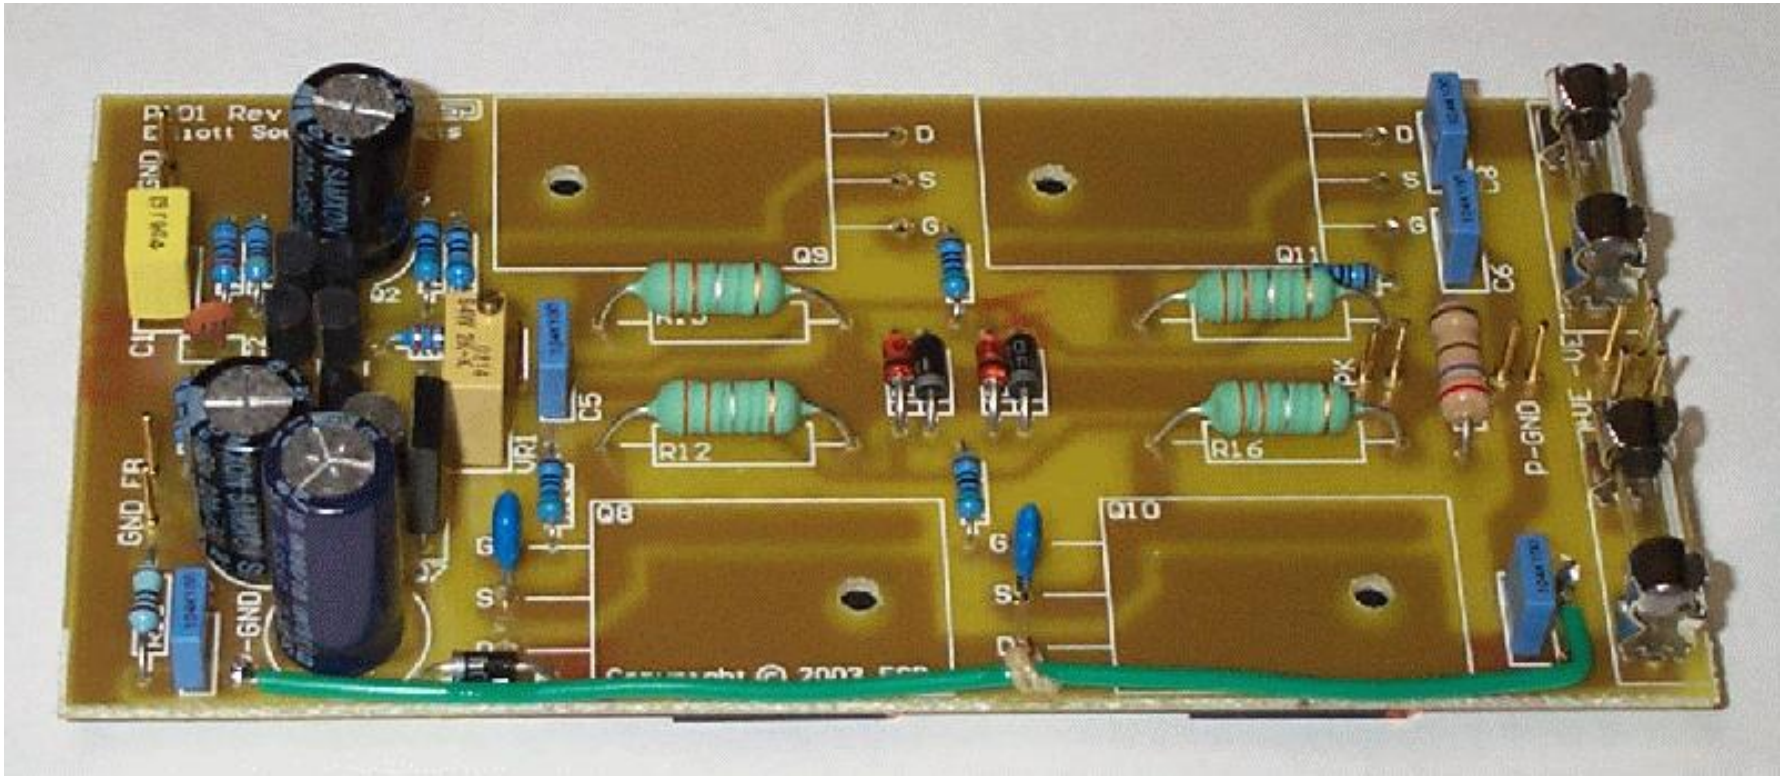
This new amplifier is designed to be as flexible as possible, with no bad habits. Indeed, it will operate stably with supply voltages as low as +/-5V (completely pointless, but interesting), all the way to the maximum supply voltage of +/-70V. The only change that is needed is to trim the MOSFET bias pot!

With the full supply voltage of +/-70V (which must not be exceeded!), RMS power is around 180W into 8 ohms, or 250W into 4ohms.

Short term (or "music") power is typically about 240W into 8 ohms and 380W into 4 ohms. Note that depends to a very great degree on the power supply, and a very robust supply is an absolute requirement for the maximum output.

Since this amp probably has more power than you will normally ever need, even if you do skimp a little on the transformer, the loss will be very small.

It is worth noting that a MOSFET amp will always produce less power than a bipolar transistor version using the same supply voltage. Even using an auxiliary supply will make only a small difference (one reason I elected not to add the extra complexity). A bipolar design using a ±70V supply can be expected to produce something in the order of 270W into 8 ohms, and well over 500W into 4 ohms. The specified MOSFETs have a rated Vds (saturated voltage, Drain to Source) of 12V at full current, and that is simply subtracted from the DC value of the supply voltage. Using the same ±70V supply with a MOSFET amp will give less power than quoted above (see below for measured figures).



Photograph of Completed Amplifier Board

The photo shows the simplicity of the PCB. The MOSFETs are mounted below the board, and are bolted down in the same way as with the P3A and P68 boards. No other mounting is needed. PCB pins are used as anchor points for the power ground link (the green wire along the front edge), so that the main current carrying tracks were not compromised by running a separate track (which would have required a reduction in size of the positive supply rail).

The entire front-end section is between the electrolytic caps, and is deliberately as compact as possible. This improves performance, by ensuring that there are no long tracks for the input stage, which will pick up noise and can seriously degrade the sound of the amplifier.

Performance Figures

The performance of this amp is such that many measurements are very difficult. Some of the more basic measurements are as shown below, based on my custom made transformers which provide ±65V unloaded ...

Parameter	Measurement	Conditions
Output Power	> 180W	< 1% THD, 8Ω
	> 275W	< 1% THD, 4Ω
DC Offset	< 20mV	Typical
Noise	< 2mV RMS	Unweighted (-54dBV)
THD	0.015%	No load, 30V RMS output, 1kHz
	0.017%	8 Ohms, 30V RMS output, 1kHz
	0.02%	4 Ohms, 30V RMS output, 1kHz
Output Impedance	< 10 mΩ	1kHz, 4Ω load
	< 25 mΩ	10kHz, 4Ω load
Frequency Response	10Hz to 50kHz	At 1W, -1.5dB

Basic Performance Figures

In particular, the distortion figures show that amp loading causes only very small variations, with any harmonics being predominantly from my audio oscillator. There are no visible or audible high order components to the distortion waveform. Output impedance was measured on a fully built amplifier, including the internal wiring. This entails around 200mm of wire in all (per channel), so the output impedance of the amplifier itself is obviously lower than quoted. For an 8 ohm load, the damping factor at 1kHz is around 800 (8 / 10 milliohms) - completely pointless of course, since any speaker lead will ruin that very quickly.

Noise was measured with inputs open-circuited, and at -54dBV may not look too wonderful, however this figure is very pessimistic. Remember that this is the unweighted measurement, with bandwidth extending to well in excess of 100kHz. Even so, signal to noise ratio (referred to full power) is 86dB unweighted, and the amp is completely silent into typical speakers. Indeed, even connecting a pair of headphones directly to the amp outputs revealed that no noise was audible. Naturally, your methods of construction will differ from mine, and you may not be able to get the same performance.

Intermodulation distortion cannot be measured with the equipment I have available, but I have included a screen capture of the three measurements I took. Most of the harmonic content visible (not that there is a great deal anyway) is present in the two generators I used, and the amplifier contributes virtually nothing.

Description

The very first thing you will notice is that I have broken with tradition with this amp, and there are no component values shown. Given the performance of the circuit, and the fact that I have already sold a couple as completed, finished amplifiers, I am not about to give away all my secrets for the design. If you want the component values, you must purchase the PCB. There are *no* exceptions, so don't ask.

The schematic of the amp is shown in Fig. 1, and it is about as simple as a high power MOSFET amplifier can get - it is considerably simpler than most, but lacks nothing in performance. The circuit diagram belies the ability of the amplifier though, so do not be tempted to think that it cannot perform as well as more complex designs - it does, and exceeds the performance of many (if not most) of them. It will be seen that I elected to use a bootstrap current source rather than an active version - there is negligible cost difference, but I was unwilling to make such a radical change after testing the prototype and being so impressed with the results. (If it ain't broke, don't fix it!)

The front end is a conventional long-tailed pair (LTP) using a current mirror load and an active current sink in the "tail". Interestingly, adding the current mirror made no difference to distortion, but reduced the DC offset to less than 25mV. The improvement was such that I elected to retain the mirror.

In tests thus far (both measurement and listening), I have been unable to detect even a hint of what is commonly referred to as the "MOSFET sound". The relatively high levels of low order distortion and suceptibility to crossover (or "notch" distortion that plague most MOSFET designs are completely missing - indeed, even with *zero* bias on the MOSFETs, crossover distortion below 10kHz is barely measurable, let alone audible!

Note Carefully:
The most critical aspect of the design is the PCB layout, and it is very doubtful that if you make your own board, that you will get performance even approaching mine. Power output is essentially unchanged, but distortion and stability are achieved by a compact and carefully designed layout for the front end and driver circuits, which minimises any adverse PCB track coupling that causes much higher distortion levels, and may cause oscillation.

This is not a ploy on my part to get people to purchase my PCBs - that has already been taken care of by leaving out the component values. The simple fact is that unless the PCB layout is done with the utmost care, any amplifier can be made to have far greater distortion levels and reduced stability margins than the published figures suggest.

Low Power Version
As shown in the schematics below (figures 1 and 2), the amplifier can be made in high or low power version, and although there is a bit of vacant PCB real estate in the low power design, it is significantly cheaper to make and will be more than sufficient for most constructors. If this version is built (using only 1 pair of MOSFETs), it is essential to limit the supply voltage to +/-56V so that it can drive both 4 and 8 ohm loads without excess dissipation. With this voltage, expect about 100W continuous into 8 ohms, and around 150W into 4 ohms. Naturally, dual MOSFET pairs may be used at this voltage as well, providing much better thermal performance (and therefore cooler operation), far greater peak current capability and slightly higher power. This version may be used at any voltage from +/-25V to +/-56V.

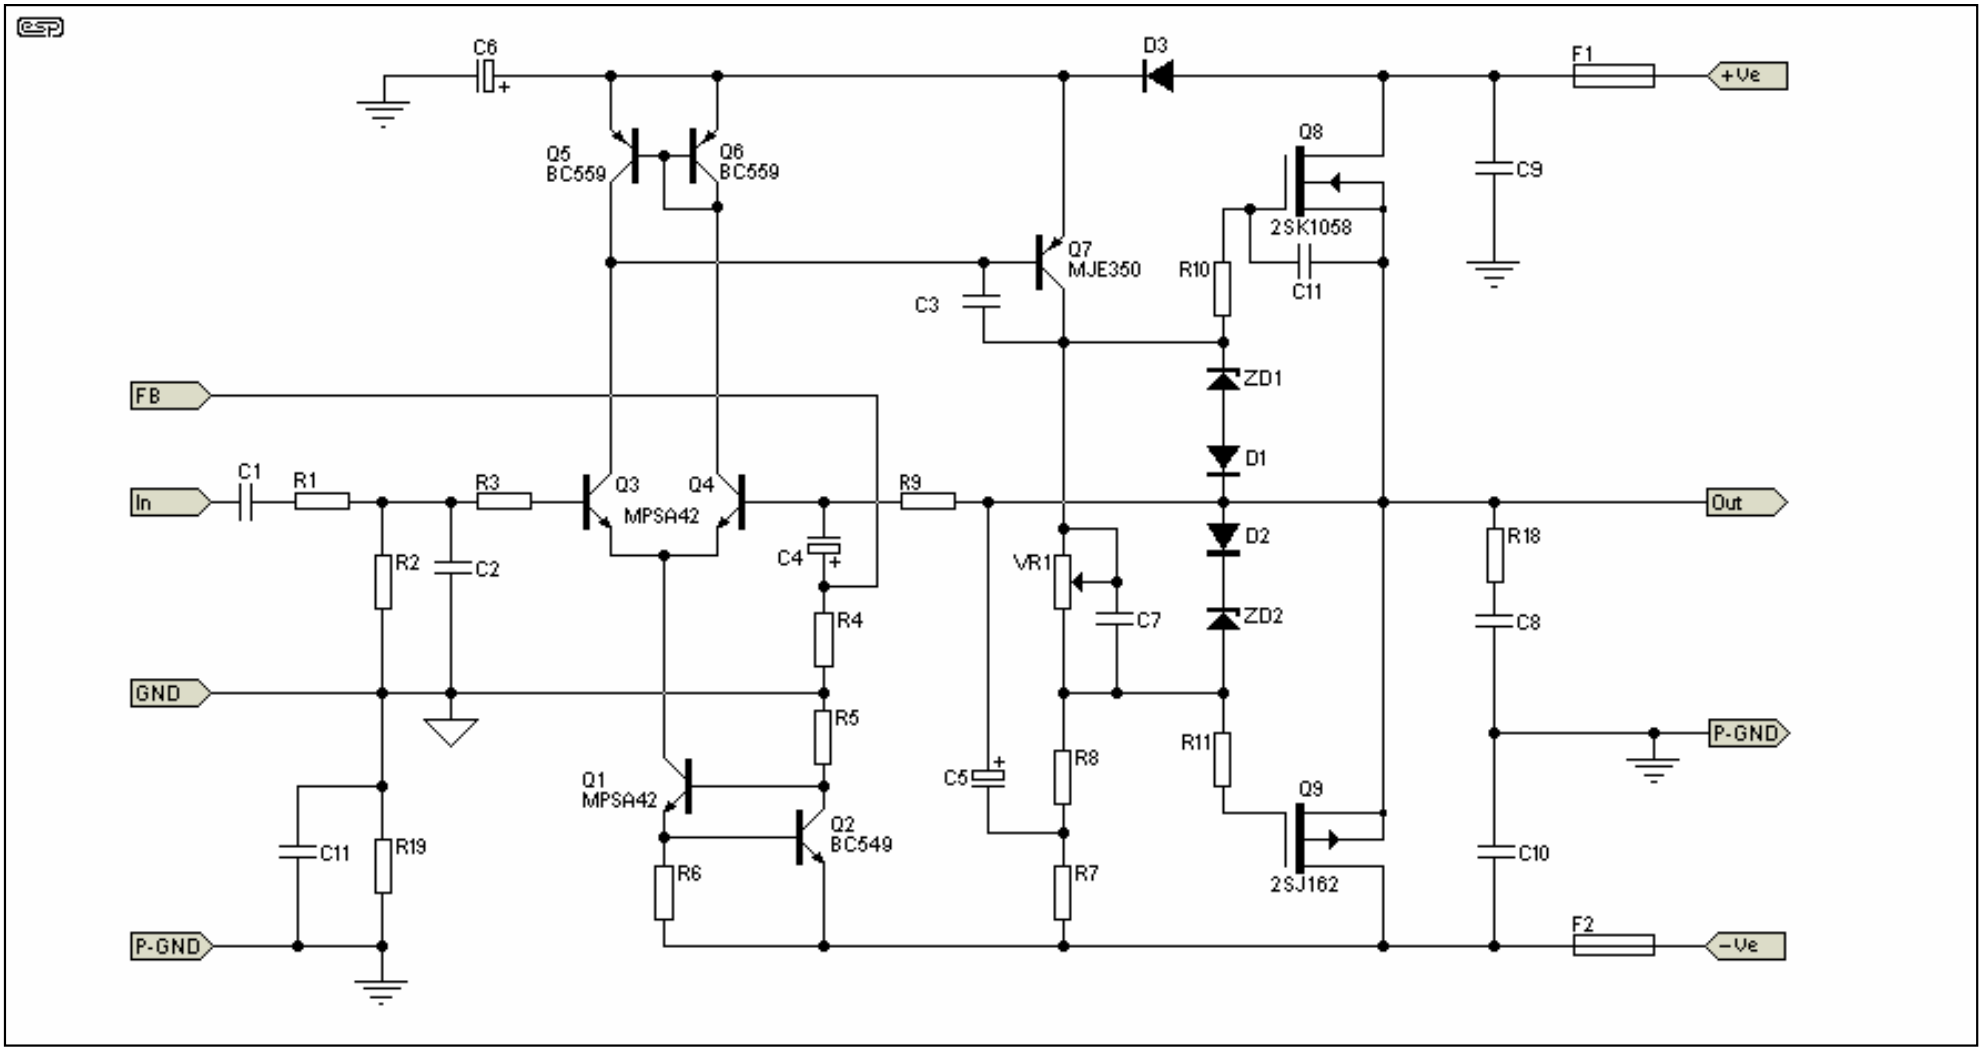

Figure 1 - Standard (Low Power) Version

The MOSFETs used are Hitachi lateral devices, 2SK1058 (N-Channel) and 2SJ162 (P-Channel). These are designed specifically for audio, and are far more linear than the (currently) more common switching devices that many MOSFET amps use. Unfortunately, they are not especially cheap, but their performance in an audio circuit is so much better than vertical MOSFETs, HEXFETs, etc., that there is no comparison. Note that using HEXFETs or any other vertical MOSFET type is not an option. They will fail in this circuit, as it was not designed to use them.

An alternative (and possibly marginally better than the 2S series) is the Exicon ECX10N16 and ECX10P16 (available from Profusion PLC in the UK). These have been used in most of the amps I have built, and they work very well. So potential constructors can verify that the semiconductors are available before purchasing a PCB, this information has now been included. All other parts are quite standard.

High Power Version

The same PCB is used, but has an extra pair of MOSFETs. Since the devices are running in parallel, source resistors are used to force current sharing. Although these may be replaced by wire links, I do not recommend this. This version may be operated at a maximum supply voltage of +/-70V, and will give up to 180W RMS into 8 ohms, and 250W into 4 ohms. Short term (peak) power is around 240W into 8 ohms and 380W into 4 ohms. These figures are very much dependent on your power supply regulation, determined by the VA rating of the transformer, size of filter caps, etc.

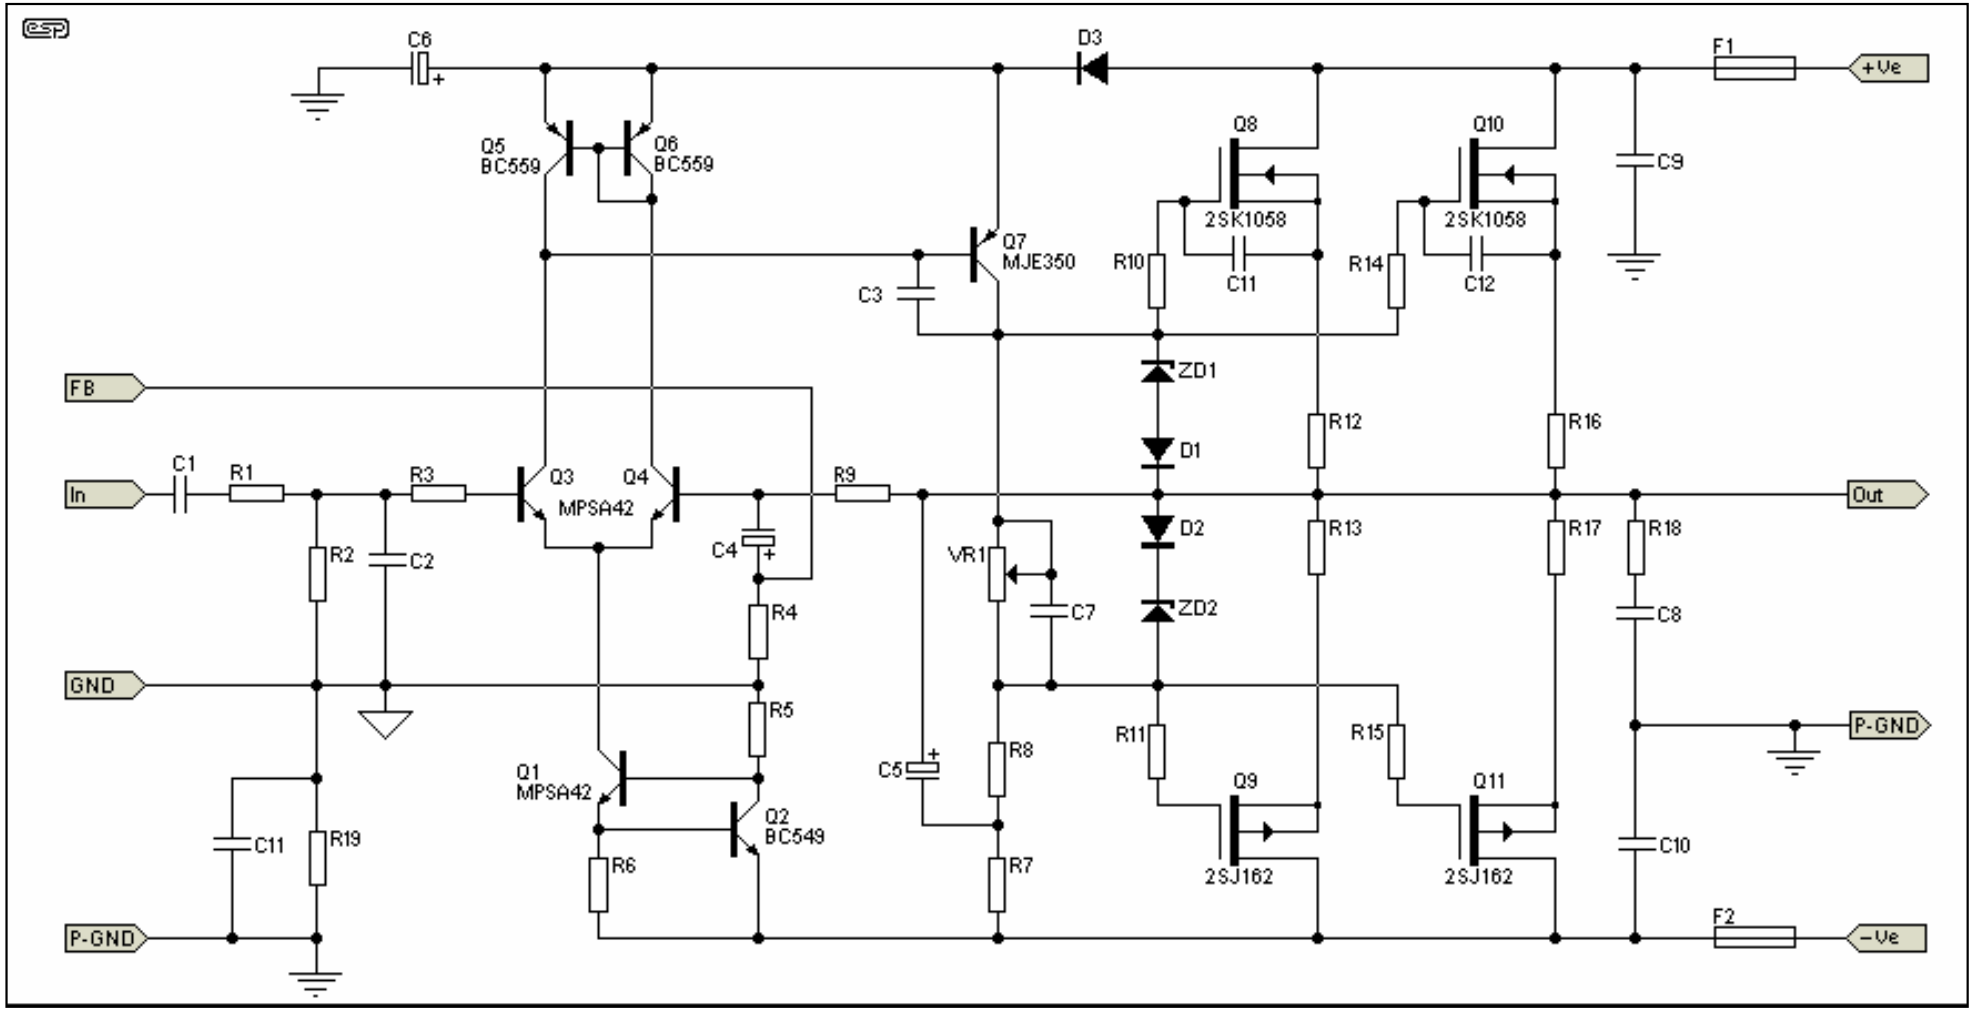

Figure 2 - High Power Version

Although not shown, the transistors and MOSFETs are the same in this version as for the low power variant.

As noted above, the PCB is the same for both versions, but for Fig. 2 it is fully populated with 2 pairs of power MOSFETs. The high

power version may also be used at lower supply voltages, with a slight increase in power, but considerably lower operating temperatures even at maximum output, and potentially greater reliability.

With both versions, the constructors' page gives additional information, and the schematics there include an enhanced zobel network at the output for greater stability even with the most difficult load. This is provided for on the PCB, and allows the amp to remain stable under almost any conditions.

The entire circuit has been optimised for minimum current in the Class-A driver, while still providing sufficient drive to ensure full power capability up to 25kHz. The slew rate is double that required for full power at 20kHz, at 15V/us, and while it is quite easy to increase it further, this amp already outperforms a great many other amps in this respect, and faster operation is neither required nor desirable.

> **Note** - There are actually two caps marked C5, and two marked C6. This is what is on the PCB overlay, and naturally was not found until it was too late. Since these caps cannot be mixed up, it will not cause a problem.

In both versions of the amp, R7 and R8 are selected to provide 5mA current through the voltage amplifier stage. You will need to change the value to use a different supply voltage ...

R7 = R8 = Vs / 10 (k) (Where Vs is one supply voltage only)

For example, to set the correct current for ±42V supplies ...

R7 = R8 = 42 / 10 = 4.2k (use the next *lower*standard value - 3.9k)

Construction

As suggested above, I strongly recommend that you purchase the PCB for this amplifier, or you will almost certainly get results that are nowhere near the amp's real ability. The PCB also makes construction a breeze, with everything except the power supply mounted on the board itself. Like many other ESP power amps, the MOSFETs are mounted underneath the board, requriing only two (or four) screws to attach the PCB and output devices. As always, full construction details will be available in the ESP secure site when you purchase the board(s).

The suggested power supply is completely conventional. Although a small amount of additional power can be obtained by using an auxiliary supply (to boost the rail voltage for the MOSFET drive stage), this is at the expense of greater complexity and more things to go wrong. The transformer for the supply should be matched to the expected power you wish to obtain from the amp. The following table shows the recommended transformer voltage and VA rating for a single channel - either use two transformers or a single unit with twice the VA rating shown for stereo.

AC Volts	DC Volts	VA	Power (8 ohms)
20-0-20	+/-28V	100	40
25-0-25	+/-35V	100	50
30-0-30	+/-42	160	80
40-0-40	+/-56V	200	150
50-0-50	+/-70V	300	240

Note that all powers shown are "short term" or peak - continuous power will always be less as the supply collapses under load. Peak power levels are usually achieved (or approached) with most music because its transients are generally between 6dB and 10dB greater than the average power output. Transformer VA ratings shown are a guide only - larger or smaller units may be used, with a marginal increase or reduction of peak power. Always use at least the size shown for subwoofer use!

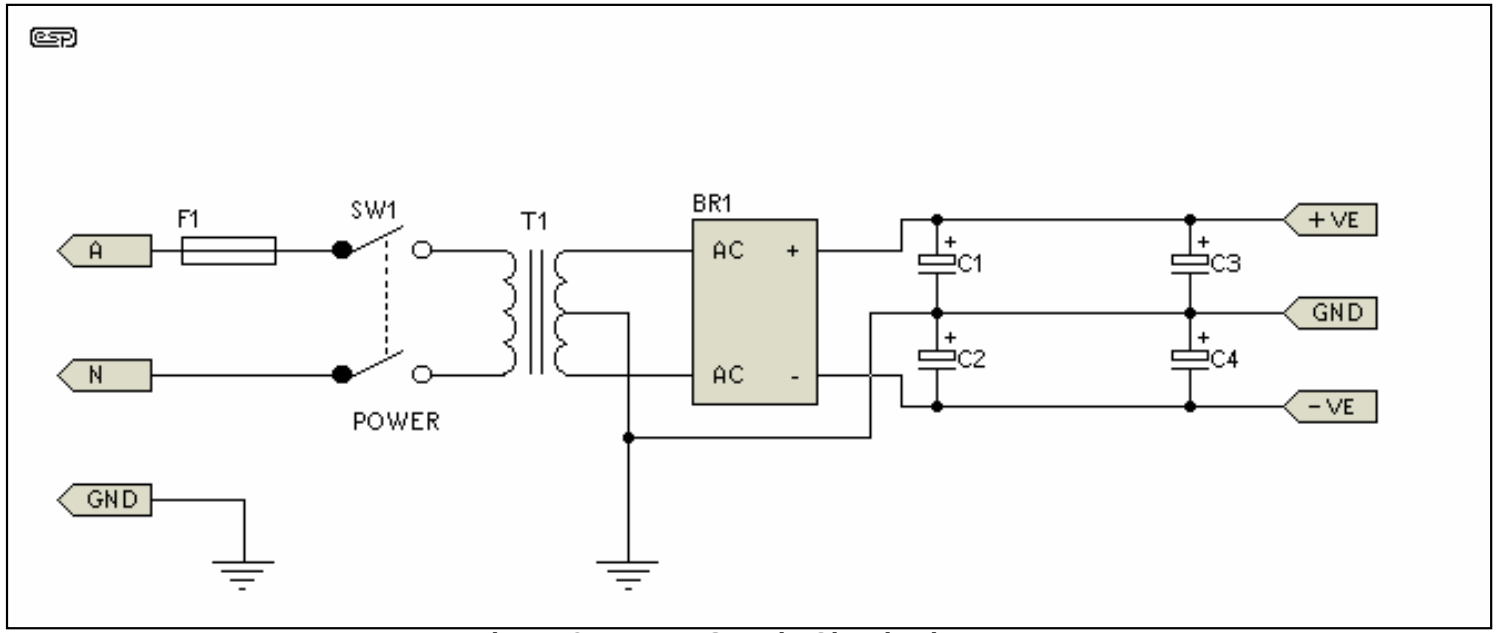

Figure 3 - Power Supply Circuit Diagram

Figure 3 shows the power supply circuit diagram for a ±56V supply, and there is nothing new about it. As I always recommend, the bridge rectifier should be a 400V/35A chassis mount type, and should be properly chassis mounted using heatsink compound.

Filter capacitors *must* be rated to at least the nominal supply voltage, and preferably higher. If possible, use 105°C rated caps, and join the earthed terminals very solidly to form the star earthing point.

Note - The fuse should be selected according to the size of the power transformer. For any toroidal transformer over 300VA, a soft start circuit is highly recommended. Use the transformer manufacturer's suggested fuse - if this information is not available, ask the supplier - *not me!*

The DC supply must be taken from the capacitor terminals - never from the bridge rectifier. Using several small capacitors will give better performance than a single large one, and is usually cheaper as well. For example, the performance of 10 x 1,000uF capacitors is a great deal better (in all respects) than a single 10,000uF cap, at between 50% to 70% of the cost of the large unit. This lunch is not free, but it is heavily discounted ;-)

When you purchase the PCB, you will not only get all component values, but will also have access to information for a power supply that is optimised for the best possible performance for a conventional supply. There is nothing especially innovative about the "advanced" supply schematic, but the overall results will surprise you.

Testing

Connect to a suitable power supply - remember that the supply earth (ground) must be connected! When powering up for the first time, use 10 ohm to 22 ohm "safety" resisors in series with each supply to limit the current if you have made a mistake in the wiring.

Death of Zen (DoZ) - A New Class-A Power Amp

Rod Elliott (ESP)
Updated 03 October 2005

Revision-A PCBs are available for this project. Click the image for details.

Project 70 is based on this design, but specifically for headphones. This is where you can really get the benefits of Class-A with none of the drawbacks.

Because the quiescent current can be quite unstable with variations in the supply voltage. Normal changes in the AC mains can cause Iq to shift above and below the preset value. A simple modification can be added that virtually eliminates the problem (or reduces it to the point where it is immaterial). This, plus another optional modification to help stabilise the bias current are included on the new Revision-A circuit board.

Introduction

The Zen - along with Zen improved, son of Zen, Bride of Zen, Second cousin of Zen (or did I imagine that one?) Class-A amp designed by Nelson Pass seems to have become popular. (See references.) I cannot imagine why, since the very concept is flawed in many ways. It has minimal feedback, but that is because it has minimal gain to start with, and appears very simple. Perhaps this is the attraction - but at what price? The capacitors needed for the power supply are massive to try to get rid of hum, and massive means expensive. The "improved" Zen is a little better, since it uses an inductor (or choke) in the supply - obviously the hum drove someone mad. Inductors are expensive too, and also hard to get, and the capacitance has been doubled in at least one version I have seen - ouch, this is seriously expensive!

Well, actually I can see why it is popular. It satisfies the requirement of many amplifier builders, in that it is simple, stable, and very tolerant of layout and component variations. The sonic characteristics will also appeal to many, due to the valve-like sound (or tube-like, if you prefer). Having looked at the original and many of the "improvements" currently on the web, I did a few tests of my own and frankly, found the amp lacking in the fidelity department. Hi-Fi this most certainly is *not*. But .... does it sound good? Apparently so, based on the number of people using (and praising) the Zen, but the feedback I have had on the DoZ so far (and my tests) is also very positive and encouraging. At the time of writing,

hundreds of DoZ amplifiers have been made, with comparatively few reported problems. The issues that have been encountered have been addressed in the Revision-A circuit boards which are now shipping.

Nelson Pass quotes Einstein as saying "Everything should be as simple as possible, but no simpler". I agree with this entirely, and quickly realised that the Zen is simpler than it should be for its intended purpose.

Therefore, I have done some serious work on "Death of Zen", a new Class-A power amplifier that will blow the Zen and all its kin into the weeds, without busting the budget or sacrificing sound quality. Minimal global feedback and lots of local feedback to ensure a very fast and linear amplifier, using the smallest number of components possible. This is the goal, and the remainder of this section explains why.

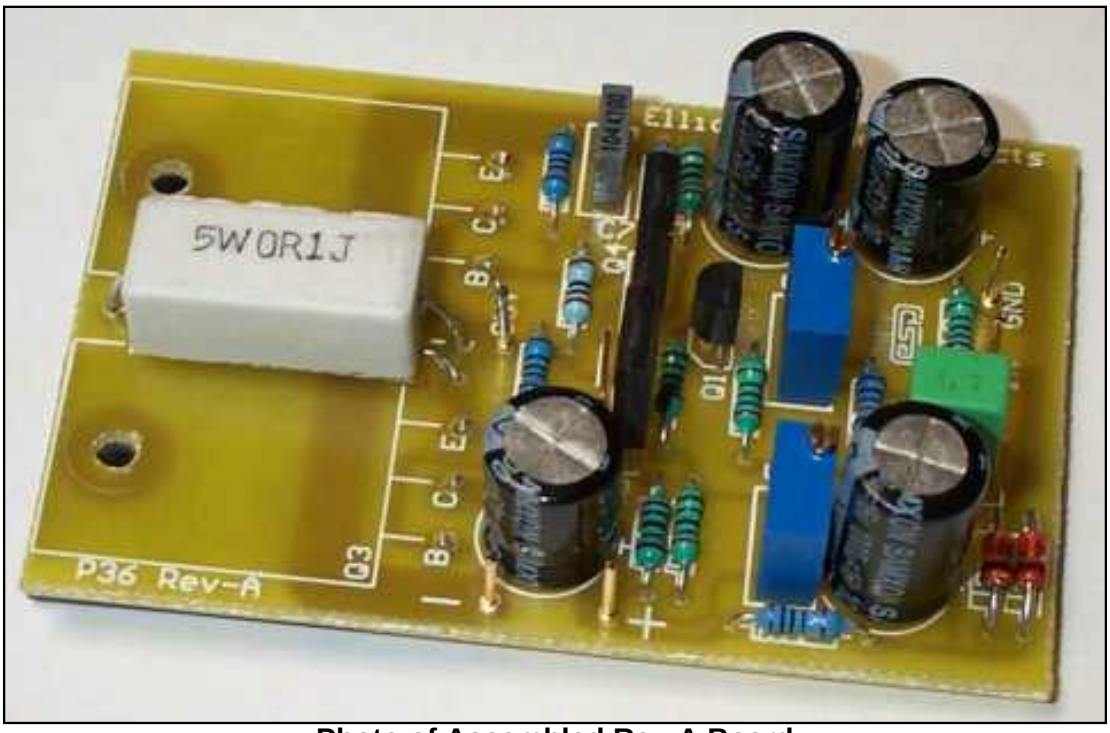

Photo of Assembled Rev-A Board

Lets look at the basic Zen concept, as shown in Figure 1. A power MOSFET is biased using a pot (needed to correct for different device characteristics) so that the voltage at the drain is about 1/2 the supply voltage. Current is limited using a constant current source, and this needs to be set to provide a current that is higher than the maximum peak current to the speaker. Since the amp is not DC coupled, an output capacitor is needed to keep the DC out of the loudspeakers. An input cap is also needed to stop the source (the preamp, or for my tests, an audio oscillator) from stealing the bias voltage.

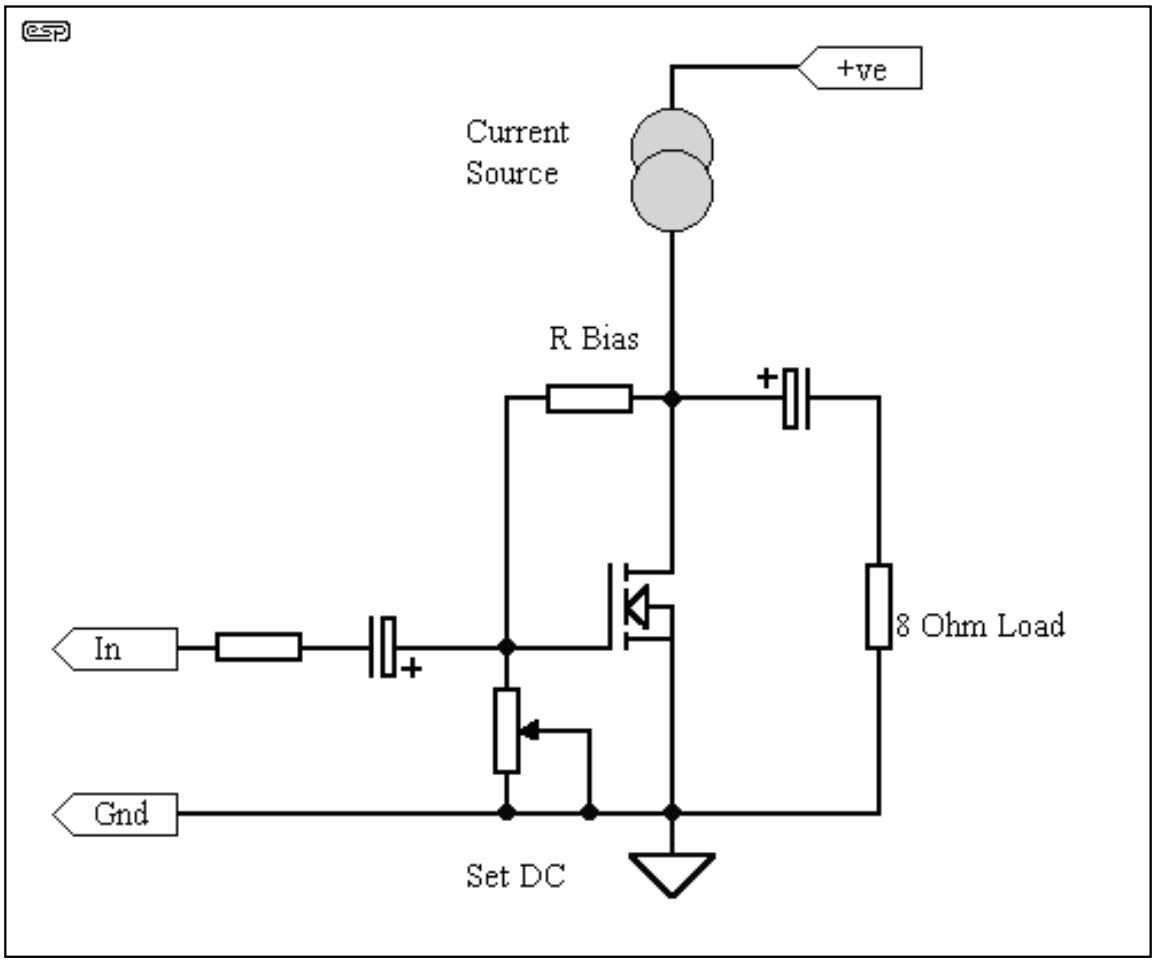

Figure 1 - Basic Zen Concept

Now at first sight the idea looks sound (pardon the pun). We do need to do some basic maths to determine the current needed, but this is easy. Using a 35V supply, the bias point will need to be about 1/2 supply (17.5V), and this means that for ideal devices the peak speaker current is +/-17.5 / 8 = 2.19A (say 2.2A). It is necessary to add a little more current to ensure that the active device current remains high enough to stay within the linear region, so lets say 2.5A

In theory, the +/- 17.5V should allow a peak power of 19W, but this is not possible due to the losses in the devices. As a result, the amp is rated at 10W, and this is reasonable. The output resistance (at DC - this is not the same as impedance) of this output stage is easily determined from Ohm's Law, so R = V / I = 17.5 / 2.5 = 7 Ohms. Although this is the resistance, the impedance will actually be fairly similar (generally lower though [small correction added - oops]). According to some, this is the first fault of the design, since damping factor will be at best 1.14 - this is a little shy of the 100 or more that most audiophiles strive for, but more on this later. With the addition of feedback (and yes, the Zen uses some feedback), the output impedance is quoted as about 1 Ohm.

Most readers of my pages will know by now that I am not a fan of MOSFETs, since they are far less linear than bipolar transistors. To me, this is the first failing, since I fully expected the distortion to be somewhat higher than I would consider acceptable for a ghetto blaster, let alone a hi-fi system.

The Big Test

I proceeded to set up a test, using a suitable MOSFET and comparing it with a transistor in the same circuit configuration. The test setup is shown in Figure 2, and I was able to directly substitute the transistor and MOSFET into the circuit, adjust the bias and run the test. Since I wanted to see distortion components alone, I simply used an 8 Ohm drain / collector load, as this is approximately equivalent to the circuit operating with a current source load and driving a speaker. I kept the operating level lower than normal to ensure that a suitable current reserve remained.

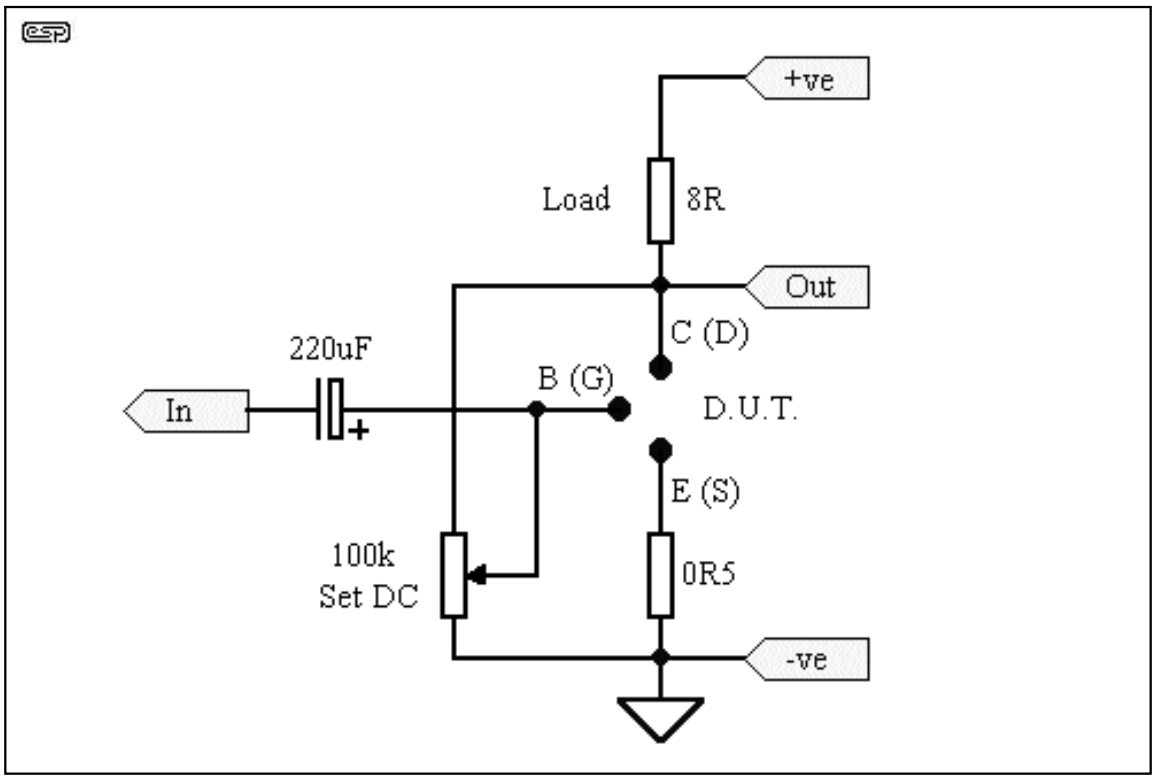

Figure 2 - The Test Setup

In the above, the D.U.T. is the device under test. Emitter, base and collector (or source, gate and drain) are connected as shown. For the power supply, I used my "monster" supply, which is variable only because I use a Variac (variable voltage transformer) to supply the incoming mains. I used a 22,000uF capacitor for added filtering (it was not enough!), and proceeded to take some measurements.

First step was to set the quiescent voltage with the pot, so I had 1/2 the supply voltage at the drain (I tested the MOSFET circuit first). With an applied DC of 30V, this meant a voltage of 15V, so the current was 1.875A or 28W dissipation (both in transistor and load - for a a total of 56W). The hum was higher than I would have liked, but I can make this disappear using the averaging capability on the digital oscilloscope.

Applying a 1kHz sine wave, I could see that the distortion was quite visible at close to clipping, and I was able to operate at a maximum of 6V RMS output before the distortion became too noticeable. I then hooked up my trusty distortion meter to see just how much there was. Remember from the test circuit that I have included a 0.5 Ohm resistor in the source to help linearise the circuit - not to too much avail it seems, since the distortion was measured at 1.58% (after hum removal), and it increased very rapidly if I increased the voltage. Hmmm. This verified my suspicions, but now I needed to test a bipolar transistor in exactly the same test setup to compare the two.

I used a darlington transistor (I dislike these too, but it was convenient and the extra gain is essential with bipolars), and was able to bias the transistor using the same circuit as before. Again, I applied a signal, and was not at all surprised to see that the maximum voltage before distortion was visible on the oscilloscope was considerably greater, and the output generally looked cleaner right up to the point of clipping. I would expect that a discrete complementary pair (the configuration I always use) will be better, but I was rushing to get this into print, so used the most convenient device to hand. At least this means that I can improve on these figures without too much trouble.

To be completely fair, I tested the distortion at 6V RMS again, and measured 1.03% - a worthwhile improvement I thought. Increasing the output to 8V, the distortion climbed to 1.18% - still less than the MOSFET, and with a much improved voltage swing. At this level, the MOSFET was delivering outrageous amounts of distortion, as it started to clip.

The measured distortions are not entirely fair, because of the distortion waveform. With the MOSFET, the distortion waveform was peaky, with quite sharp transitions (indicating high order harmonics). The RMS value is probably too low, and certainly does not indicate accurately the audible effect of the distortion. By comparison, the bipolar transistor had a very smooth and almost perfect 2nd harmonic, with very little evidence of any high order harmonics at all. Asymmetry in the residual distortion waveform showed that there was also 3rd harmonic distortion, but at a lower level - I think I will have to have a listen to the residual signal to determine the "musicality" or otherwise of the distortion I measured.

29 Oct - Further Tests

The following day, I decided to buy a MOSFET rather than use the one I had, and selected a MTP3055 as a budget device designed for audio and switching. I still don't know exactly what the other one is supposed to be for, but it shouldn't matter - bipolar transistors can be selected for linearity, but it isn't that big a deal. Not so with MOSFETs as I discovered - the new one was markedly better than the original, but still fails to touch the bipolar. Incidentally, the darlington bipolar I used was a TIP141, and is designed for switching (lest I be accused of fiddling my results by device selection). I did not retest the 60N06 at the lowest level, but given the other results I could see no point.

Since I now have 3 separate test results, I have tabulated them below.

Output Voltage (RMS)	TIP141 Darlington	MTP3055E MOSFET	60N06 MOSFET
2.5	0.05% (approx)	0.47%	N/T
6.0	1.03%	1.02 %	1.58%
8.0	1.18%	1.80%	> 2%

Table 1 - Device Comparisons In The Test Circuit

It would be useful to carry out these tests with a completely hum free supply so that the distortion is not affected by the supply ripple, but by averaging the measured result with the oscilloscope I believe the results are accurate enough for comparison, especially since the same configuration was used for all tests.

Quite obviously, the bipolar is a winner at low levels (where the distortion is most noticeable), and I am sure that using a nice linear transistor such as the complementary pair, these results would show the superiority of the bipolar transistor even more clearly. Again, as the supply limits are approached and the current through the devices varies the most, the bipolar is again well ahead.

UPDATE: The MTP3055 distortion figures actually are very close to those published by Pass Laboratories for the Zen, so this validates the test circuit I used, and that the figures are not exaggerated in any way. (27 Nov 99)

Full Test Of Death Of Zen (DoZ) Concept

The next step was to test something close to the final configuration, to see what things had an effect (profound or otherwise) on the performance. I still used the TIP141, knowing that I can improve on this greatly as I progress, although as the final circuit shows I eventually chose not to use a compound pair after all. Figure 3 shows the test circuit, still using the 8 Ohm resistor as a load, but I ran these tests using my bench supply to eliminate the hum problems. All tests were performed at an output of 6V RMS (equivalent to the 8V tests above, due to the lower supply voltage).

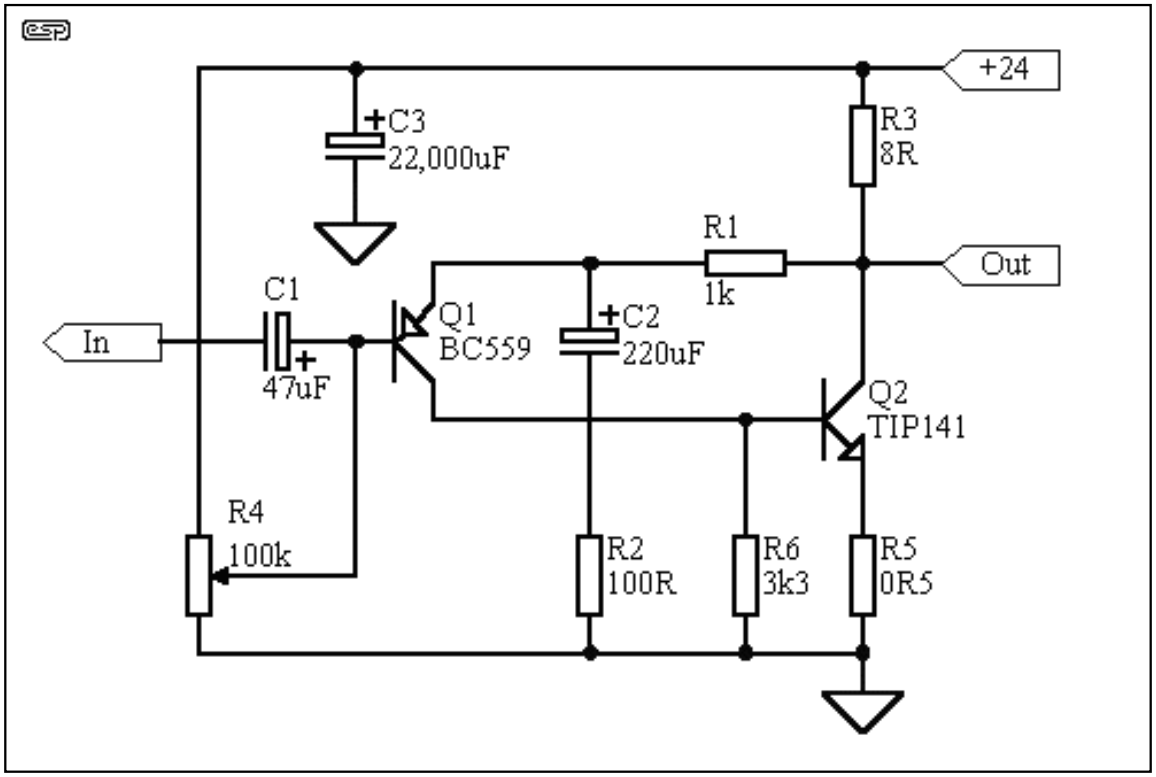

Figure 3 - DoZ Test Circuit

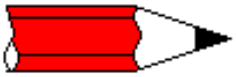
This is the basic configuration I will be using for the final design, although there will be some resistor value changes as I get closer to the final circuit, and the load resistor will be replaced by a constant current source. For those who want to try the circuit with a high output impedance, I will also include the modified feedback network.



STOP ! - Do not build this circuit as a real amplifier. This is a test circuit, designed to verify some basic parameters of the design. The final design is shown in Figure 4.

Some interesting things came to light during testing, especially when I included the resistor (R6) from base to earth on Q2. With no resistor, I measured a distortion of 0.15%, and this was almost completely 2nd harmonic. There was a very noticeable degradation of the positive going slope on a 10kHz square wave, and a fairly low slew rate resulted. Adding the resistor improved this dramatically, and reduced the distortion to 0.05% - but it was now almost completely 3rd harmonic.

This will create a conundrum for some - would you rather have very low levels of 3rd harmonic distortion, or considerably larger amounts of 2nd harmonics (bearing in mind that the 3rd harmonics are still there). I cannot see any good reason to tolerate any more distortion than is absolutely necessary, so considering the much better slew rate (and therefore high frequency performance), I will be including this in the final design. You might want to leave it out if you want the 2nd harmonics, but I don't think the end result will be very satisfactory.

This is due to the transistor's turn-on and turn-off characteristics becoming more symmetrical by providing a base discharge path, but I did not expect such a large difference. The frequency response extends to over 100kHz at full power (6V RMS for these tests), and square wave response shows that the amp is both fast and stable - and this with a very ordinary switching darlington. I saw no evidence of measurable distortion above the 3rd - there must be some, but I have no way of measuring it. The 3rd harmonic appears to be an almost perfect sine wave, with some very small variations.

Slew rate is better than 6V/us (positive going) and over 20V/us negative going - not as good as some, but I blame the TIP141 for this. I have checked the specs on it, and it is a fairly slow device (like most darlingtons) as confirmed by these tests.

None of this testing has been done with a circuit board. In all cases I simply bolted the device to a heatsink, and attached the other components as required. Power connections were all made using alligator clip leads. Since I have used exactly the same "rats-nest" wiring for all testing (including these last tests), and I have not been able to induce additional (or reduced) distortion by moving leads about, the amp looks as if it will be fairly tolerant of assembly methods (all known assembly methods will be superior to what I have done so far).

More Testing

So, there I was on Saturday (27 Nov), thinking suddenly - "I wonder how the amp would work with a MOSFET instead of the transistor?" Off to the workshop and I tried it. The answer is ... horrible. Apart from the greatly reduced voltage swing because of the topology, the distortion at 1V (125mW into 8 Ohms) was about 0.4%, and I was mightily disappointed.

You see, I really would like to use a MOSFET in an amp that I would like listening to, because the idea appeals to me. They are fast, need minimal drive current, and the overall concept is wonderful. But they still don't sound any good - what a shame.

Thus chastened, I thought I would just have a quick muck about with the current source (having re-installed the bipolar transistor) and listen to it on a speaker. Even with the slow TIP141 transistors (I used one for the current source too), the rats-nest wiring I was using instantly caused me problems (clip leads all over the place, and components supported by sky-hooks and each other).

The issues were easily sorted out (re-arrange the clip leads :-), and I ran some distortion tests with and without a load. Distortion was almost exactly the same as previous testing, and I was finally able to measure the actual output impedance, which measured at 0.22 Ohms. Not too shabby for such a simple amp.

As for the sound, well I must admit that it sounded just like an amplifier. I couldn't hear any nastiness, and even with the limited power it was quite loud enough. The main problem I have now is that I don't have any conventional hi-fi speakers (mine are biamped), so was forced to listen on one of my lab speakers. Even there I am limited, since the main lab system is tri-amped. SInce the unit is hardly portable in its test condition, I will have to rely mainly on the distortion meter and my oscilloscope until I have a complete unit built.

One thing I have realised in all of this testing, is that a Class-A amp is a far more irksome thing to design and test than a Class-AB amp. This is partly because of the high current that is always present (and the fact that massive heatsinks are needed just to do simple testing), and partly because in this design I am trying to achieve maximum performance from minimum components - this has turned out to be more difficult than expected, and some of the simplest changes can make a great difference to the performance.

I am now leaning more and more towards the concept suggested by John Linsley Hood [3], where the bias current is modulated to provide Class-A but with less quiescent dissipation. You would be surprised how hot a pair of 1 ° C/W heatsinks get with a quiescent current of 2.5A and a supply of 40V. Mind you, I did manage to get 18W into 8 Ohms at the onset of clipping, but with the sinks just lying on the bench I had to be careful that the whole amp didn't destroy itself. For further tests, I had to build it properly - what a pain!

---

12 December Tests

So, pretty much having made up my mind on the topology, I set about building the amp. I must say that the final result lived up to nearly all expectations, and works extremely well. One word of warning - I used TO-3 case transistors, and I strongly suggest that you do the same. No plastic case device has good enough case to heatsink thermal resistance, and with a final dissipation of 28W per device, even the TO-3s get hot.

For ease of working (and so it would stabilise quickly) I only used a small heatsink, and ran a 12V fan at 6V to keep it cool. At 1/2 voltage, the fan was very quiet, so you might want to consider this as a possibility for Class-A amps in general.

The final circuit (at least for the time being) for the DoZ is shown in Figure 4, and it can be seen that it is a bit different from the last attempt. This being the full and proper circuit, it is fully functional, and I have tabulated test results below.

After all the experiments I carried out before, it turns out that the current source is more critical than I would have hoped. Although this is a simple circuit, it is supposed to supply a constant current at any frequency, and this is harder than you might imagine. R7 and R8 were added in an attempt to speed up the current source, and were only partially successful. As it stands, the amp will provide full power up to about 16kHz, which is actually more than enough for any application.

For final testing you will need two multimeters, one to measure current and the other for voltage. If you only have one, use a 1 Ohm resistor in series with the power supply positive lead. When you measure 1 Volt, this means that the amp is drawing 1 Amp. The resistor can remain in circuit, providing a useful reduction in supply ripple. You will lose 1.7V at operating current, and a 5W resistor is sufficient - it will get hot though.

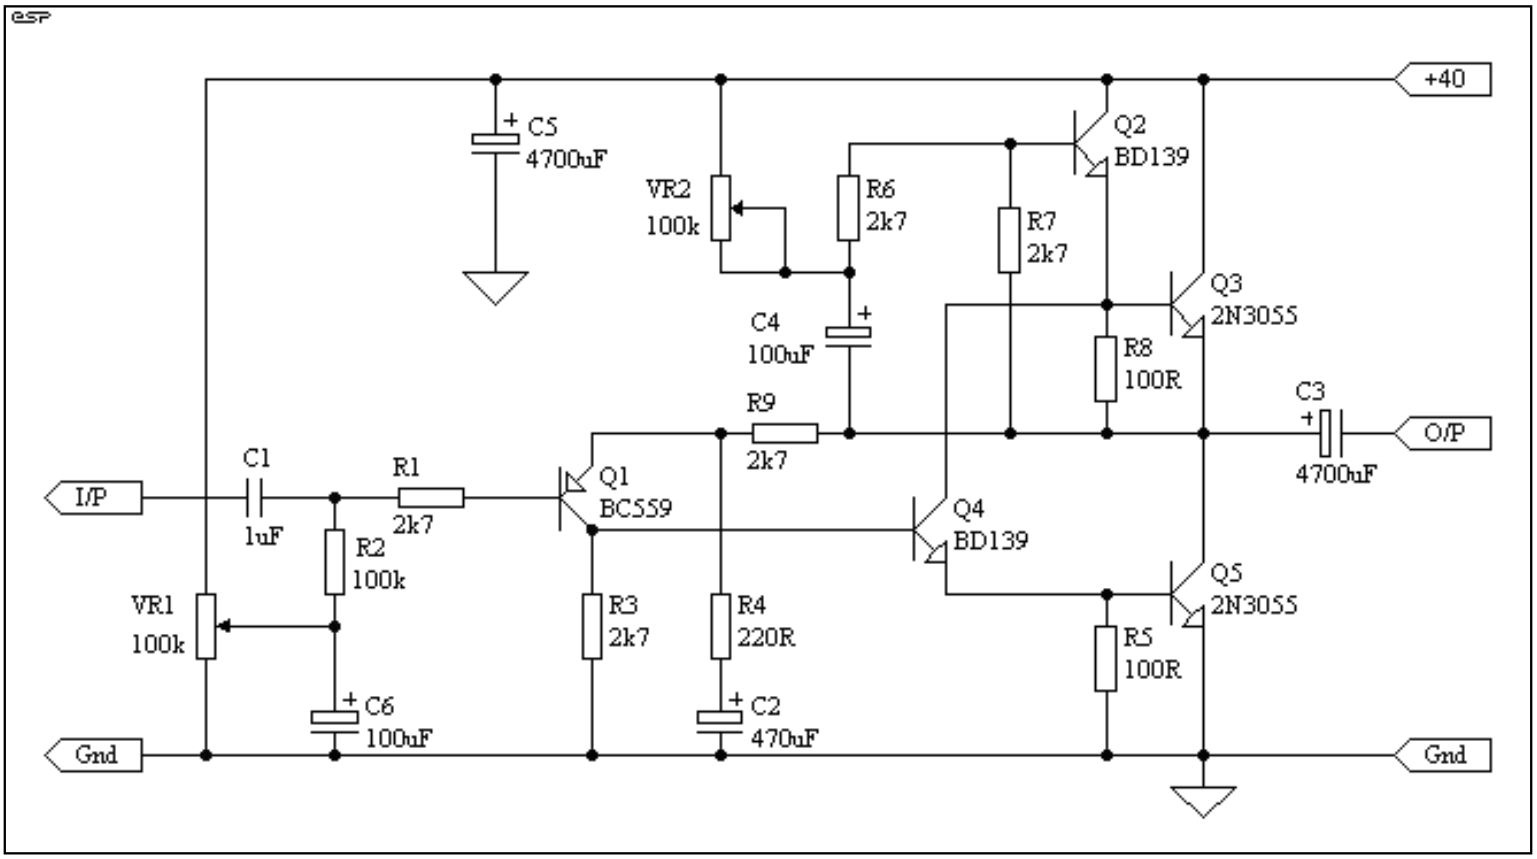


Figure 4 - Semi-Final DoZ Circuit

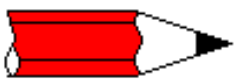

Q3 and Q5 (the output transistors) must be on a substantial heatsink (see below), and Q2 and Q4 also need heatsinks. These do not need to be especially large - TO-220 U-shape heatsinks will be fine (or make suitable sinks with scrap aluminium). The drivers get excessively hot with no heatsink.

A quick circuit description is in order. VR1 is used to set the DC voltage at the +ve of C3 to 1/2 the supply voltage (20V for a 40V supply), by setting the voltage at the base of Q1. The 100uF cap ensures that no supply ripple gets into the input. Q1 is the main amplifying device, and also sets the gain bt the ratio of R9 and R4. As shown, gain is 13, or 22dB, providing an input sensitivity of about 1V for full output.

Q4 is the buffer for the output transistor Q5, and modulates the current in Q2 and Q3. VR2 is used to set quiescent current, which I found needs to be about 1.7A for best overall performance. C4 and R6 are part of a bootstrap circuit, which ensures that the voltage across R6 remains constant. If the voltage is constant, then so is the current, and this part of the circuit ensures linearity as the output approaches the +ve supply.

After some more testing, I found that the optimum quiescent current was 0.75 times the peak speaker current. At lower currents, third harmonic distortion predominates, while at higher current distortion seems to remain stable (but device dissipation is increased).

You will notice that there is no zobel network on the output, and the amp is unconditionally stable without it.

Before applying power, set VR1 to the middle of its travel, and VR2 to maximum resistance (minimum current). Be very careful - if you accidentally set VR2 to minimum resistance the amp will probably self destruct - more or less immediately.

With an ammeter (or 1 Ohm resistor) in series with the power supply, apply power, and carefully adjust VR2 until you have about 1A. Set VR1 to get 20V at the +ve of C3, and re-check the current. As the amp warms up, the current will increase, and you need to monitor it until the heatsinks have reached a stable temperature. If necessary, re-adjust VR2 and VR1 once the amp has stabilised. If you use a heatsink of more than 0.5°C/W the amp will overheat and will be thermally unstable - *this is not desirable* (*note use of extreme understatement* :-

I used a 40V supply, and was able to obtain 20W at the onset of clipping. Clipping is a lot smoother than most solid state amps, and the amp has no bad habits as it clips. Using a 1uF capacitor directly across the output caused no problems, other than some mild overshoot with a square wave input.

14 Oct 2000 - Update

As the supply voltage changes with normal variations in AC mains voltage, the quiescent current also shifts. This is not desirable, and is easily solved with the addition of a resistor and a zener diode (or a series string for odd voltages). If you are using a regulated supply, this mod is not needed.

The process is very simple. First, measure the actual nominal supply voltage - the amp(s) must be connected. Subtract 5 to 7 volts from the measured voltage, to obtain a value that can be matched by standard zener diodes. For example, your supply voltage might be 38V, so a zener voltage between 31 and 33 volts is needed. Since 33V is a standard voltage, that will be fine.

The complete updated circuit is shown in Figure 5, and also shows the actual circuit used on the PCB (excluding the modification described here). The voltage for the quiescent current setting and output voltage is now reasonably well fixed, so mains voltage variations will have very little effect on the overall current of the output stage. Minor variations are also prevented from causing slow voltage shifts at the output. These were never audible, as the circuit is deliberately very slow, but eliminating them cannot be a bad thing. The modification requires that one track be cut, and a resistor and zener (or

zener string) attached to the underside of the board. Despite the sound of this, it is completely painless :-)

D1 and D2 are zener diodes - you may only need one of them, depending on your supply voltage. The selection process is described fully below. Within the useful range of zeners, the following values are standard and suitable for the purpose ...

10V 12V 15V 16V 18V 20V 24V 30V 33V

Values higher than 33V are uncommon in retail electronics outlets, and anything lower than 10V is not recommended in a series string for this application.

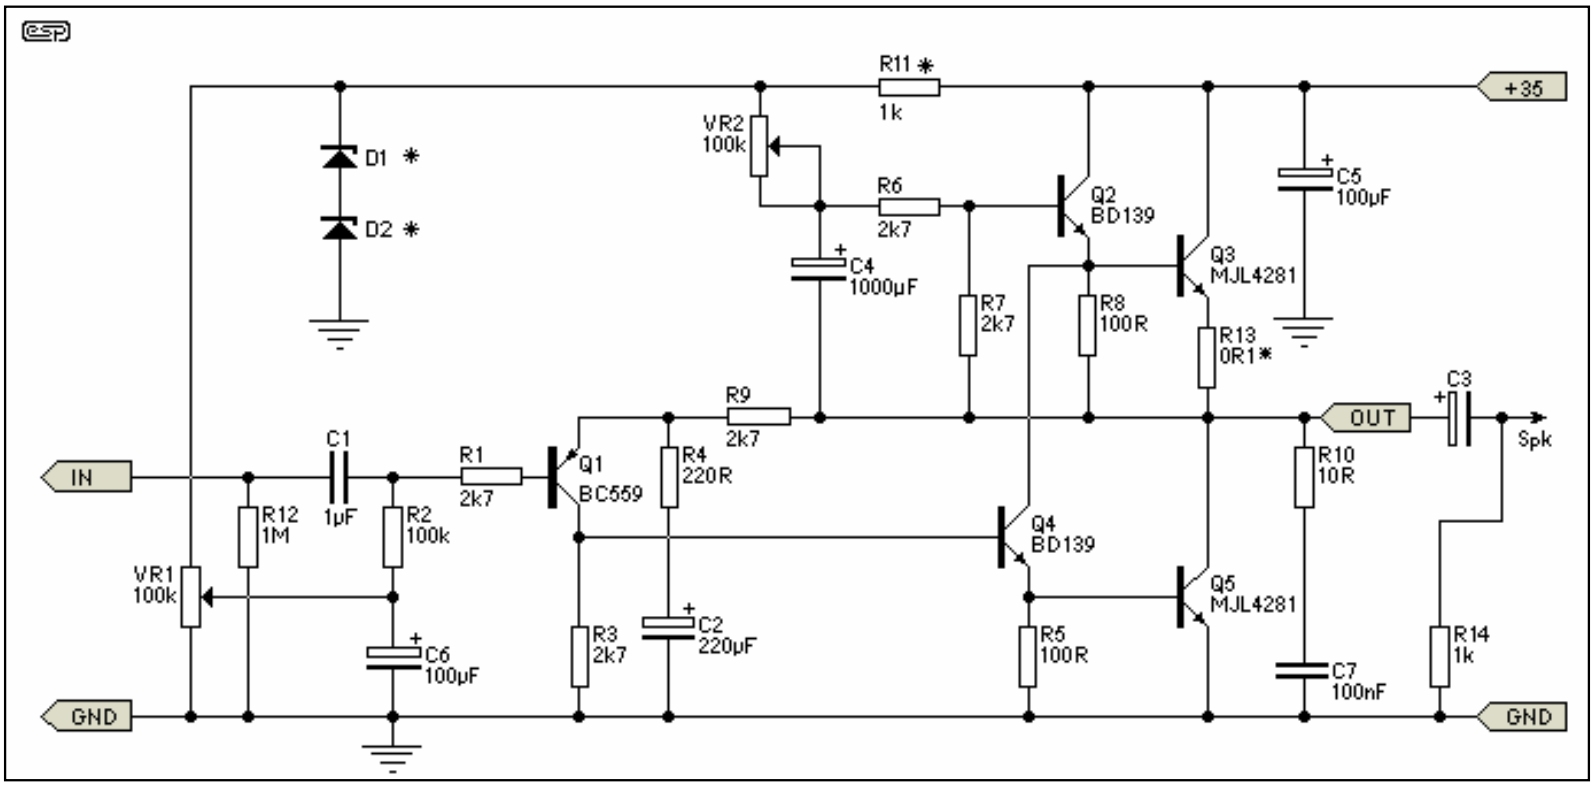

Figure 5 - The Complete DoZ Schematic (With Iq Stabilisation)

* These components are optional.

There are a few other small changes to the circuit, but these are simply to reflect the PCB design and are of no real consequence. A zobel network has been included - not because the amp needs it, but just in case a reactive load that may cause instability is connected. C5 has been reduced in value so it will fit on the board, and C3 (still very much needed !) is mounted off the board as it is too large for PCB mounting (it would almost double the board size).

A quick calculation example for the zener rating and resistance are in order, so it is properly understood. The maximum zener current for a given voltage is easily calculated ...

Iz = Pz / Vz where Iz is zener current, Pz is the power rating, and Vz is the zener voltage

Small zeners are typically rated at 400mW and 1W. A 33V 400mW zener therefore has a maximum current of 12mA. Allowing for a resistor voltage drop of 5 to 7 volts means that the zener current will be 5 to 7 mA (1V across 1k gives 1mA). Since it is recommended that zeners be operated at between 5% and 80% of the maximum rated current, this fits very nicely into our requirements.

Should you find that you need a zener voltage of (say) 36V, then two 18V zeners would be the most appropriate. Try to ensure that the zener current is at least 5% of the maximum, or the regulation will not be as good as it should be. This means that you will need to use a pair of higher voltage zeners in preference to one high voltage and one low voltage.

For example, 36V (near enough) can also be created with a 33V and a 3.3V zener in series. The 3.3V zener will have a maximum current of 120mA (assuming 400mW), and you will barely achieve the 5% minimum current needed (6mA in this case).

The modification described here does not change the measured performance of the amp, and creates no audible differences whatsoever. It is designed to stabilise the quiescent voltage and current, and it does that quite well. Some small variations will still be measured, but are so reduced in magnitude as to be considered negligible for all practical purposes.

Test Results

On the basis of the tests, I would rate this amp at 15W, although I did get more. Distortion rises with increasing level, and starts to get a bit high above 15W - at low power (such as a couple of watts) the distortion was about the same as the residual of my oscillator, which means that it must be below 0.04%, but I have no idea just how low it gets. All distortion components are predominantly second harmonic at all tested levels.

I simply used components as I found them, and did no matching or any selection. All test results are based on the prototype, which uses ordinary resistors, a couple of old salvaged computer caps for the high values, and standard electrolytics for the others. The input capacitor is an MKT polyester type.

Supply Voltage	40V
Quiescent Current	1.7A
Maximum power 8 Ohms	20W (15W)
Output Noise (unweighted)	<1 mV
Distortion @ 1kHz, 15W	< 0.2%
Output Impedance	0.378 Ohm
Frequency Response (-0.5dB @ 1W)	<10Hz to >50kHz

Table 2 - Measured Performance Of Figure 4

I could hear no noise at all, even with power supply ripple of 300mV peak-to-peak. The noise level I

measured was about 0.5mV, but it is not easy to measure accurately at such low levels. There appeared to be no residual hum that I could see on the oscilloscope, even with averaging turned on.

From this it appears that the amp is quite tolerant of supply ripple, and a simple supply will probably be fine. I tested with my normal "monster" supply, which has a fair bit of ripple, and still could not measure any supply hum at the output. A suitable power supply would be the capacitance multiplier circuit (Project 15), or a simpler one can be used. I shall work out the details of a suitable power supply and describe it within the next couple of weeks.

The amp is extremely tolerant of voltage, so for less power, use a lower voltage supply - no other changes are necessary. I found that the amp worked perfectly with supplies down to 15V, but less than 20 is unlikely to be useful (even this will only give about 4.5 Watts into 8 Ohms).

Do not try to increase the power by using a higher voltage, as the dissipation in the transistors will exceed their ratings. If you need more than 15W, I strongly suggest that you use a circuit such as the 60W amp (Project 3A), which actually has lower distortion than this design.

The amp will also tolerate a short circuit with no ill effects (I wouldn't keep it up for too long though), and even (blush) reverse polarity. I accidentally connected the supply up backwards while testing, and thought "Oh, no. Now I'll have to rebuild the blessed thing" (if the truth be known I thought something much shorter!). However, I connected the supply the right way 'round, and away it went, as if nothing had ever happened. This is *not* an experiment I suggest to others.

I found that the design is also unaffected by quite a few component variations. When I first started testing there were no emitter-base resistors in the current source, and when I added them, I simply readjusted the two pots to get everything back where it was. I retested distortion after making the changes, and could measure no difference.

Final Test Results + More Info

Before I finish with this project, I have tried some faster transistors (see below). The ones I used initially are the absolute base model 2N3055/1, so I tested with something faster (but with less power - I used plastic 130W devices). The 2N3055 comes in a whole bunch of different flavours - fast, slow, 60V, 100V etc. The ones I have are slow (FT is only 800kHz) 60V devices (I salvaged them from a bunch of old power supplies).

I do not suggest that you use plastic case transistors unless the supply voltage is kept below 35V, or if you must use plastic cased devices (such as TIP3055s) use two transistors in parallel. The latter method will make a nice simple amp quite complex. Otherwise, you can use MJL1381 transistors. These are very nice devices, and have a sufficiently high power rating so that parallel operation is unnecessary.

As it stands, this amp is so simple that I wired mine with everything just soldered directly to the output transistors (which I put in sockets), and a couple of insulated stand-offs. I might even put in a photo of it - it looks rough (only because it is), but who cares.

Also, something for the experimenter. I will be providing the info on how to increase output impedance. The calculations are too irksome to work through, so I suggest that you do it experimentally, and this allows you to tweak the impedance while you are listening. Be careful though, because it also changes the gain, so don't confuse a change in volume as a change in sound quality (our ears will do this very easily, and are easy to trick in this way).

16 Dec 99: I tried transistors with an fT of 2.5MHz, and it made only a slight difference to the speed of the amp (slight, as in not worth the effort). Distortion remained about the same, and the amp remained stable.

I also tested the amp into 4 Ohms while still set up for 8 Ohms, and it managed 10W at a distortion of about 0.4% (far too high for my liking). I had to reduce the voltage and increase current so it clipped symmetrically. I have prepared a table of voltage, current, impedance and expected power below for those who want to experiment further.

Z (ohms)	Volts	Iq (Amps)	Diss. (W)	Power
4	40	3.40	136.00	32.41
8	40	1.70	68.00	19.81
16	40	0.85	34.00	10.87
4	35	3.00	105.00	24.51
8	35	1.50	52.50	15.02
16	35	0.74	25.90	8.26
4	30	2.50	75.00	18.01
8	30	1.30	39.00	10.89
16	30	0.63	18.90	6.01

Table 3 - Operation At Different Voltage And Impedance

The table is not meant to be too accurate, but as a guide only (the figures were calculated in a spreadsheet, using a fairly basic empirical formula). Note that with a dissipation of 136W, 4 Ohm operation from a 40V supply is not recommended. Trying to get a continuous 68W of heat each out of transistors and into a heatsink is extremely difficult, even with TO-3 transistors. Even 34W each requires meticulous attention to detail with the transistor mounting if you want to keep the thermal resistance (and hence temperature) down.

If you can't keep your fingers on transistors, then they are hotter than I like to operate them - I know they will take much more, but it shortens their life.

In reality, the amp can be operated into any impedance you like, while still set up for 8 Ohm operation. Just remember that for lower impedances, the output will not clip symmetrically, and output power is reduced. At higher impedance, the power is reduced, but so is distortion.

One problem with such a simple design is that the quiescent current is supply voltage dependent. Mostly this will not cause major problems, particularly if a generous heatsink has been used (any why would you use anything else?). It does require that the current is set carefully, and should be monitored to make sure it cannot reach destructive levels.

Heatsink

As I have said before, this amp needs a really, *really* good heatsink, as do all Class-A amplifiers. If you have a few metalworking skills and tools, have a look the site below - its a neat idea, and you can save a lot of hard earned by making a monster heatsink yourself. Have a look at my article on heatsinks to see what sort of radiating surface is best. A thin coat of flat black enamel paint seems to be the most effective in my experience (other than black anodising, which is the overall winner).

There used to be a site that showed you how to make your own heatsinks, but sadly, it has departed this Web. Basically, these were the complete plans for a chassis and heatsink, so you can make it exactly the size you want. When I get an opportunity, I will generate the files to show you how it can be done, and post that as a separate project.

Conclusions

From everything that has gone on during development, I feel that my anti-MOSFET stance is justified for a Class-A design, at least, and that the concept of such an ultra simple amplifier is flawed if low distortion is the ultimate goal. Certainly, some degree of low order harmonic distortion is not unpleasant, and may even add some degree of musicality to an otherwise "clinical" sound, but the cost (i.e. loss of definition of complex passages, etc) is too high for my liking.

Even the bipolar transistor version is unacceptable in the most basic configuration, since although the distortion is lower, it is still too high - this does not qualify as hi-fi by any definition. The addition of global negative feedback (as shown in Figure 3) is the ONLY way to reduce the distortion to within acceptable limits.

In the introduction, I said that I would discuss the damping factor issue further, and so I shall. In my article on impedance (see references), I went into some detail about one of my amps that I modified to have a very high (about 200 Ohms) output impedance. The overwhelming majority of people who heard it said that it sounded just like a valve amp - but what is the sound of a valve amp when its at home?

Firstly, I have to disagree with the "overwhelming majority" to some extent. There are other subtle differences between my modified amp and a valve amp that cannot easily be eliminated. As long as the level is reasonably low (not even thinking about clipping), these differences are difficult to detect by ear, but include:

Valve Amp	Modified Transistor Amp
Increasing distortion with level (> 0.05% and rising)	Relatively constant distortion (< 0.01%)
Distortion is almost all low order	Some higher order components
Medium output impedance (about 2 to 6 Ohms, typically)	Very high output impedance (> 200 Ohms)
Relatively low bandwidth	Wide bandwidth

Table 4 - Valve Vs Transistor Amplifiers

The output impedance is by far the most noticeable effect, and results in apparent better bass (but not always - it is sometimes peaky and with some speaker systems becomes "flabby"), and also an improvement in high frequency performance. As the impedance of a speaker rises - either at low frequencies as it approaches resonance, or at high frequencies due to the inductance of the voice coil - a normal amp simply delivers less power. This is because if the voltage is fixed (by the gain of the amp), then less power is delivered to a higher impedance than a lower impedance.

Likewise, where there are impedance dips - often caused by crossover networks - the "normal" amp will deliver more power, often to the detriment of the acoustic balance. An amp with a high(ish) impedance can be thought of as a constant power device - for any given input voltage, the power will remain constant regardless of variations of load impedance. This is not strictly true, of course. No amp can be tailored so the output impedance is just exactly right to give equal power regardless of impedance, but you can get passably close.

What this means is that the speakers will provide more output at the frequencies you are unused to hearing from them, and less where they might have sounded too prominent. The overall sound is not always more accurate (often less so), but it is different, and will generally *seem* to sound better. If my tests are any guide (I hope so!), then most speakers actually benefit from a small amount of induced output impedance, and I am using this technique on my own system for the bass drivers.

UPDATE: Indeed, Nelson Pass mentions this very point, and advises that some speakers will not like the output impedance of the Zen, and will not sound the way they should. (27 Nov 99)

The Zen (and all derivatives thereof) will produce exactly this phenomenon, and I suspect that this is one of the main attractions. If this is the case, the DoZ amplifier should be just what you are looking for. Although more complex than the Zen (but only marginally), it will provide pure Class-A at passably low distortion levels.

I aimed for an output power of at least 12 Watts (Wow - that much!), obtained 19W, and even this will require some fairly large heatsinks to keep temperatures down to reasonable levels. The power supply is much cheaper than that of the Zen, and can use a basic supply or a capacitance multiplier to eliminate ripple, without sending the builder broke with the cost of high value capacitors. The output is capacitor coupled, allowing a simple single supply and no DC servos to try to minimise the DC offset.

I have also designed a simple, high performance preamp circuit (all discrete Class-A), which looks pretty good so far (it has been built and tested - see Project 37). Simulations of this indicated that I will

be completely unable to measure the distortion (less than 0.0001%) because it is so far below the limits of my equipment. The reality is a little different, but the distortion is still very low, and frequency response is very good indeed.

Both the power and preamp are completely new designs, but due to the limited number of sensible amplifier topologies, will almost certainly look like something you have seen already. I have yet to include (as an option) the ability to increase the output impedance up to about 8 Ohms, so you can have the one benefit of the Zen approach without the shortcomings.

A Simple Capacitance Multiplier Power Supply For Class-A Amplifiers

Rod Elliott - ESP (Original Design / Basic Principles)

Introduction

Since I have provided the schematic for John L Linsley-Hood's Class-A amplifier, I felt that some readers may wish to experiment with the concept. Unfortunately, a very low ripple power supply is needed for all Class-A amps, and the most common solution is to use a regulated supply. A basic circuit is provided in the article, but it is assumed that the builder knows all the pitfalls. The supplied schematic is in fact for a capacitance multiplier filter (not a regulator), but is somewhat lacking (I feel) and can be improved dramatically.

While the performance of a true regulated supply will be excellent (if properly designed and built), there are a number of problems for a high-current, low ripple design if regulators are used. Two of the main ones are:

- The regulated output voltage must be lower than the lowest possible voltage from the rectifier/filter combination - including mains ripple. This depends on transformer regulation and mains variations.
- The circuit must be capable of dissipating all excess voltage from the rectifier/filter at the highest possible mains voltage.

For the sake of the exercise, assume that we want the following specifications:

- Output Voltage - 20 Volts (+ve and -ve)
- Output Current - 2.5 Amps max. (1.25 Amps average)
- Mains Voltage - 220 VAC nominal
  - 260 VAC Maximum
  - 200 VAC Minimum

These specifications are typical, since Europe uses 220V mains, Australia uses 240V - the voltages can easily be scaled for the US 115V mains supply - and all are subject to variations, both long and short term.

We are not actually all that interested in the mains input voltage, only the possible variations of the output of the transformer / rectifier / filter combination.

For a regulated output of 20 Volts, we need a minimum input voltage of about 23 Volts, since most regulator circuits have a "dropout" voltage, below which they cannot regulate. This voltage is the absolute minimum, including the mains ripple which will be superimposed on the DC (See Fig 1). Note that for all calculations I am assuming 50Hz mains supply. The results will be slightly different for 60Hz (as used in the US), but are not significant.

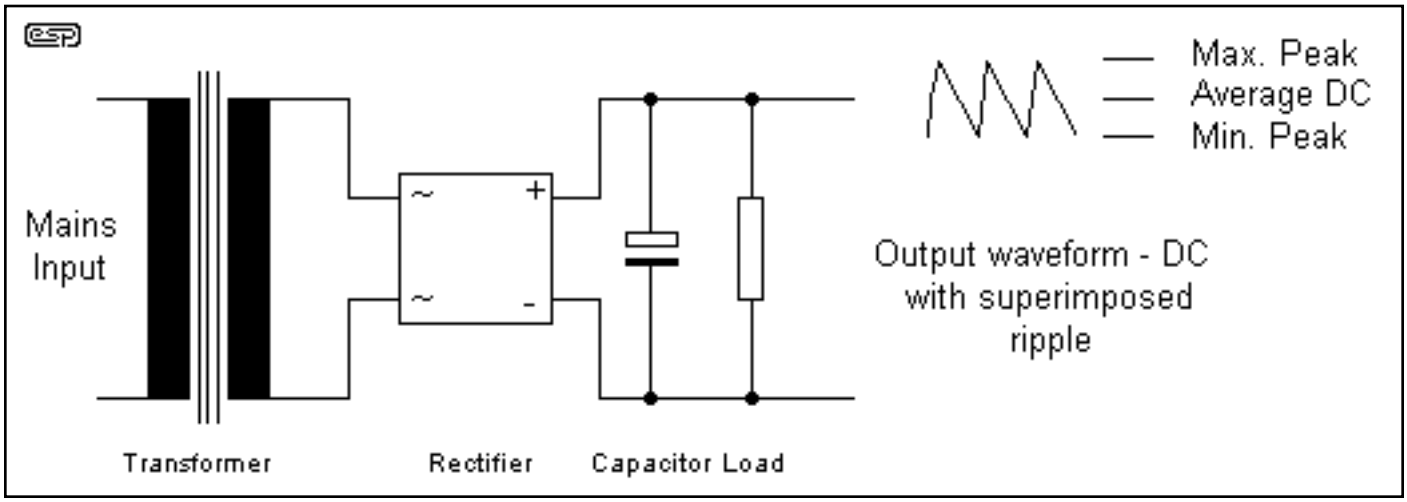

Figure 1 - Basic Rectifier

Once the regulator's input voltage drops below the dropout voltage, regulation will naturally fail, and ripple will appear at the output. This will eventually find its way to our ears, causing much muttering and complaining, and rude words surely cannot be far behind !

Design Considerations - Regulator

We must assume that the transformer / rectifier / filter will have a regulation in the order of 10% (this is fairly typical for a full-wave bridge rectifier). Using the normal 1.414 RMS to peak conversion (the square root of 2), plus a few assumptions based on experience, we therefore have our minimum requirement:-

- Transformer output (at no load) - 16.3 V RMS (each supply) plus diode losses (0.65V) = 17.6V (approx)
- Assume 0.3 Ohm equivalent series resistance in transformer and rectifier diodes
- Assume a filter capacitance of 4700uF as an initial value

This will provide a no load voltage of about 23.5 Volts as expected. When loaded to about 2.5 Amps, this will change:

- Output voltage falls to 19.5 V DC (average)
- Ripple voltage is just over 1 Volt RMS (1.5 Volts peak, triangular wave)
- Minimum output voltage is now 19.5 - 1.5V ripple = 18 Volts

(These figures were simulated, but reality will be suspiciously close!)

It can be readily seen that far more voltage is needed to ensure that the minimum voltage of 23 Volts is maintained. It turns out (again from my trusty simulator) that a transformer voltage of 22 V RMS is needed, which provides an average DC of 25.4 Volts, less about 2 Volts peak ripple. Close enough.

Now comes the really nasty bit! All of the above must be the case at the lowest possible mains voltage. For the sake of (my) sanity, this is assumed to be 200 V AC, so at the above worst case maximum of 260V, the 22V output of the transformer is now 28.6V. At full load (2.5A), this yields a DC voltage of nearly 35V average.

So the regulator will have a minimum input voltage of 25.4 Volts, and a maximum of 35V, so power dissipation will be:

- 6.75 Watts average at minimum input voltage and 1.25A average current
- 18.75 Watts average at maximum input voltage (also at 1.25A)
- Somewhere in between for nominal mains supply voltages and output current variations.

Note that the above figures are for the 1.25A average, but peak dissipation (at 2.5A) will be double, at about 37W for the worst case. This is a lot of heat to dispose of, and must be catered for. I should also mention that a minimum of 200V AC for a nominal 220V is probably optimistic (10% of 220V is 22V) and in reality we may need to cater for even lower voltages. This makes the equation even worse !

To accommodate the worst case, the heatsink for the power supply must be capable of ensuring the maximum device temperature is not exceeded at the highest mains voltage anticipated. At no "normal" mains voltage may the regulator come out of regulation, or severe ripple will appear at the output, degrading the sound quality, and causing audible hum (at double the mains frequency, and with a triangular waveshape, which sounds horrid).

Capacitance Multiplier - Design Considerations

The only real thing to worry about is the degree of filtering needed! We must assume that at least 3 Volts will be lost across the capacitance-multiplier filter, to ensure that the DC input (including ripple component) always exceeds the output voltage.

Because there is no regulation, the power amplifier must be capable of accepting the voltage variations from the mains - every standard power amplifier in existence does this quite happily now, so it is obviously not a problem. Note that the output power is affected, but this happens with all amps, and cannot be avoided without a regulator.

We can now design for nominal mains voltage (say 220V AC), and with very simple circuitry, provide a filter which will dissipate no more than about 4 Watts in normal use - regardless of mains voltage. Figure 2 shows the basic configuration of a capacitance-multiplier filter, where the capacitance appearing at the base of the output device is effectively multiplied by the gain of the device - thus a 1000uF capacitor appears (electrically) to be a 1 Farad (yes, 1,000,000uF) cap, assuming a gain of 1000 in the output device.

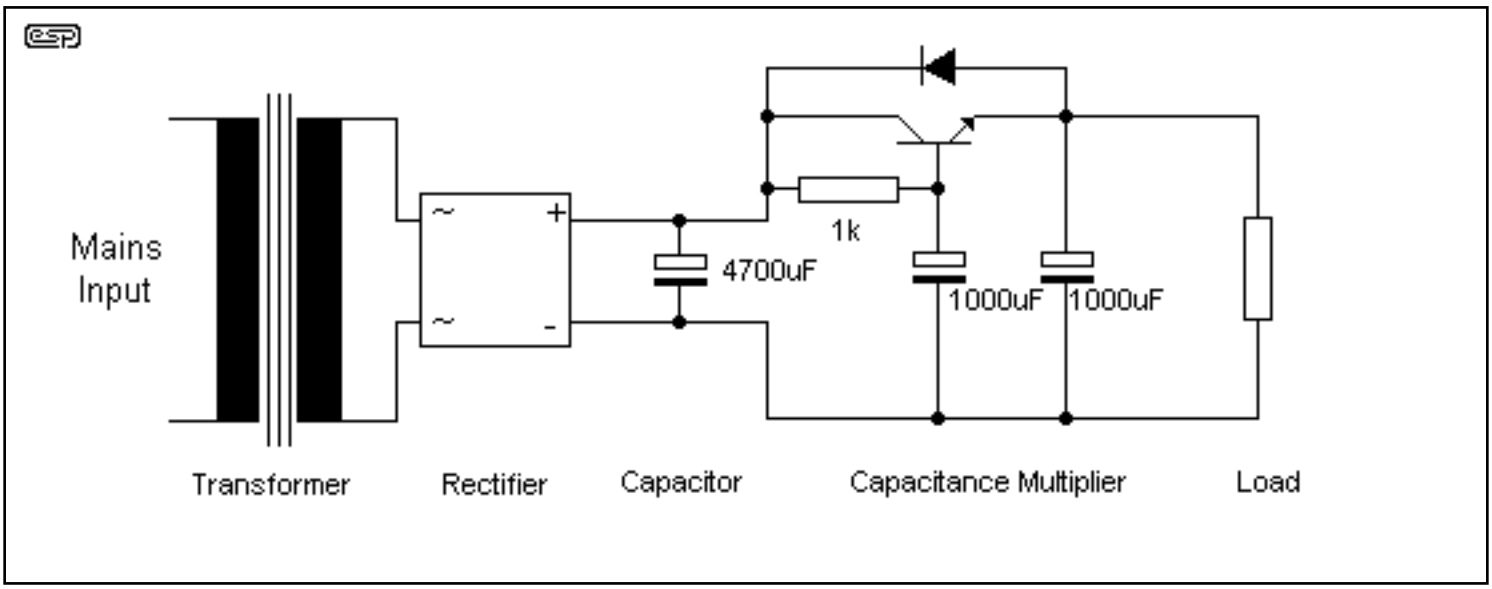

Figure 2 - Single (Basic) Capacitance Multiplier

One could simply use a pair of 1F caps for a dual supply, but I have noticed a dearth of such devices (other than the 5V "Supercaps" used for memory backup in computers). Since they will need to be rated at about 35V, and be capable of considerable ripple current, I cannot help but feel that this is not a viable option.

Both methods will provide a ripple of well under 5mV RMS, but the multiplier has the advantage of removing the triangular waveform - it is not a sinewave, but has a much lower harmonic content than would be the case even with a 1F capacitor.

To obtain a gain of 1000 for a transistor, we need to use a darlington - either an encapsulated darlington device, or a pair of "ordinary" transistors connected in a darlington pair (See Figure

3). The latter method is my preferred option, since it allows greater flexibility in obtaining devices, and will often have better performance.

The Final Design

The simple capacitance multiplier filter described above is quite satisfactory as a starting point, but its final operating characteristics are too dependent on the gain of the output transistors. What is needed is a circuit whose performance is determined by resistors and capacitors, and which is relatively independent of active devices (although these will still have an impact on the degree of filtering provided).

We can also improve the ripple rejection, and the final circuit for a dual supply is shown in Figure 3. This circuit reduces ripple to less than 200uV with typical devices (160uV as simulated), and dissipates less than 4 Watts per output transistor at 1.25A continuous operating current. It is unlikely that you will achieve this low hum level in practice, since real wire has resistance. However, with careful layout you should easily be able to keep the output hum and noise to less than 10mV, and this level is more than acceptable for any power amp application.

By splitting the capacitance with an additional resistor, we create a second order filter (12dB/ octave rolloff), which reduces the hum more effectively, and also removes more of the higher order harmonics (which tend to make a "hum" into a "buzz" - much more audible and objectionable). The resistor to ground stabilises the circuit against variations in transistor gain, but increases dissipation slightly. This is done deliberately to ensure that there is sufficient voltage across the multiplier to allow for short term variations.

The 12k resistor shown may need to be adjusted to suit your transistors and supply voltage. Reducing the value increases dissipation in the output devices and lowers output voltage. It is unlikely that any benefit will be obtained by increasing this resistor, other than increased hum (hardly a benefit).

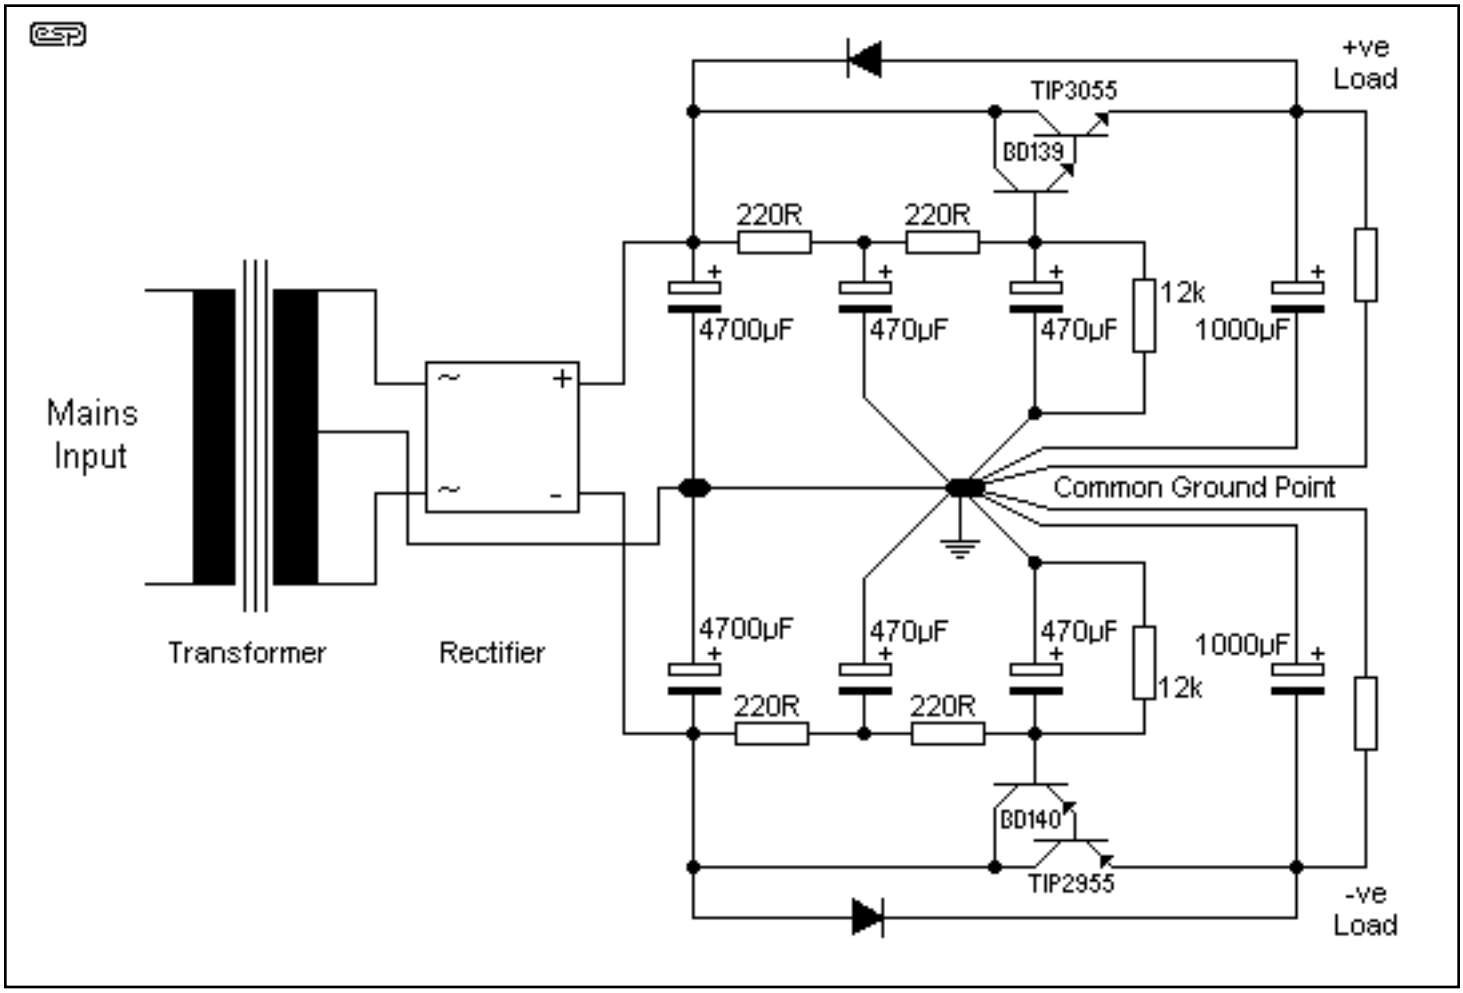

Figure 3 - Complete Dual Capacitance Multiplier

This is an easy design to build, but requires great care to ensure that ripple currents are not superimposed on the output because of bad grounding or power wiring practices. The schematic is drawn to show how the grounds of the various components should be interconnected, using a "star" topology. If this is not followed, then excessive hum will be the result.

The previous drawing (which you may have downloaded or printed) showed the bridge output not directly connected to the main filter capacitors - this was not my original intention, and the correct method is shown above. Normally, in a schematic diagram the idea is to show the connections, rather than the physical circuit layout. This diagram is an exception, and the physical layout should match the schematic (in as much as that is possible, at least).

Note that the transformer is centre-tapped, and requires equal voltage on each side - in this case, somewhere between 18 and 22V AC. It is most important that the centre-tap is connected to the common of the two input filter capacitors (4700uF), and that this common connection is as short as possible. Use of a solid copper bar to join the caps is recommended. Likewise, a solid copper disk (or square) is suggested for the common ground, tied as closely as possible to the capacitor centre tap. The resistance of the main earth connection is critical to ensure minimum hum at the output, and it cannot be too low.

Because the circuit is so simple, a printed circuit board is not needed, and all components can be connected with simple point-to-point wiring. Keep all leads as short as possible, without compromising the star grounding. For convenience, the driver transistors may be mounted on the heatsink, which does not need to be massive - a sink with a thermal resistance of about 5 degrees C per Watt (or better) should be quite adequate (one for each output device). Remember that the lower the thermal resistance, the cooler everything will run - this improves reliability.

Increasing the capacitance (especially at the input) is recommended, and I would suggest 10,000uF as the ideal instead of the 4700uF shown. This will reduce hum even further, and provide greater stability against short term mains voltage changes. Increased output capacitance will help when powering Class-AB amplifiers, to account for their sudden current demands. I do not recommend more than 4,700uF, as the charging current will be very high.

Although generic transistor types (such as the 2N3055) can be used, it is better if devices with somewhat more stable characteristics (from one device to the next) are used. Plastic (T0-220) devices are fine for the output as shown, but if higher voltage or current is needed you might have to use TO-3 types.

For the components, I would suggest the following as a starting point (or equivalents):

Output Transistors	TIP3055 (TIP2955 for the -ve supply)
Drivers	BD139 (BD140 for the -ve supply)
Resistors	1/4W metal film for all resistors
Diodes	1N4001 or similar
Electros	No suggestions, but make sure that their operating voltage will not be exceeded, and observe polarity. (Bypassing with polyester is not really necessary, but if it makes you feel better, do it)
Bridge rectifier	20 to 35A Amp bridge is recommended. This is overkill, but peak currents are high, especially with large value capacitors. Also ensures minimum diode losses at normal currents.
Transformer	Use a toroidal. Power (VA) rating for supply as shown should be as required for the amplifier. A dual 20W Class-A amp will ideally have a minimum transformer rating of 200VA - 5 times the amplifier power. (Note that VA is sometimes incorrectly quoted in watts). Primary voltage is naturally dependent upon where you live.

Matching the output and driver transistors is not be necessary, but will result in marginally

improved performance if done. Use devices with the highest gain possible for best results.

To use the above circuit in single-ended mode, the transformer will need only a single winding (or paralleled sindings if this is possible). Simply wire the transformer and bridge as shown in Figure 2, and leave off the negative multiplier circuit (i.e. everything below the common ground point).

Using A Capacitance Multiplier Filter With Class-AB Amps

Note that this circuit is quite suitable for Class-AB amplifiers, but since their current requirements vary so widely adding a (much?) larger capacitance to the output, is a must. The diode is recommended as shown to prevent the possibility of reverse biasing (and destroying) the transistor(s) when power is removed.

The benefits of such filtering are subtle, but worth the effort. Many power amps are now built with truly massive capacitance after the rectifier. This reduces hum which is introduced into the signal during loud passages. In theory, this is inaudible - but if so, why do amps with very large capacitor banks always seem to sound better? (Or so the reviewers keep telling us.)

If you are desirous of trying this circuit with a Class-AB amp, I would strongly recommend that the input to output voltage differential be increased (reduce the 12k resistor to do this), or you are unlikely to be pleased with the result. For optimum performance (depending on output voltage, the current variation, etc), I would suggest that a differential of 6V to 10V should be Ok, depending upon the power of the amp. Dissipation will need to be calculated (or measured), and remember that Class-AB amps can (and do) create peak currents which can be very high indeed. For the 20V (nominal) supply shown, peak current into an 8 ohm load is 2.5A (which was the design goal in the first place), but if the voltage is increased, peak currents increase in proportion.

As an example, consider a 100W amp (8 ohms). Peak current into a resistive load is about 3.6A, but when driven into a typical speaker load (whose impedance dips to (say) 3 ohms), the peak current will be 9.6A. This is not mere speculation, but harsh reality - such peak currents are quite common - one of the reasons many manufacturers quote the peak output current of their amps. These specs. can be as high as 40 Amps (for a 100W unit), which is probably overkill, but should be remembered.

It must be remembered that this circuit acts in a manner very similar to a regulator - just without the regulation. If the output current is highly transient in nature, the circuit will allow hum to pass if the input voltage suddenly drops due to increased load (in the same way a regulator will).

Also note that the supply voltage to the power amp(s) will be modulated by the instantaneous current drain of the amp (which happens with "conventional" supplies too). Maintaining a voltage differential sufficient to accommodate these variations is imperative.

WARNING: Because this power supply is mains operated, there is the risk of electrocution if extreme care is not exercised while constructing or testing the unit. If you are not confident in your abilities with mains powered equipment, ***do not attempt construction*** under any circumstances .... please!

PA versus Powered Mixer

by "Frank D" <fdo.nospam@> > Sep 24, 2004 at 07:06 PM

We are a four piece band with 2 guitars, bass, and acoustic drums. I'm looking for amplification that as well as voice(3 Mics), will also mic my kick drum and maybe accept a keyboard. We'll be playing smaller venues and basement/garage jams. My local dealer suggested a SoundTech PMXR200 power mixer. Any suggestions out there RE: PA versus Powered Mixer

Negative feedback doesn't always decrease amplifier distortion!

By John Atkinson

December 21, 1997 — Martin Colloms argues persuasively in the January 1998 *Stereophile* that negative feedback is not the panacea that amplifier designers believe it to be. His experience of an amplifier (the Cary CAD-805C) and a preamplifier (the Conrad-Johnson ART) that use no negative feedback other than local degeneration, yet have sound quality better than he has previously experienced, convinces him that even when a design's closed-loop distortion appears to be acceptably low, the listener is still aware of an amplifier's very distorted open-loop behavior.

In the Six/1997 issue of *Audio Electronics*, an article by Jan Didden, "Feedback---Curse or Blessing?," provides supporting evidence for Martin's conjecture. Didden summarizes research performed by the late British engineer Peter Baxandall (though no reference is given). Baxandall found that, as loop negative feedback is introduced to a solid-state (FET) amplifier circuit, the amplitude of the low harmonics is reduced by the feedback ratio, as expected. But what was not expected was that the amplitudes of the higher harmonics *increased* as the feedback was increased in level. These high harmonics started to decrease in level only when the amount of loop negative feedback crossed a threshold. With 40dB of negative feedback, the level of the fifth harmonic was still higher than it was without any feedback!

So what, you may be asking yourself? The point is that the higher harmonics are considerably more audible than the low harmonics, and are subjectively more unpleasant. You can test this yourself with *Stereophile Test CD 2*, which includes a track allowing listeners to determine for themselves how much second- and seventh-

harmonic distortion they can hear with a pure tone. While it's hard to hear 1% of second-harmonic content, 0.1% of seventh-harmonic is still audible to many listeners.

So before you dismiss audiophiles in love with the sound of single-ended tube amplifiers as anachrophilic tweako-cultists, you should note that the open-loop behavior of such designs is extremely linear compared with that of typical push-pull solid-state designs. This means that they can get away with a very small amount of loop negative feedback, and that what harmonic distortion they *do* have is almost all low-order.

Capacitor ESR Ratings

ESR Equivalent Series Resistance

See the Cap wizard
Surplus Capacitors
Secret Capacitor codes

The ESR rating of a capacitor is a rating of quality. A theoretically perfect capacitor would be loss less and have an ESR of zero. It would have no in-phase AC resistance. We live in the real world and all capacitors have some amount of ESR. To understand why let us review what a capacitor is and what they are made of and how we rate them.

What is a Capacitor?

A capacitor consists of two conductive metal plates separated by an insulating dielectric. The dielectric can be made of glass, ceramic, Tantalum oxide, or plastics such as polyethylene or polycarbonate. Even air can be used as the dielectric. When the capacitor holds some energy in the form of extra electrons on one plate and electron holes on the other we say that the capacitor is charged.

Farads

Capacitance (C) is the amount of charge per volt of potential that a capacitor holds. (C =Q/V where Q = coulombs (the unit of charge) and V = Volts)

Capacitance is measured in farads, but most often a small fraction of a farad thus:

- micro-farads uF millionths (10^{-6}) farads
- pico-farads pF (10^{-12}) farads (sometimes called 'puffs' in engineering slang)

The energy stored in a capacitor is $E = CV^2/2$ E is in joules.

Thus, the average power in watts is $P_{av} = CV^2/2t$ where t = time in seconds.

The maximum voltage rating and its capacitance determine the amount of energy a capacitor holds. The voltage rating increases with increasing dielectric strength and the thickness of the dielectric. The capacitance increases with the area of the plates and decreases with the thickness of the dielectric.

Thus, the capacitance of a capacitor (C) is related to the plate area (A), plate separation distance (d) and permittivity (ε) of the dielectric by the following equation:

$C = \varepsilon A/d$ Here A and d are based on meters as the unit and ε is in coulombs squared per Newton-meters squared notice the force unit involved - it explains why capacitor microphonics (remember the good old condenser microphone?) and a mechanical failure mode of capacitors).

Dielectric Constants

Dielectric constant (k) gets it's value by comparison of the charge holding ability of a vacuum where k = 1. Thus, k is the ratio of the capacitance with a volume of dielectric compared to that of a vacuum dielectric.

$K = \varepsilon_d/\varepsilon_0$ Where ε_d is the permittivity of the dielectric and ε_0 is the permittivity of free space

Air has nearly the same dielectric value as a vacuum with k = 1.0001. Teflon, a very good insulator, has a value of k =2 while the plastics range in the low 2s to low 3s. Mica gets us a k =6. Aluminum oxide is 7, Tantalum's k is 11 and the Ceramics range from 35 to over 6,000.

Dielectric constants vary with temperature, voltage, and frequency making capacitors messy devices to characterize. Whole books have been written about choosing the correct dielectric for an application, balancing the desires of temperature range, Temperature stability, size, cost, reliability, dielectric absorption, voltage coefficients, current handling capacity (ESR). (Ivan Sinclair wrote a nice book on passives; unfortunately, it is out of print. This points to the fact that our universities are no longer teaching this material). See the Secrets of capacitor codes page for more information

Dielectric strength

Dielectric strength is a property of the dielectric that is usually expressed in volts per mil (V/.001") or volts per centimeter (V/cm). If we exceed the dielectric strength, an electric arc will 'flash over and often weld the plates of a capacitor together.

Q or Quality Factor

The *Q* of a capacitor is important in tuned circuits because they are more damped and have a broader tuning point as the *Q* goes down.

$Q = 1/RX_C$ where X_C is the capacitive reactance *where* $X_C = 1/(2\pi FC)$ and *R* is the soon to be defined term of ESR.

Q is proportional to the inverse of the amount of energy dissipated in the capacitor. Thus, ESR rating of a capacitor is inversely related to its quality.

Dissipation Factor

The inverse of Q is the dissipation factor (δ). Thus, $\delta = ESR/X_C$ and the higher the ESR the more losses in the capacitor and the more power we dissipate. If too much energy is dissipated in the capacitor, it heats up to the point that values change (causing drift in operation) or failure of the capacitor.

Ripple Current Rating

The ripple current is sometimes rated for a capacitor in RMS current. Remembering that $P = I^2R$ where R in this case is ESR it is plain to see that this is a power dispassion rating.

Dielectric Absorption

This is the phenomenon where after a capacitor has been charged for some time, and then discharged, some stored charge will migrate out of the dielectric over time, thus changing the voltage value of the capacitor. This is extremely important in sample and hold circuit applications. The typical method of observing Dielectric Absorption is to charge up a cap to some known DC voltage for a given time, then discharge the capacitor through a 2 ohm resistor for one second, then watch the voltage on a high-input-impedance voltmeter. The ratio of recovered voltage (expressed in percent) is the usual term for Dielectric absorption.

The charge absorption effect is caused by a trapped space charge in the dielectric and is dependent on the geometry and leakage of the dielectric material.

ESL

ESL (Equivalent Series Inductance) is pretty much caused by the inductance of the electrodes and leads. The ESL of a capacitor sets the limiting factor of how well (or fast) a capacitor can de-couple noise off a power buss.

The ESL of a capacitor also sets the resonate-point of a capacitor. Because the inductance appears in series with the capacitor, they form a tank circuit.

ESR Defined

ESR is the sum of in-phase AC resistance. It includes resistance of the dielectric, plate material, electrolytic solution, and terminal leads at a *particular frequency*. ESR acts like a resistor in series with a capacitor (thus the name Equivalent Series Resistance). This resister can cause circuits to fail that look just fine on paper and is often the failure mode of capacitors.

To charge the dielectric material current needs to flow down the leads, through the lead plate junction, through the plates themselves - and even through the dielectric material. The dielectric losses can be thought of as friction of aligning dipoles and thus appear as an increase (or a reduction of the rate of decrease -- this increase is what makes the resistance vs freq line to go flat.) of measured ESR as frequency increases.

As the dielectric thickness increases so does the ESR. As the plate area increases, the ESR will go down if the plate thickness remains the same.

To test a Capacitors ESR (see the Cap Wizard) requires something other than a standard capacitor meter. While a capacitor value meter is a handy device, it will not detect capacitor failure modes that raise the ESR. As the years go by, more and more designs rely on low ESR capacitors to function properly. ESR failed caps can present circuit symptoms that are difficult to diagnose.

Formulas at a glance

(if you can't see the formulas it is time to get a browser update)

$$\delta = \frac{ESR}{X_c}$$

$$X_c = \frac{1}{2\ \pi CF}$$

$$\mathrm{X_L} = 2\ \pi \mathrm{LF}$$

$$\omega = 2\ \pi \mathrm{F}$$

$$\mathrm{I} = \frac{\mathrm{E}}{\sqrt{R^2 + \left(\omega\ \mathrm{L} - \frac{1}{\omega\ \mathrm{C}}\right)^2}}$$

$$\mathrm{F_r} = \frac{1}{2\ \pi\sqrt{LC}}$$

Where *k* = dielectric constant, *A* = area, *t* = thickness of the dielectric, *Q* = coulombs the unit of charge, and *V* = Volts

$$C = \frac{(8.85 \times 10^{-12})kA}{t}$$

$$C = \frac{Q}{V}$$

Where *A* (area) and *d* (thickness) use meters as the unit and ε is in coulombs (squared per Newton-meters squared), ε_d is the permittivity of the dielectric, and ε_0 is the permittivity of free space

$$C = \frac{\in A}{d}$$

$$k = \frac{\in_d}{\in_0}$$

Where energy E (in joules) stored in a capacitor is given by

$$E = \frac{CV^2}{2}$$

Thus, the average power in watts where t = time in seconds.

INDUCTANCE OF A STRAIGHT WIRE

Tim Healy, Santa Clara University

This note concerns the inductance of a straight wire. Surprisingly, it is not easy to find an expression for the inductance of a straight piece of wire, and it is far more difficult to find out how that expression was obtained. And yet this result is very useful as a building block for more complex structures, and also because the inductance of a wire is important in high frequency or high speed electrical circuits.

The first really convenient derivation of the inductance of a wire which I have been able to find is due to Rosa(1). The first dilemma which Rosa faced is that there is no unambiguous definition of how to define the inductance of a straight wire. If we consider the wire in isolation we ignore the question of how the current gets to the wire. But that current, however it is delivered, will affect the flux which is developed in the vicinity of the wire. But this flux is a part of the definition. Rosa resolved the dilemma arbitrarily (there is no other way) by defining the inductance as the ratio of the flux developed in the region bounded by lines perpendicular to the beginning and end of the wire. Let's look at Rosa's own words in which he recognizes the dilemma in the definition.

"I have derived the formulae in the simplest possible manner, using the law of Biot and Savart in the differential form instead of Neumann's equation, as it gives a better physical view of the various problems considered. This law has not, of course, been experimentally verified for unclosed circuits; but the self inductance of an unclosed circuit means simply its self-inductance as a part of a closed circuit, the total inductance of which cannot be determined until the entire circuit is specified. In this sense the use of the law of Biot and Savart to obtain the self-inductance of an unclosed circuit is perfectly legitimate."

One might question here what the word 'legitimate'. Rosa has made an assumption in order to obtain a result. That is fine, but I don't think you should say it is legitimate, in the sense of being according to law. There is no law to guide this assumption. In any event let us proceed to the solution. The approach is the following.

1. Set up the geometry of a point at some distance from a straight line.

2. Write dH from Biot Savart at that point. Let the current equal one for simplicity.

3. Find the total H due to all of the current in the line by integrating over the line.

4. Set B = uH.

5. Find the magnetic flux phi in a differential area which is parallel to the wire by integrating B over this area which is a fixed distance from the wire.

6. Find the total flux phi over all of the area from the edge of the wire to infinity by integrating over the distance from the wire to infinity.

7. Since the current was set equal to one, the total flux equals the inductance.

I am not going to put in the full derivation until I find a more math-friendly language than HTML. You can get the full derivation by contacting me (thealy@scu.edu), or by looking up the original Rosa reference below.

The total low frequency inductance (internal plus external) of a straight wire is:

$$Ldc = 2L[\ln(2L/r) - 0.75]nH$$

where Ldc is the "low-frequency" or DC inductance in nanohenries (nH), L is the length of the wire in cm, and r is the radius of the wire in cm.

This result is based on the assumption that the radius r is much less than the length L, which is commonly true.

For sufficiently high frequencies skin effects cause the internal inductance to go to zero and the inductance becomes:

$$Lac = 2L[\ln(2L/r) - 1.00]$$

Discussion of Riposte

http://www.atceramics.com/pdf/technotes/effective_capacitance_vs_fr.pdf talks about self-resonant frequency. The "parasitic inductance" does not exist inside the capacitor. However, the article is very primitive, because the graphs go in the wrong direction, with C increasing with frequency, anyway. The alleged L reduces the C, not increasing it as the author seems to think.

This guy is stumbling in the right direction, but he gets his number wrong. Inductance caused by the legs should be proportional to the length of the legs.

“Lead length alters a capacitor's range of operating frequency. Here a 2 uf capacitor's self-resonance decreases from 490 kHz to 290 kHz when its leads are lengthened from 3/8 inch to 3 inches. In other words, the capacitor's usable operating range is reduced by almost half.”

The amount of nonsense drifting around the world, of which the above are examples, is vast.
See my 1978 article at http://www.electromagnetism.demon.co.uk/z001.htm ; "Series inductance does not exist. *Pace* the many documented values for series inductance in a capacitor, this confirms experience that when the so-called series inductance of a capacitor is measured it turns out to be no more than the series inductance of the wires connected to the capacitor. No mechanism has ever been proposed for an internal series inductance in a capacitor."
The key point in my article is that "No mechanism has ever been proposed for an internal series inductance in a capacitor."
The IEE and IEEE have helped to cause the confusion to escalate by suppressing my 1978 article http://www.electromagnetism.demon.co.uk/z001.htm , which puts an end to a capacitor's series inductance. Also, competent experimentation will show that a capacitor has no internal series inductance. http://www.ivorcatt.com/em_test04.htm

In 1963 I bought the EH-125 pulse generator. This delivered a –10v step with a 100picosecond fall time into a 50 ohm load (e.g. 50 ohm

coax.).

The pulse generator could also deliver a –ve 10v spike with a width of 150psec. I decided to try to create a positive 10v spike. I cut into the 50 ohm coax, and joined the incoming inner to the outgoing outer via a red 1uF tantalum capacitor. I also joined the incoming outer to the outgoing inner via another 1uF tantalum capacitor. Further downstream I found that I had a positive 150psec spike with no discernable degradation (in rise time or pulse width) compared with the initial –ve spike. That is, I had a +ve 10v spike with a width of 150psec.

It is interesting to calculate the physical width of a 150 psec wide spike travelling down normal coax, which has a dielectric with a dielectric constant of 2. Whereas light travels one foot in vacuo in one nsec, it would travel 8 inches in material with a dielectric constant of 2. Thus, a 150psec spike in the coax has a width of about one inch. So I sent a TEM spike with a width of 1 inch through these 1uF capacitors. [Note 1] Obviously, I kept their legs short. It is sad that during the ensuing 40 years the New York IEEE and the London IEE prevented me from informing electronic engineers that they did not have to add “high frequency” decoupling capacitors to their logic boards, that the 1uF would do perfectly well on its own. This obstruction has cost the industry many millions of pounds. However, a bolshie IEEE and a bolshie IEE cost us a lot more than that in other ways. Ivor Catt 22apr02

Note 1.
Anyone who wants to play with frequencies can be told that the fundamental of the 150psec spike will be around 3GHz. Put that in your “self-resonant” pipe and smoke it! IC

Note 2.
As the spike passes the capacitors placed to each side, the situation is as in http://www.ivorcatt.com/2_1.htm Figure 14. The characteristic impedance of each capacitor is very small, less than 1% of 50 ohms.

Thus, the mismatch is less than 2%, causing a minimal reflection of less than 1%.
At the same time, if the legs of the capacitors are kept down to a total of one quarter of an inch in length, and the two parallel legs represent a quarter inch transmission line of characteristic impedance 150 ohms, then the mismatch will cause a reflection of 50%, see http://www.ivorcatt.com/1_4.htm Figure 11 and the reflection formula. This will be reduced by the fact that the 150psec spike covers a distance of one inch and a half, so that the reflections on entering the 150 ohms region tends to be masked by the opposite mismatch on re-entering the 50 ohm impedance of the next section of coax. This reduces the reflection to one sixth, i.e. 8%.

Google Hit no. 7 for "self resonant frequency" + capacitor

This article high on the Google hit list has row of capacitors, and each one decouples (digital electronic equipment for) its particular frequency range.
This farce is obvious if one realises that a 2uF capacitor is made by glueing together two 1uF capacitors. Thus, a supposedly "high frequency capacitor" is merely the front little bit of a 1uF capacitor. Of course, you can ruin the performance of either by leaving it with long legs, making a series one-turn inductor to stifle its performance. However, the idea that a 10pF capacitor has shorter legs than a 1uF capacitor is based on nothing at all.

What is so tragic is that the formula these clods use for self resonant frequency, 1/ sqrt LC , means that if C is big, then the resulting calculated "self resonant frequency" is low. This is a sensible idea if a resonant circuit is being designed out of a discrete C and a discrete L,

where L can be varied. But if, as in our case, we (have legs of fixed length and) can only vary the value of C, then the calculation deludes. If we start with a pair of legs of fixed length, that is, with a fixed external L, then the bigger the C, the lower the resonant frequency according to the formula w = 1/ sqrt LC. These buffoons are buying capacitors for the very reason that they have less capacitance, not that they have less L. They buy these “high frequency capacitors” for the very reason that, lacking much C but helping the w = 1/ sqrt LC formula, they are inferior at doing the decoupling job that they have been bought to do. All their nonsense is counter-productive. This was pointed out in my book more than 20 years ago. Since digital electronics took over from radio as the majority of electronic engineering 40 years ago, it is high time the radio men gave us at least some access to the IEEE, the London IEE and to Cambridge and MIT. Even a single digital electronics course by someone who understood the subject at either MIT or Cambridge University would help a lot. I would love to give it. However, I am sure the radio men will continue to shut me and my colleagues out, as they have done for a number of decades, hoping that their antique radio theory will continue to appear to address the needs of digital electronic equipment. http://www.ivorcatt.com/em_test04.htm Ivor Catt 18may02

Since a capacitor is a two-conductor transmission line with very low characteristic impedance, the transient impedance that it presents to a step is resistive, not reactive. This is the way it behaves when decoupling digital circuits; as a local energy store for the 5v supply with a very low resistive source impedance, not a reactive source impedance. Calculation of the impedance is made by using the normal formula for the characteristic impedance of a transmission line made up of two parallel plates with width a and separation b. See p73 of my book “Electromagnetics 1”, pub. Westfields 1975. The (resistive) impedance is very low because the dielectric constant is very high indeed, and the separation b is tiny. Ivor Catt 18may02

In the surreal world created with inappropriate mathematical stunts by physically ignorant operators, a capacitor is looked on with disdain, not because it has more L, but because it has more C.

http://www.ivorcatt.com/em_test04.htm Ivor Catt 18may02

@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@

Recap. Take the formula for the resonant frequency for an inductor-capacitor tank circuit.

The frequency (in radians per sec.) squared equals (1/ inductance x capacitance)

Thus, either increase in inductance or increase in capacitance reduces the resonant frequency. This has led physically ignorant mathematical mugwumps to think, not that the best capacitor has the least capacitance, which even they might realise is ridiculous, but that the best capacitor has the least inductance, making it able to perform to a much higher frequency up to its higher resonant frequency. They have failed to realise that they would realise their dream, of a high self resonant frequency, by reducing the capacitance just as well as by reducing the inductance. They think that it is an accident that lo value capacitors have the highest self resonant frequency. They think it is because of the difference in inductance, which it is not.

However, all this is nonsense when decoupling digital logic. What matters with digital logic is the transient performance of a decoupling capacitor, when some switching logic wants to grab as much charge as possible to launch down a transmission line towards the next logic gate. The true model, which should have replaced the series L C R model for a capacitor, was already published in 1978, http://www.electromagnetism.demon.co.uk/z001.htm , and has been ignored for 24 years by radio men who continue to teach and publish the old model which is inappropriate and damaging in digital electronics. Note that today, most capacitors are used in DC voltage decoupling.

The only way out of this impasse is for students to create problems during the lecture when lecturers continue to pump out the old, wrong drivel. Otherwise these lecturers and text book writers will continue to copy and repeat each other from a bygone age when electronics was about radio, and such a misconception about the physical nature of a capacitor was not so damaging. http://www.ivorcatt.com/em_test04.htm Students have much to gain by disrupting their lectures. It is probably more difficult to learn and be examined in material which is false. Ivor Catt. 18may02.

@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@

In 1965, living in the USA, I telephoned the design engineers in Sprague, who manufactured capacitors. They told me that they tested for the high frequency performance of a capacitor by testing at 5kHz and 50kHz, and deduced its performance at 1MHz and above using the series L C R model. Thus, the published self-resonant frequency of a capacitor is the result of lo frequency testing extrapolated using the L C R model.

By making this error, engineers in the capacitor manufacturers might have doubled their companies' sales, ensuring that a second "high frequency" capacitor would be added to every 1uF decoupling capacitor

in every digital system. Ivor Catt 18may02.

Understand Capacitor Soakage to Optimize Analog Systems

Dielectric absorption can cause subtle errors in analog applications such as those employing S/H circuits, integrating ADCs and active filters. But knowing how to measure this soakage and compensate for it helps you minimize its effects.

Veteran circuit designers often got a shocking introduction to dielectric absorption when supposedly discharged high-voltage oil-filled paper capacitors reached out and bit them. Indeed, the old oil-filled paper capacitors were notorious for what was once called soakage -- a capacitor's propensity to regain some charge after removal of a momentary short. Today, you won't find very many of these capacitors in use, but you will still encounter soakage. Do you know how to deal with it?

Nowadays, you're more likely to notice the effects of dielectric absorption in some more subtle way, perhaps in the performance of an integrator that can't be reset to zero or a sample/hold that refuses to work correctly. But whether you literally feel its effects or merely observe them in a circuit's behavior, dielectric absorption is an undesirable characteristic that every capacitor possesses to some degree. This characteristic is inherent in the dielectric material itself, although a poor manufacturing procedure or inferior foil electrodes can contribute to the problem.

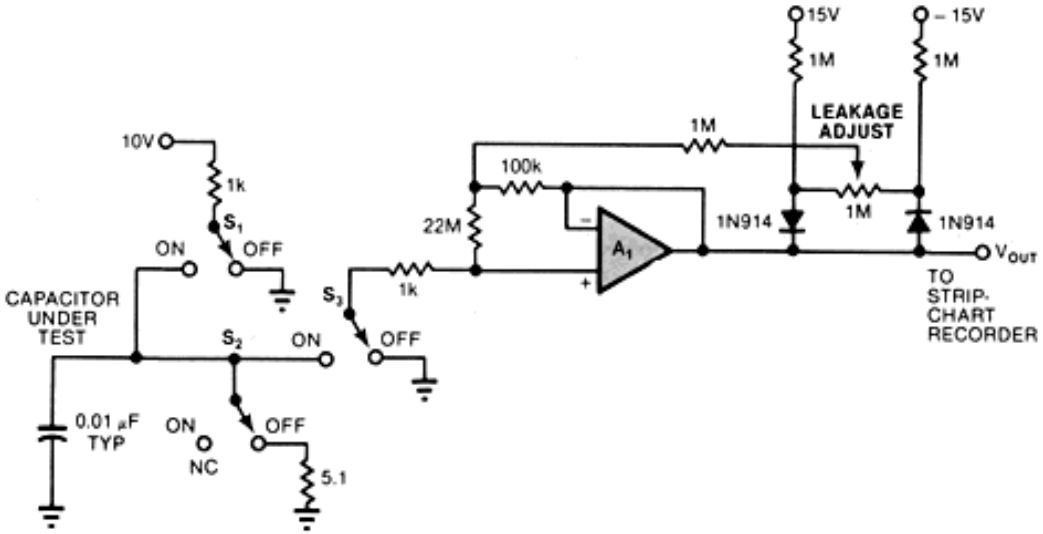

Fig 1 - A simple test fixture lets you evaluate dielectric absorption at low speeds. To use the one shown here, start with all switches off and throw S_1 and S_2 on for 1 min; throw S_1 and S_2 off and wait 6 sec, throwing S_3 on during the wait period. Next, turn S_2 on and watch V_{OUT} for 1 min. To compensate for leakage, leave all switches off for 1 min and then throw S_2 and S_3 on. Monitor V_{OUT} for 1 min and subtract this value from the V_{OUT} value obtained earlier. (View a larger version of the image.)

Indeed, soakage seems an apt term for dielectric absorption when you note what the capacitor seems to be doing. Consider a typical example: A capacitor charges to 10V for a long time T and then discharges through a small-value resistor for a short time t. If you remove the short circuit and monitor the capacitor terminals with a high-impedance voltmeter, you see the capacitor charge back to 0.1%, 1% or as much as 10% of the original voltage. For example, a 1-µF Mylar capacitor charged to 10V for 60 sec (T_{CHARGE}) and discharged for 6 sec ($T_{DISCHARGE}$) charges to 20 or 30 mV after 1 min (T_{HOLD}). Fig 1 shows a simple evaluation circuit for measuring this characteristic.

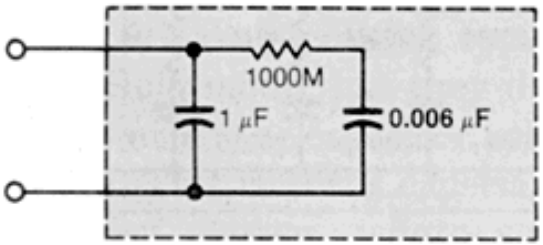

Fig 2 - To model the soakage characteristic of a 1-µF Mylar capacitor, consider a circuit that incorporates a 0.006-µF capacitor to represent the dielectric's charge-storage characteristics.

A capacitor exhibiting dielectric absorption acts as if during its long precharge time the dielectric material has soaked up some charge that remains in the dielectric during the brief discharge period. This charge then bleeds back out of the dielectric during the relaxation period and causes a voltage to appear at the capacitor terminals. Fig 2 depicts a simple model of this capacitor: When 10V is applied for 1 min, the 0.006-µF capacitor gets almost completely charged, but during a 6-sec discharge period it only partially discharges. Then, over the next minute, the charge flows back out of the 0.006-µF and charges the 1-µF capacitor to a couple of dozen millivolts. This example indicates that a longer discharging time reduces soakage error but that discharging for only a small fraction of that time results in a larger error. Illustrating this point, Fig 3 shows the results of conducting Fig 1's basic test sequence for 1-, 6- and 12-sec discharge times. Note that the capacitor tries to remember its old voltage, but the longer you hold it at its new voltage, the better it forgets -- in the Fig 3 case, soakage errors equal 31 mV at $t_{DISCHARGE}$=l sec, 20 mV at $t_{DISCHARGE}$=6 see and 14 mV at $t_{DISCHARGE}$=12 sec.

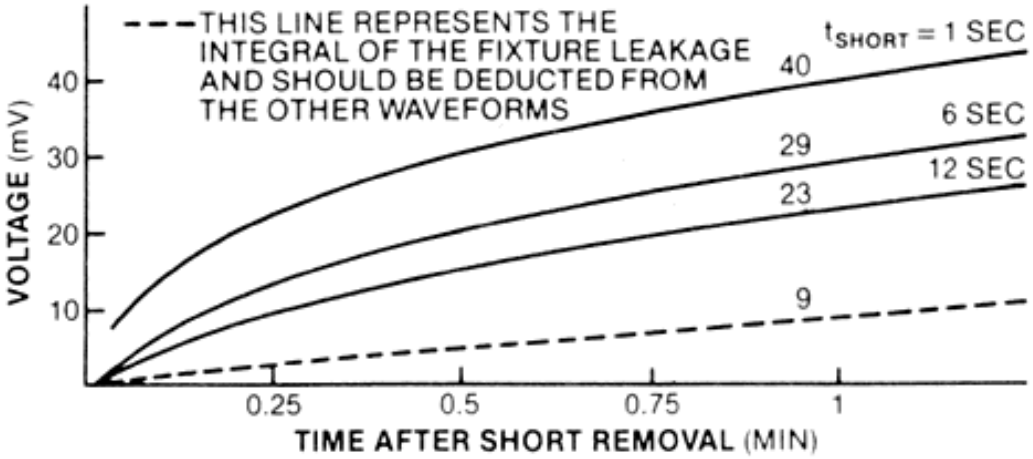

Fig 3 - Obtained using Fig 1's test circuit, these dielectric-absorption-measurement results for a 1-µF capacitor shown that longer $t_{DISCHARGE}$ times reduce soakage-caused errors.

High-speed tests predict S/H performance

You might now ask whether these low-speed tests have any bearing on a capacitor's suitability in fast millisecond or microsecond sample/hold applications. If you repeat the Fig 1 experiment for T_{CHARGE} = T_{HOLD} = 1000 µsec and $t_{DISCHARGE}$ = 100 µsec, you see very similar capacitor-voltage waveforms but with about 10-times-smaller amplitudes. In fact, for a constant T:t ratio, the resulting soakage error decreases only slightly in tests ranging in length from minutes to microseconds.

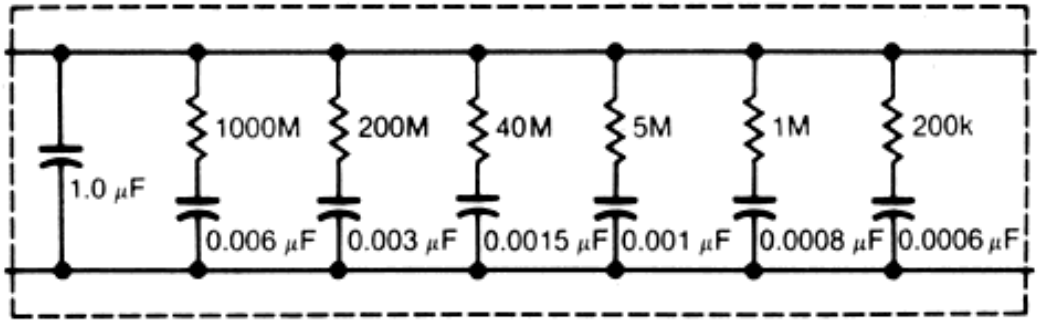

Fig 4 - More precise than Fig 2's equivalent circuit, a capacitor model employing several time constants proves valid for a wide range of charge and discharge times. This model approximates a Mylar capacitor.

Fig 4's circuit approximates this capacitor characteristic, which you can observe on actual capacitors by using Fig 5's test setup. Here, a sample/hold IC exercises the capacitor under test at various speeds and duty cycles, and a limiter amplifier facilitates close study of the small residual waveforms, without over-driving the oscilloscope when the capacitor is charged to full voltage.

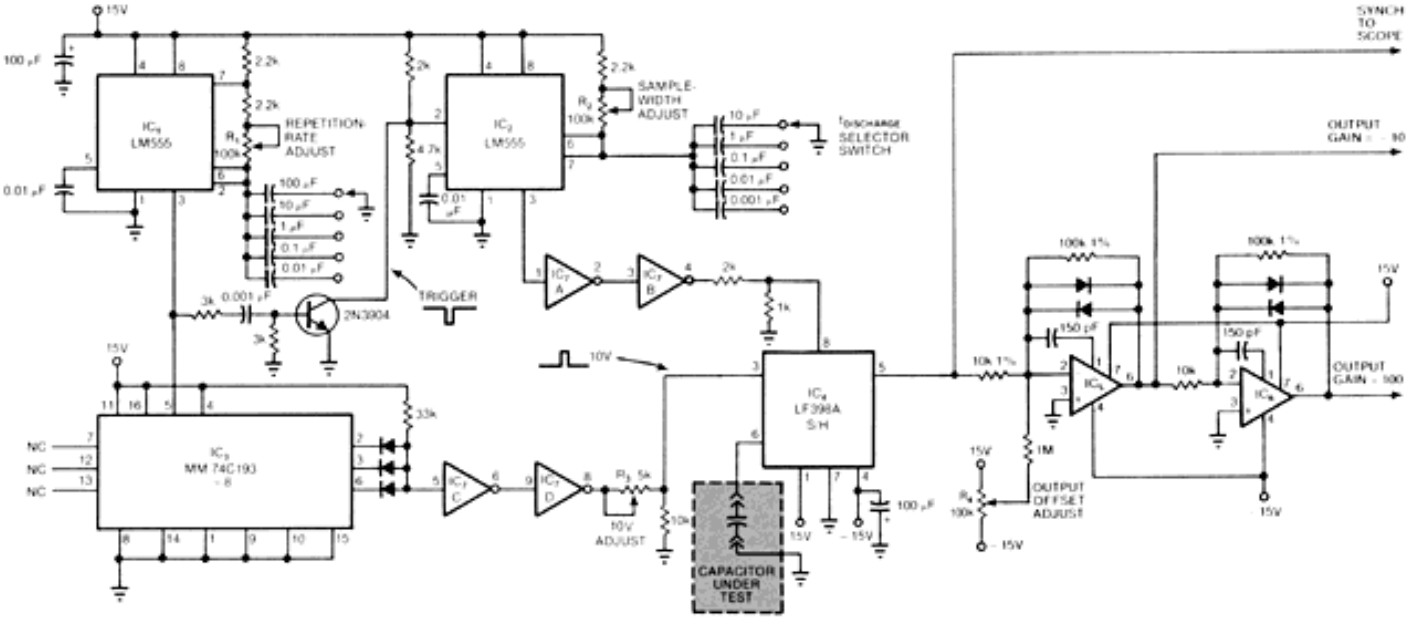

Fig 5 - Capable of automatically sequencing the dielectric-absorption tests, a circuit employing timers, a sample/hold and limiting stages allows you to make measurements for a wide range of T_{CHARGE}, T_{HOLD}, and $t_{DISCHARGE}$ values. Fig 7 shows the results obtained using the circuit shown here. (View a larger version of the image.)

Notes:

1. ALL DIODES = 1N914

3. IC7 = MM74C04
4. USE R4 OR -10 GAIN TO KEEP SCOPE WAVEFORM BELOW 200mV SO AS TO AVOID DISTORTION OR FALSE ATTENUATIONS

Such experiments illustrate that if you put a certain amount of charge into a less-than-ideal capacitor, you will get out a different amount of charge, depending on how long you wait. Thus, using low-soakage capacitors proves important in applications such as those involving high-resolution dual-slope integrating ADCs. And sure enough, many top-of-the-line digital voltmeters do use polypropylene (a low-soakage dielectric) devices for their main integrating capacitors.

But dielectric-absorption characteristics are most obviously detrimental in applications involving sample/holds. Manufacturers guarantee how fast these devices can charge a capacitor in their Sample mode and how much their circuits' leakage causes capacitor-voltage droop during the Hold mode, but they don't give any warning about how much the capacitor voltage changes because of soakage. This factor is especially important in a data-acquisition system, where some channels might handle small voltages while others operate near full scale. Even with a good dielectric, a sample/hold can hurt your accuracy, especially if the sample time is a small fraction of T_{HOLD}. For example, although a good polypropylene device can have only 1-mV hysteresis per 10V step if T/t=100 msec/10 msec, this figure increases to 6 mV if the T/t ratio equals 100 msec/0.5 msec. Because most sample/hold data sheets don't warn you of such factors, you should evaluate capacitors in a circuit such as Fig 5's, using time scaling suited to your application.

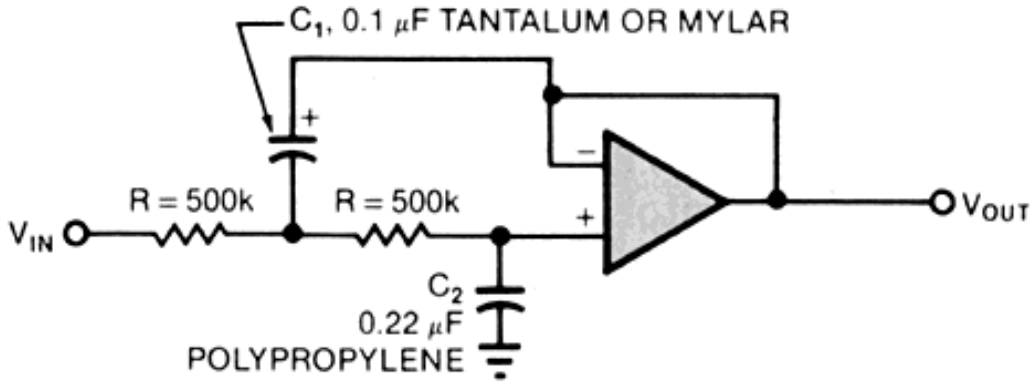

Fig 6 - Soakage can present problems when you're designing a fast-settling amplifier or filter. In the circuit shown here, for example, C_1 can be a Mylar or tantalum unit, but making C_2 a polypropylene device improves performance.

Other applications in which soakage can degrade performance are those involving fast-settling ac active filters or ac-coupled amplifiers. In Fig 6's circuit, C_1 can be a Mylar or tantalum unit because it always has 0V dc on it, but making C_2 polypropylene instead of Mylar noticeably improves settling. For example, settling to within -0.2 mV for a 10V step improves from 10 to 1.6 sec with the elimination of Mylar's dielectric absorption. Similarly, voltage-to-frequency converters benefit from low-soakage timing capacitors, which improve V/F linearity.

Some dielectrics are excellent at all speeds

Fortunately, good capacitors such as those employing polystyrene, polypropylene, NPO ceramic and Teflon dielectrics perform well at all speeds. Fig 7 shows the characteristics of capacitors using these dielectrics and others such as silver mica and Mylar. In general, polystyrene, polypropylene or NPO-ceramic capacitors furnish good performance, although polystyrene can't be used at temperatures greater than 80°C. And although NPO ceramic capacitors are expensive and hard to find in values much larger than 0.01 µF, they do achieve a low temperature coefficient (a spec not usually significant for a S/H but one that might prove advantageous for precision integrators or voltage-to-frequency converters). Teflon is rather expensive but definitely the best material to use when high performance is important. Furthermore, only Teflon and NPO ceramic capacitors suit use at 125°C.

Fig 7 - Soakage-measurement results for a variety of capacitors illustrate the effects of $t_{DISCHARGE}$ values on dielectric-absorption-caused errors. Note the curves for two different samples of NP0 ceramic capacitors intersect.

If you look at Fig 7's dielectric-absorption values, you can see wide differences in performance

for a given dielectric material. For example, polypropylene sample A is about as good as B at t=6 see, but B is four times better at high speeds. Similarly, NP0-ceramic sample A is slightly worse than NP0-ceramic sample B at low speeds, but A is definitely better at high speeds. And some Mylar capacitors (sample A) get better as speed increases from 1000 to 100 µsec, but others (sample B) get worse. So if you want consistently good performance from your capacitors, evaluate and specify them for the speed at which they'll be used in your application. Keep in mind that because most sample/holds are used at much faster speeds than those corresponding to the 1- or 5-min ratings usually given in data sheets, a published specification for dielectric absorption has limited value.

In addition, other dielectrics furnish various levels of performance:

- Because any long word that starts with poly seems to have good dielectric properties, how about polycarbonate or polysulfone? No -- they are about as bad as Mylar.
- Does an air or vacuum capacitor have low soakage? Well, it might, but many standard capacitors of this type are old designs with ceramic spacers, and they might give poor results because of the ceramic's hysteresis.
- If a ceramic capacitor is not an NP0 device, is it any good? Most of the conventional high-K ceramics are just terrible -- 20 to 1000 times worse than NP0 and even worse than tantalum.
- Is silicon dioxide suitable for small capacitances? Although Fig 5's test setup, used in preparing Fig 7's chart, only measures moderate capacitances (500 to 200,000 pF), silicon dioxide appears suitable for the small capacitors needed for fast S/Hs or deglitchers.

Cancellation circuit improves accuracy

A practical method of getting good performance with less-than-perfect capacitors is to use a soakage-cancellation circuit such as one of the form shown in Fig 8, in which a capacitor of the type modeled in Fig 4 serves as an integrator. (Only the first two soakage elements are shown.) The integrator's output is inverted with a scale factor of -0.1, and this voltage is then fed through one or more experimentally chosen RC networks to cancel the equivalent network inherent in the capacitor's dielectric material.

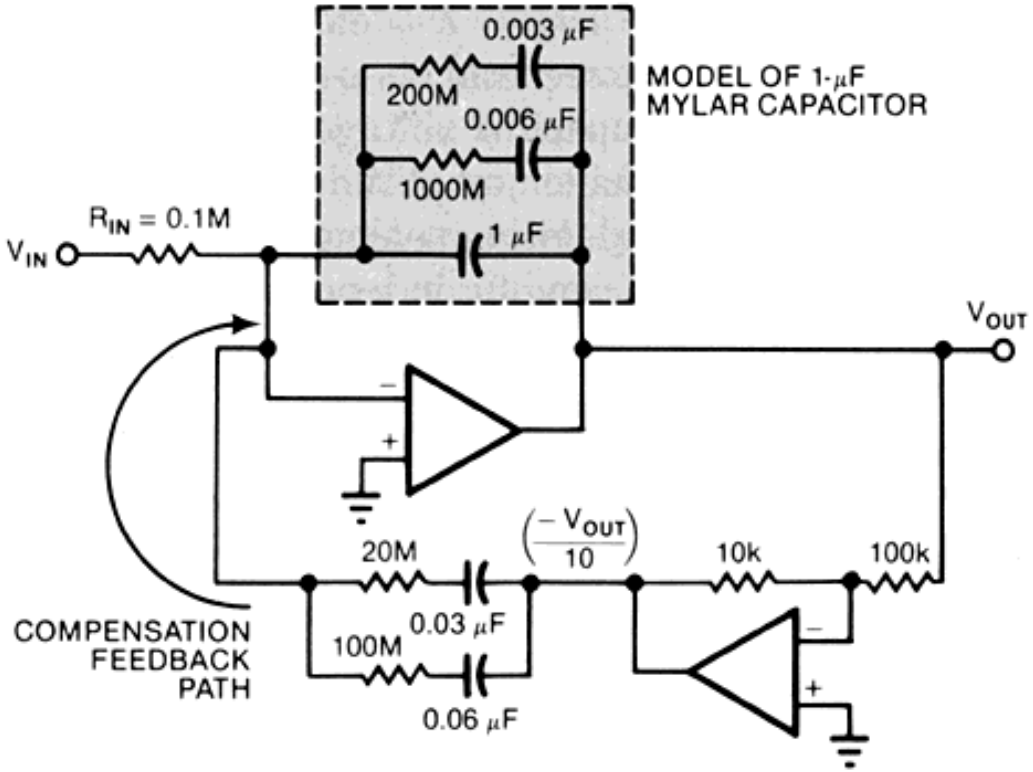

Fig 8 - You can compensate an integrator for dielectric absorption by feeding its inverted output back to the input through one or more experimentally chosen RC networks, which cancel the equivalent network inherent in the capacitor's dielectric material.

Fig 9 shows a practical sample/hold circuit with an easily trimmed compensator. This network provides about a 10-fold improvement for sample times in the 50- to 2000-µsec range (Fig 10). Although this compensation is subject to limitations at very fast or slow speeds, the number of RC sections and trimming pots employed can be extended.

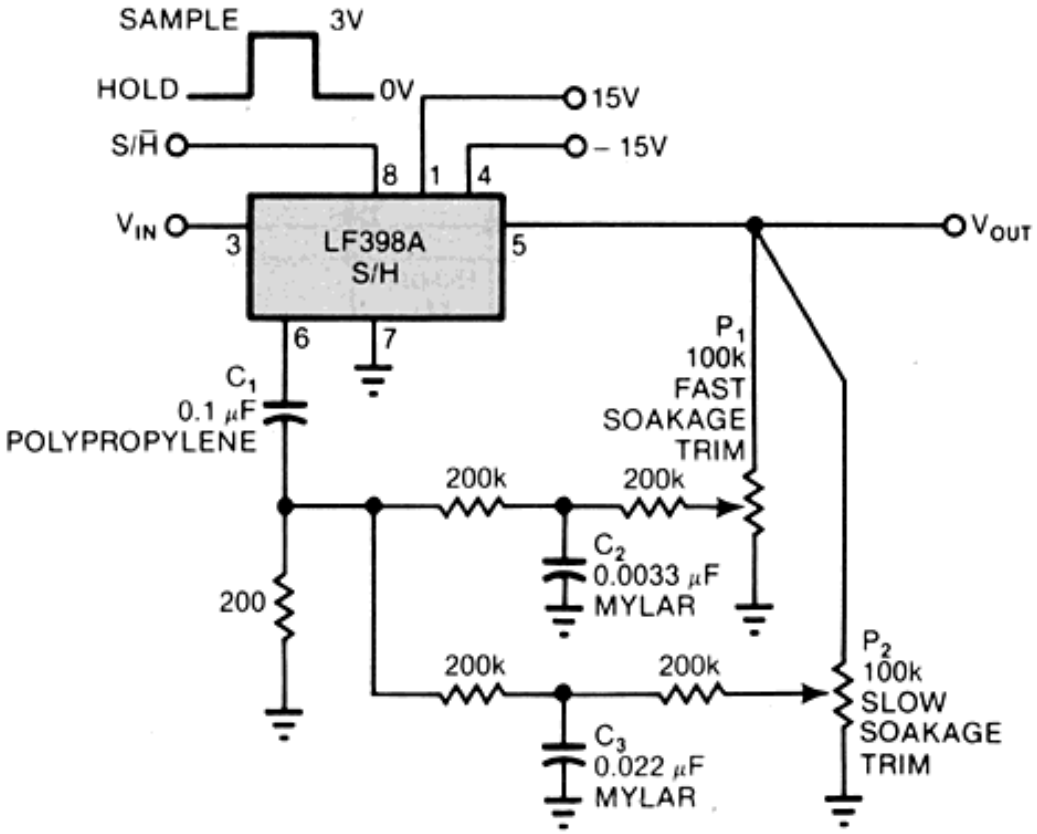

Fig 9 - Adding compensation circuitry to a sample/hold yields better-than-Teflon performance with a polypropylene capacitor. Using Teflon capacitors in such circuits can yield a 15- to 17-bit dynamic range.

Simple circuits similar to Fig 9's or Fig 8's have been used in production to let inexpensive polypropylene capacitors provide better-than-Teflon performance. In turn, using these compensator circuits with a good Teflon capacitor furnishes a dynamic range of 15 to 17 bits.

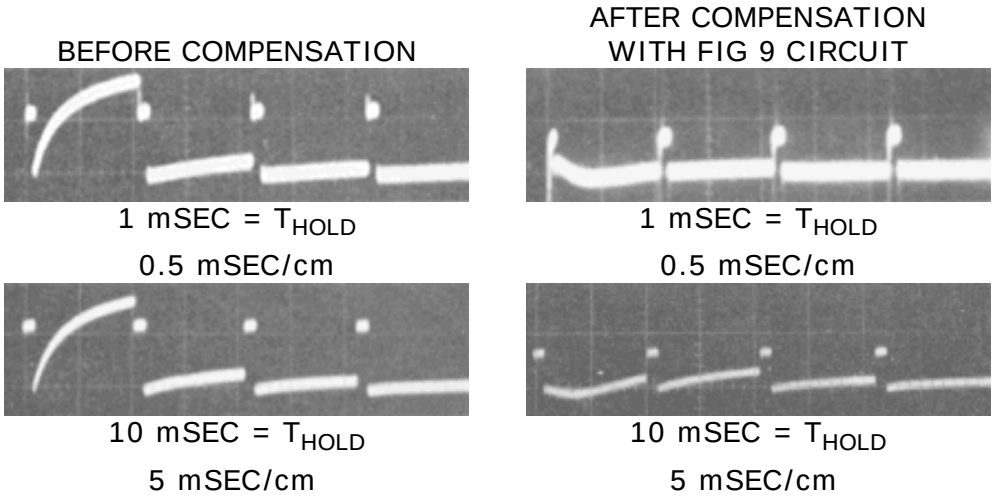

Fig 10 - Adding Fig 9's compensation network to a sample/hold circuit yields a 10-fold performance improvement for sample times of 50 to 2000 µsec; additional RC networks and trimming pots can extend the time range. The short pulses represent normal S/H jumps and occur during the sample time. The exponentially rising waveform during the hold time results from soakage. Note that soakage effects are still visible during the second hold period.

RAP Update: *FIFTEEN years ago, back in 1982, when I wrote this, I had never seen any study of capacitors and their "soakage" -- nor of the kind of circuits you could use to shrug off the effects of soakage. Nobody ever talked about this, at high speed.*

To this day, I have not seen any other articles that covered either subject. So this is still about the prime source of info on how to evaluate capacitors for soakage, AND how to build good Sample-and-Hold circuits, so as to NOT get hurt by that soakage.

Introduction To Capacitors

release 3.7

"...has many omissions and contains much that is apocryphal, or at least wildly inaccurate..."
Douglas Adams
The Hitchhiker's Guide to the Galaxy

This site started out as a simple exercise in web page making that sort of got out of control. Once I started writing, I found it hard to stop.

A few disclaimers: Some of the information in this "FAQ" should be considered to be generalities. Material source, processing and capacitor construction can greatly affect a capacitor's electrical properties. Different manufacturers tend to have different opinions on the characteristics of their dielectric materials. For example, most show polystyrene as having a slight negative temperature slope while at least two show it as being slightly positive. When in doubt, contact the manufacturer to guarantee that the parameter you are interested in is good enough for your needs. This is especially true when using the various graphs. These should be used more for comparing different capacitor types than for hard design data. That is best obtained from individual manufacturers. In some cases, construction variations so distort the basic capabilities of the material that it seemed best not to include graphical data. When using charts of dielectic characteristics, it is best to look at a number of sources. One chart for example, shows the dielectric absorption of mica to be around 0.003%, another shows it to be more like 0.5%. They can´t both be right (.5% is probably closer).

Another disclaimer: If the graphs sometimes look a little odd (less than optimal colors for example) blame Microsoft. Translating Excel 2000 graphs to GIFs does not seem to work as well as with earlier versions of Excel. I´ll look into this someday. Drawings made in TurboCAD were another problem. No program I have can both import them correctly, and correctly export them to GIF format. The next version may correct this.

Much of the available quantitative information of capacitors is not very complete. Dissipation factor vs. temperature is almost always shown for 1 kHz. DF vs. frequency is normally shown for 20C or 25C. If you want to know the DF of polyester at 95C @ 20 kHz, you will probably be out of luck. Certainly the manufacturers have some of this sort of information (the good ones anyhow), but it is rarely published. It´s the rare hobbyist who needs to know that sort of thing however. If you are looking for information on just the dielectric, as opposed to a finished capacitor, the material manufacturers often have very complete information.

On the other hand, as consumer electronics moves into GHz frequencies, designers need information on dielectric behavior that may not yet be available.

Some capacitor parameters are difficult to measure with good absolute accuracy. An instrument for measuring dissipation factor for example, may give good relative results for comparing different capacitors, but not agree with another brand of instrument on the actual numbers.

The information given here is as good as I can make it, which probably means it has its share of errors. There are also many omissions; my main interest is in analog electronic applications so that is how this FAQ is oriented. There is some mention of high-power capacitors, but sort of thing is too specialized for good coverage here. This is meant as an introduction to capacitors, not a book. This FAQ is aimed more at students, hobbyists, scientists, and new engineers than at electronics "insiders". It does not (yet) contain a dictionary of terms, that has been done by other people. Not covered are some specialized types like feed-through capacitors and trimmers. In any case, there are references to other sources for some of the things I omitted.

This is also a good place to note that some limitations mentioned, like size, voltage ratings, packaging, temperature

ratings, etc., will usually only apply to high-volume capacitor manufacturers. There are specialty manufacturers who can make most anything you can think of.

What is a Capacitor?

A capacitor is a energy storing device made up of two parallel conductive plates separated by an insulating (dielectric) material. When a voltage is applied across the plates, the electric field in the dielectric displaces electric charges, and thus stores energy. It is assumed that there are no free charges in the dielectric (at least in the ideal case), and that while they are displaced, they are not free to move around as in a conductor. The closest analogy in the mechanical world is probably energy stored by a spring. Dielectrics come in two types, "polar" and "nonpolar". Molecules where the "center-of-gravity" (as it were) of the negative and positive charges are at the same point are nonpolar. If this isn´t the case, the molecule is polar. H_2O, for example is polar, but H_2 is nonpolar.

The plates may be actual metal plates of various shapes but are most often in the form of metal foil or a metal film deposited on the insulating material. Since the first capacitor was invented, the Leyden jar, almost every conceivable dielectric material and form has been tried by someone. Wax, paper, plastics, ceramics, glass, oils, minerals, electrochemical films, air, etc., either alone or in combination such as paper/wax, paper/epoxy, plastic/plastic, paper/oil, plastic/oil have been used, to name just a few. Some people seperate capacitors types into "electrostatic" and electrolytic". This is really an artificial distinction, more of a construction detail than a fundamental difference.

Characteristics

The reason for the many types of capacitors is cost and performance. Different capacitor types are better at different things. No capacitor is just pure capacitance and there is no perfect capacitor at the perfect price. Every capacitor type has a number of parasitic elements associated with it such as leakage, ESL, and ESR, plus special quirks all its own. This makes it tricky to select just the right capacitor for every application.

Factors of concern to the user include (but are not limited to):

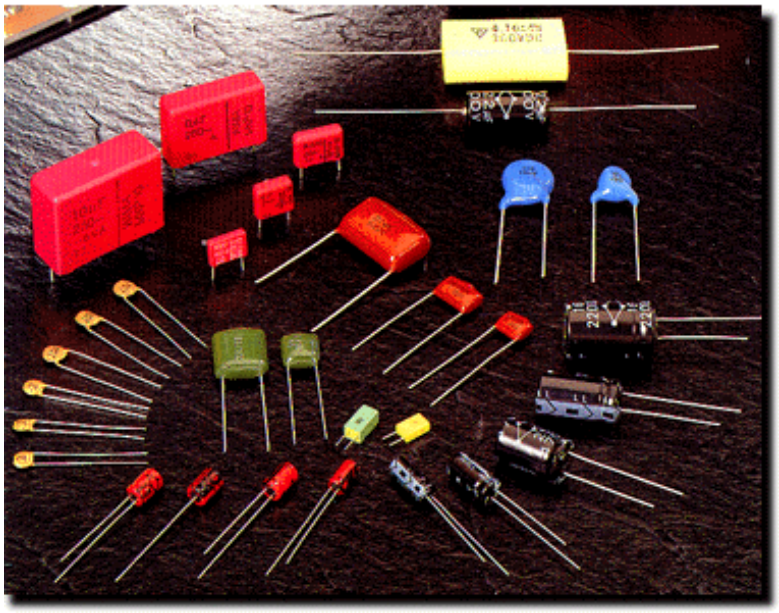
- Aging rate, mostly of concern for ceramic capacitors although all capacitors age, however little. Film capacitors typically age less than 1% over their life, while some ceramics may age >10%. With films at least, manufacturers tend to disagree over exact numbers. This is probably due to differences in test methods.
- **Capacitance vs. frequency**, determined by both the dielectric and construction details.
- **Capacitance vs. size** (or "volumetric efficiency") . Mainly determined by the dielectric constant (K) (sometimes called "permittivity") of the dielectric and its voltage breakdown vs. thickness. For a given dielectric, size tends to vary as the square of the voltage rating. This is a crude approximation at best. It assumes that the dielectric makes up most of the volume of the capacitor. In some capacitors, the packaging and associated materials actually makes up most of the volume. It also assumes that the breakdown voltage increases linearly with the thickness of the dielectric, also a dubious assumption.
- Capacitance Drift vs. Temperature, normally given as ppm/deg C. Every dielectric has a different temperature slope. This can be as low as +- 30 ppm/C for C0G ceramics (even +-15 ppm/C for special porcelain RF capacitors) to thousands of ppm/C for electrolytics and some plastic films. An old trick for getting reduced drift is to parallel two capacitors which have opposite temperature drifts, such as polyester and polypropylene, or polystyrene and polycarbonate. The temperature drift for a given dielectric can vary from one manufacturer to another however, making this technique uncertain. Polycarbonate for example, is shown by some manufacturers to have a slightly positive slope, and slightly negative by others. Caps with mixed dielectrics exist, but are not common.
- **Capacitance vs. voltage**, mostly of interest for Class 2-4 ceramic capacitors, and for some glass types.
- **Cost and availability.**
- **Current-carrying capacity**, of concern when the capacitor must handle high alternating current which would cause self heating. This a problem for electrolytics, and for film and ceramic capacitors used in high frequency and/or high current applications. Manufacturors often have guidelines.
- **Dielectric absorption** (or DA), sometimes called "soakage", "voltage retention", and other things. In high-voltage power cables it´s called "return voltage". A capacitor, once charged, stubbornly retains part of the charge, even after being discharged (shorted for some number of seconds), as if it had "soaked" into the dielectric. DA is modeled as an infinite series of RC networks in parallel with the primary capacitance, where the Rs are mostly very large and the Cs are smaller than the nominal capacitance. DA is a source of error in precision integrators and sample-and-hold circuits. Large high-voltage oil-filled capacitors (exceptionally high DA) can be shorted, yet retain enough charge to be dangerous. They are normally shipped with a short across the terminals that should not be removed until the part has been installed. High-voltage capacitors in TV sets are also still dangerous after being discharged, as is the parasitic capacitance in large oil-filled, high-voltage transformers and some high-voltage cables. There is a "standard" test for

DA (actually, everyone seems to do it a little differently). The capacitor is charged to some voltage for one minute (often 100 volts, but others can be used), and is then shorted for two seconds. After one minute, the recovered voltage on the capacitor is read using a very high impedance meter. The DA is expressed as the ratio between the recovered voltage and the charging voltage, in percent. MIL-C-19978D calls for a 5 minute/5 second/1 minute sequence. These tests are useful for comparing dielectrics, but don't really tell you just how a capacitor will perform in your application. In particular, the difference in DA of various dielectrics as seen one minute after the short is removed does not necessarily precisely correlate with the difference in DA as seen in the first few 10s of ms. In general, Teflon, polystyrene, and polypropylene are the best (as low as 0.02%), while the electrolytics, high-k ceramics, and oil-filled are the worst (1% on up). Impregnated film caps tend to have a DA that reflects the impregnant more than the film. Given the RC model for DA, it would make sense that the dielectrics with the highest insulation resistance (which also tend to have the lowest dielectric constant) would have the lowest dielectric absorption. There is also a significant difference from part to part. However, while the RC model is usefull for predicting how DA will behave, it does not reflect the underlying physics. See Space Charge. Also see: http://www.national.com/rap/Application/0,1570,28,00.html

- **Dissipation factor** (DF), of concern for AC power applications. DF is usually expressed in % or in ratio to unity (1% = .01). DF is equal to ESR/X_c . Actually, this is an approximation which ignores X_l, but it is usually close enough.

  Like most everything else about capacitors, it changes with time, frequency, and temperature. DF is the result of three loss factors. Metal losses (the resistance of the leads, end terminations, and the metal foil or film), the insulation resistance (mostly very small), and the dielectric losses. For film capacitors, film-foil types will have a lower dissipation factor than metallized film, especially at high frequency, because the metal losses will be lower.
- **Dissipation factor vs. applied voltage**, mostly of concern for Class 2 (and higher) ceramic capacitors.
- Dissipation factor vs. frequency.
- Dissipation factor vs. temperature.
- Equivalent series resistance (ESR), mostly of concern in high-frequency power applications and for power-supply filtering in high-speed digital systems. ESR is measured at different frequencies, depending on how a capacitor will be used. For cheap electrolytics this will be 120 Hz, for high-quality tantalums, it will usually be 100 kHz. Although measured in ohms, it is not independent of frequency, and in electrolytics, is somewhat higher at low frequency than at high frequency.
- **Equivalent series inductance (ESL)**, seen as an inductance in series. Mostly of concern for power-supply filtering in high-speed digital systems, and in RF applications.
- **Frequency range**. Some capacitors, like mica and C0G ceramic are usable to the GHz range. Others, like tantalum and polyester, become unusable somewhere in the 100 kHz to 1 MHz area (depending on construction details) due to loss of capacitance and increase in dissipation factor.
- Line filter capacitors. As a matter of safety, capacitors used to filter line (mains) power for electronic equipment, must meet strict performance requirements. The Europeans have lead the way in this, while American and Canadian requirements have been more lax.
- Insulation resistance (IR), seen as a resistance in parallel. This is referred to as "insulation resistance" when the leakage is very low (film capacitors), and as "leakage current" when the leakage is high (electrolytics). Electrolytic capacitors may have the most leakage, but it is also of concern for film capacitors in some analog applications (integrators, sample-and-hold circuits). For films, the lower the dielectric constant, the higher the insulation resistance tends to be. Data sheets normally state it in megohm-microfarads. To determine the IR for a given capacitor, divide the M-uF value by the actual capacitance. Although film capacitors and C0G ceramics have the best IR, all things being equal, low-quality ceramics can still work in some leakage-sensitive applications if the value is low, the voltage rating is high, and you can live with their other shortcomings.
- Markings. It can sometimes be a challenge to determine the characteristics of some capacitors from their markings. This partly due to size limitations, partly to a lack of universally followed standards, and partly to the failure to consistently follow the standards that do exist.
- **Mounting options**.
- **Noise.** Mostly of concern for electrolytic capacitors, due to leakage.
- Packaging and construction. Construction details and sealing methods can have a significant impact on performance and reliability. Most capacitor types require that air and moisture are sealed out to prevent degradation or contamination of the dielectric and corrosion of the metal film. The best Military-grade capacitors may be hermetically sealed in metal and glass. Lesser types may be molded in plastic, dipped in epoxy, or inserted in a plastic case and sealed with epoxy or urethane. The moisture absorption of the dielectric dictates the encapsulation methods allowed. As surface mounting of components replaces through-hole construction, a new problem faces the designer: can you get the capacitor you need in a surface mount package? Some capacitor types, like ceramics, are well suited to surface mounting. Others, like polystyrene and polypropylene, do not stand up to the heat of soldering and are not available for surface mounting.
- Reliability. Reliability and expected lifespan are of special concern in high-temperature, high-current, and high-voltage applications. However, capacitors used in more ordinary applications also have reliability issues.

- **Surge current capability**. Of concern for high-current pulse applications. Manufacturers will specify a maximum current or a maximum dV/dT (in volts/usec.) for capacitors rated for high-current applications.
- **Temperature limits**. Some dielectrics are limited to as low as 85C operating temperature while others can go to the 200-400C region. I have seen references to aerospace capacitors that can work to at least 1000C.
- **Voltage limits**, both operating and surge.



Capacitor Types

You can roughly divide all capacitors into four groups: film, ceramic, electrolytic, and miscellaneous.

FILM CAPACITORS

Film includes a variety of polymers, such as polyester, polycarbonate, Teflon, polypropylene, and polystyrene. Traditional film capacitors were only available in modest sizes, <10 uF. In recent years, film capacitors have sought to leverage their superior longevity compared to electrolytics, to move into some applications that call for much larger parts, even to thousands of uF. Film capacitors come in two broad categories, film-foil, and metallized film. Film-foil capacitors are made of alternating layers of plastic film and metal foil, while metallized film capacitors have the metal vacuum deposited directly on the film. In general, film-foil is better at handling high current, while metallized film caps are much better at self-healing. Various hybrid types can also be found.

Pros: The film capacitors mostly have reasonably well behaved electrical properties and offer many tradeoffs of performance and cost for people with precise requirements. The main parameters of interest include capacitance vs. temperature, dissipation factor, and dielectric absorption. Their main virtues include low leakage and low aging.

Cons: The main drawback of film capacitors is their low dielectric constants (K), which is only partly offset by their relatively good breakdown voltages. That means that film capacitors are physically large for their capacitance. Their Ks vary from a low of about 2.2 for Teflon to about 8 for PVDF (rarely used). Unfortunately, the rule-of-thumb is that the higher the K (and therefore the smaller the size), the worse the electrical properties tend to be. Film capacitors have not made an entirely graceful transition into the age of surface mounting. While some film dielectrics are suitable for surface mounting, most can't withstand the heat of soldering. Even polyester, the toughest of the traditional films, is barely good enough. However, capacitor makers have responded by developing several new dielectrics. SMD film capacitors are not as widely second-sourced as other capacitors however.

CERAMIC CAPACITORS

Ceramic capacitors offer a broad range of size vs. performance tradeoffs and are easily the most popular in numbers sold. Ceramic capacitors are available from < 1 pF to 1000s of uF.

Pros: The main virtue of ceramic capacitors are their relatively high dielectric constants. This can vary from C0G with a K of up to 60, which has excellent electrical properties but is relatively large and expensive, to ceramics with Ks in the tens of thousands but with very poor electrical properties. Large- value ceramics can compete with electrolytic capacitors in high-frequency applications like switch-mode power supplies because of their lower ESR. Ceramic capacitors are especially suitable for surface mounting due to their heat resistance, mechanical integrity, and the ability to make them in very small packages at low cost, for portable equipment. This has greatly added to their usage. To some extent ceramics are slowly displacing other types of capacitors.

Cons: Low breakdown voltage means that the low-K ceramics (Class 1), the ones with the good electrical properties, have poor volumetric efficiency, and are usually found only in small values. High-K ceramics (Class 2 and higher) have poor electrical properties, which are highly dependent on temperature, voltage, and frequency, plus a significant aging rate. Unlike many other capacitors, ceramics have no self-healing mechanism. This means that manufacturers must maintain a high level of quality control over the dielectric. Ceramics are most cost affective in small sizes at present. Very large ceramics are a bit of a challenge, especially in SMD.

ELECTROLYTIC CAPACITORS

"Electrolytic" means any capacitor that requires a conductive layer between the dielectric and one electrode. In the original electrolytic capacitor, the layer was an actual electrolyte, a conductive salt in a solvent. Some electrolytic capacitors today don´t actually use an electrolyte, but the word is still commonly used, to the annoyance of some. Electrolytic capacitors are made by growing a oxide film, the dielectric, on a metal, the anode, by electrochemical means. The films are very thin with fairly high Ks (roughly 10-25) which make for a lot of capacitance in a small package. The resulting devices pass current much better in one direction than the other, making a rectifier of a sort. Because of this, the metals are sometimes called "valve" metals. The metals presently used are aluminum, tantalum, and niobium.

Pros: Electrolytic capacitors are best used when you need a lot of capacitance in a small space and at a reasonable price, such as power supply filtering, or energy storage. They are available in sizes far beyond that of other capacitors. Aluminum electrolytics are presently available from 0.1 uF to several F. I have no idea why someone would use a 0.1 uF electrolytic capacitor however. Tantalum electrolytics are available from 0.1 uF to a few thousand uF.

Cons: Marginal electrical properties means that these capacitors must be applied with care. The parameters to be watched include leakage, service life vs. temperature, ESR, ESL, and low-temperature performance. Unlike other capacitors, electrolytic capacitors are not inherently non-polar, but non-polar types are available. Electrolytics are widely available in SMD packages, at least in moderate sizes, but users complain of more reliability problems than with through-hole styles.

MISCELLANEOUS DIELECTRICS

Miscellaneous capacitors include materials like glass, mica, porcelain, and even gas and vacuum. A few exotic dielectrics like silicon dioxide and sapphire are used in niche applications like microwave capacitors and trimmers. Some are available in surface-mount packages.

Pros: The electrical properties of the miscellaneous capacitors are generally most similar to film capacitors. However, they all have electrical properties that make them useful in some special applications.

Cons: These materials also have Ks similar to plastic films so they have no advantage in size. Except for mica, these capacitors are commonly available only in small sizes, <1 uF. They also tend to be more expensive than other capacitors of similar size.

Anyone who has corrections or additional information is more than welcome to contribute. If you have an idea for additional topics, expansion of existing topics, if something unclear, if you see an outright error, whatever, let me know. The site is still in its infancy, and I don´t really have a clear vision of what it will grow into. I would especially like to hear from the capacitor engineers of the world, they are the people who should have written this FAQ, but didn't. So far, my attempts to get these people involved has had limited success. It would be nice if an expert with specific knowledge would offer additional or corrected information not available to me.

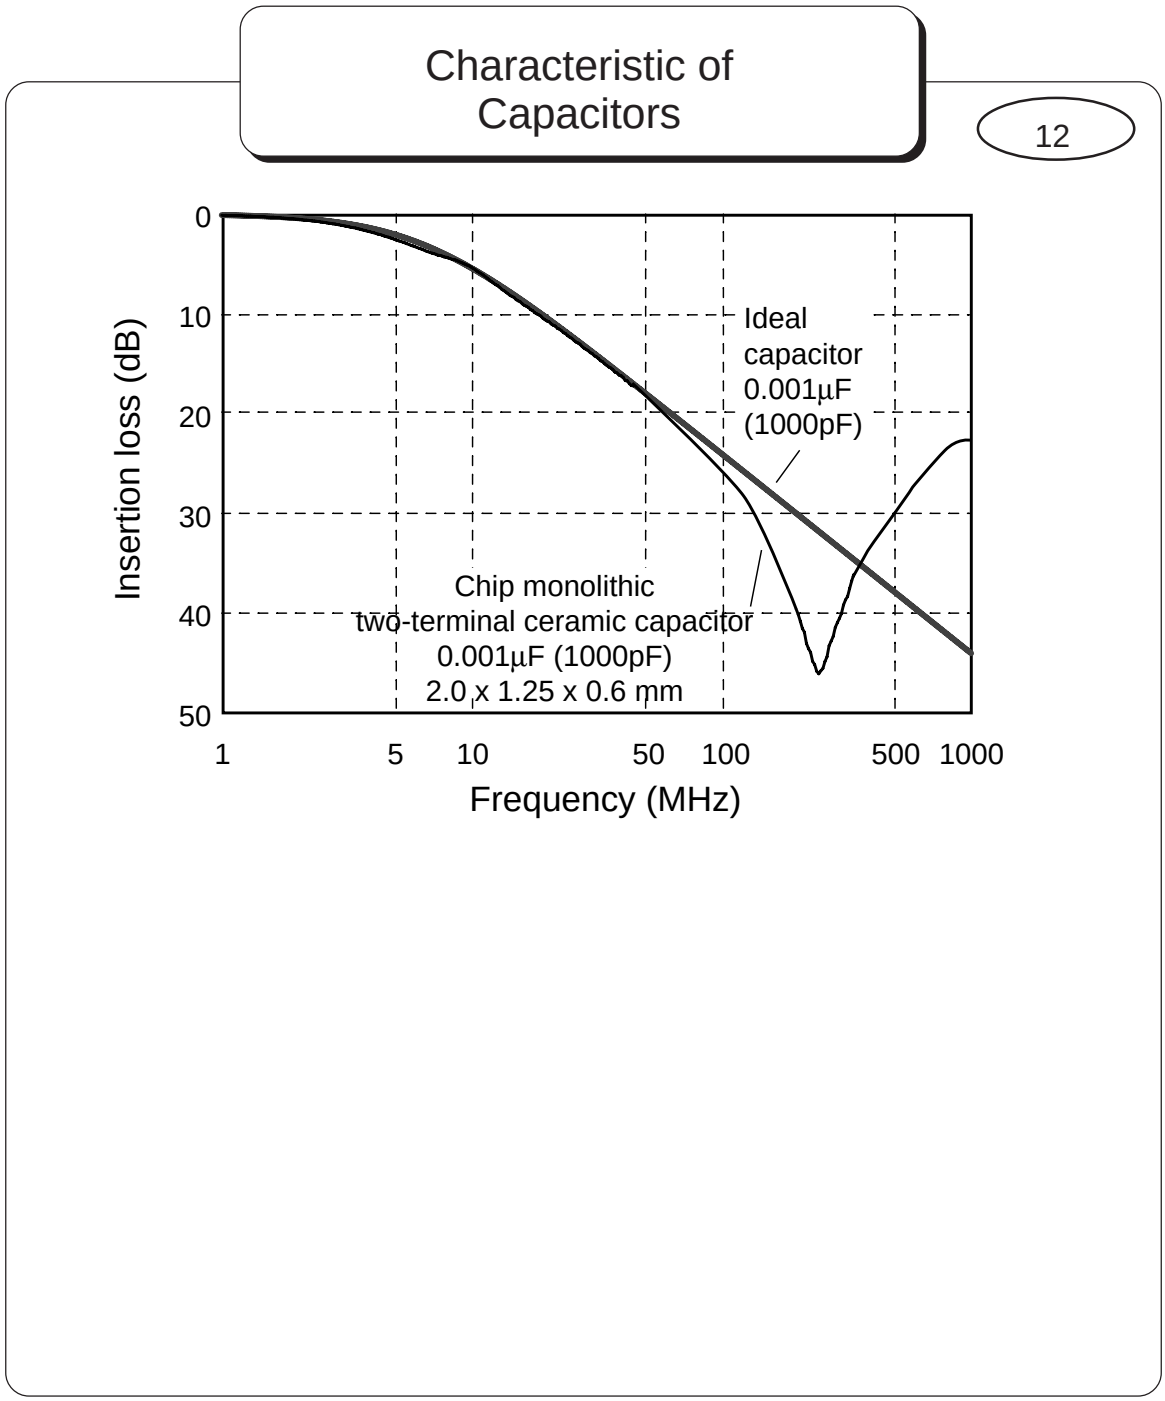
3. Noise Suppression by Low-pass Filters

3.5. The Effect of Non ideal Capacitors



This section and the following sections describe the necessity and performance of capacitor-type EMI filters.

With the ideal capacitor, the insertion loss increases as the frequency becomes higher. However, with actual capacitors, the insertion loss increases until the frequency reaches a certain level (self-resonance frequency) and then insertion loss decreases.

[Notes]

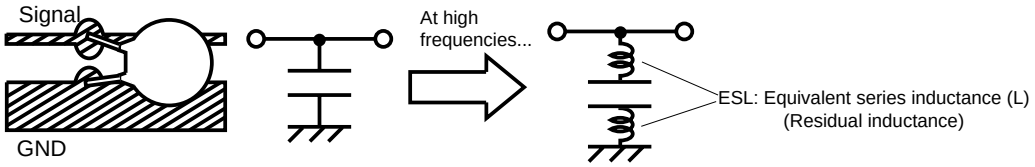
3. Noise Suppression by Low-pass Filters

3.5. The Effect of Non ideal Capacitors

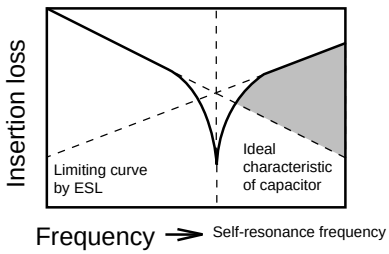
The Effect of Non ideal Capacitors

13

(a) Equivalent circuit of capacitor



(b) Effect by residual inductance



Self-resonance frequency

The frequency at which resonance occur due to the capacitor's own capacitance, and residual inductance. It is the frequency at which the impedance of the capacitor becomes zero.

From $j2\pi fL + 1/j2\pi fC = 0$,

$f = 1/2\pi\sqrt{LC}$

f: Self-resonance frequency

C: Capacitance

L: Residual inductance

[Notes]

The insertion loss of capacitors increase until the frequency reaches the self-resonance frequency and then decrease due to residual inductance of the lead wires and the capacitor's electrode pattern existing in series with the capacitance.Since noise is prevent from going through the bypass capacitors to the GND,the insertion loss decrease.The frequency at wich the insertion loss begins to decrease is called self-resonance frequency.

3. Noise Suppression by Low-pass Filters
3.5. The Effect of Non ideal Capacitors

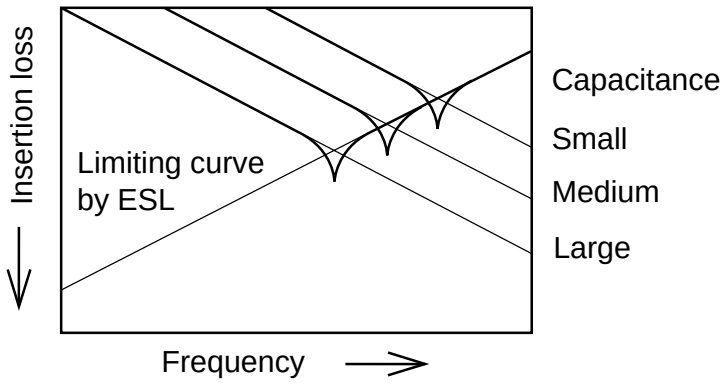
The Effect of ESL

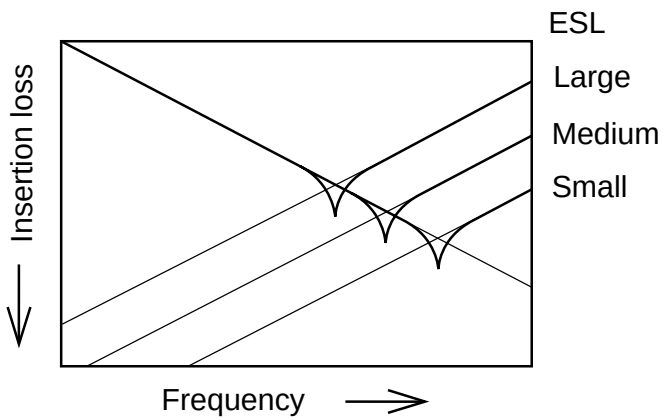
14

At frequencies higher than the self-resonance frequency, the insertion loss does not change regardless of whether the capacitance value is increased or decreased.

⇩

For use in a high-frequency range, a capacitor with a high self-resonance frequency, i.e. small residual inductance (ESL), must be selected.





[Notes]

When the residual inductance is the same, the insertion loss does not change at frequencies above the self-resonance frequency, regardless of whether the capacitance value of the capacitor is increased or decreased. Therefore for greater noise suppression at frequencies higher than the self-resonance frequency, you must select a capacitor with a higher self-resonance frequency, i.e. small residual inductance.

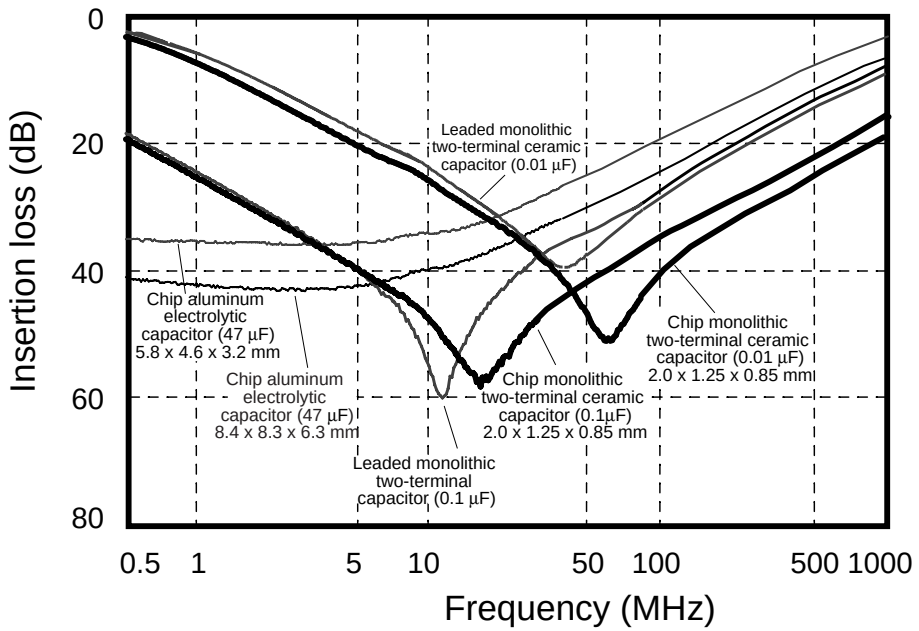
3.6. Characteristic of Typical Capacitors

Insertion Loss Characteristics of Typical Two-terminal Capacitors

15



[Notes]

The above drawing shows examples of insertion loss measurements of typical capacitors. For leaded capacitors, the insertion loss is measured with the lead wires cut to 1 mm.

3. Noise Suppression by Low-pass Filters
3.5. Characteristic of Typical Capacitors

Typical ESL Values for Capacitors

16

Type of Capacitor	Residual inductance (ESL)
Leaded disc ceramic capacitor (0.01 μF)	3.0 nH
Leaded disc ceramic capacitor (0.1 μF)	2.6 nH
Leaded monolithic ceramic capacitor (0.01 μF)	1.6 nH
Leaded monolithic ceramic capacitor (0.1 μF)	1.9 nH
Chip monolithic ceramic capacitor (0.01 μF, Size: 2.0 x 1.25 x 0.6 mm)	0.7 nH
Chip monolithic ceramic capacitor (0.1 μF, Size: 2.0 x 1.25 x 0.85 mm)	0.9 nH
Chip aluminum electrolytic capacitor (47 μF, Size: 8.4 x 8.3 x 6.3 mm)	6.8 nH
Chip tantalum electrolytic capacitor (47 μF, Size: 5.8 x 4.6 x 3.2 mm)	3.4 nH

[Notes]

The above table shows typical residual inductances (ESL) values for capacitors, which are calculated from the impedance curves shown on the previous page.
The residual inductance varies depending on the type of capacitor. It can also vary in the same type of capacitor, depending on the dielectric material and the structure of the electrode pattern.

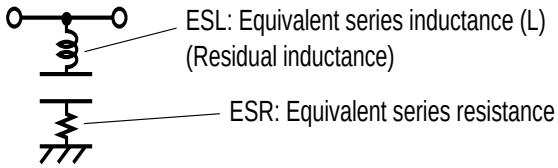
3. Noise Suppression by Low-pass Filters

3.8. The Effect of Equivalent Series Resistance

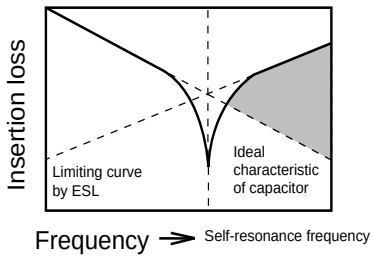
The Effect of Equivalent Series Resistance

20

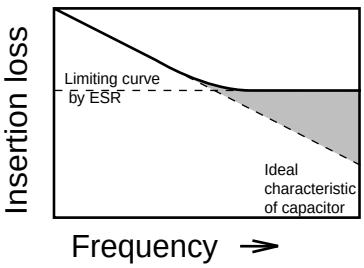
(a) Capacitor's equivalent circuit with ESL and ESR



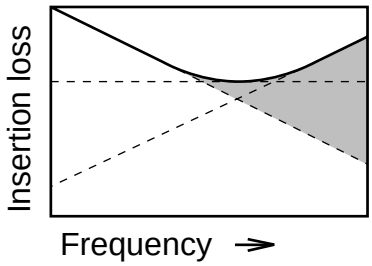
(b) Affect by ESL



(c) Affect by ESR



(d) Insertion loss frequency characteristic of actual capacitor affected by ESL and ESR



The second factor that causes deterioration in the characteristic of capacitors is equivalent series resistance (ESR). The insertion loss will be lower due to ESR caused by the electrode and material.

The ESR is very low in ceramic capacitors but higher in aluminum electrolytic capacitors.

- **Even a single, straight piece of wire has some inductance!**

We generally associate inductance with a loop or coil of wire. However, even a straight piece of wire, **or your electrode**, has some self-inductance. This can be important if you are dealing with low impedances at high frequencies.

- My good, old 1962-63 edition of the CRC Handbook is a wealth of information! It contains a section on "*Radio Formulae*" (ref 1) that gives the inductance of a straight piece of round wire or rod:

$$L = 2l\left[2.303\log(4l/d) - 1 + \mu/4 + (d/2l)\right]$$

In this equation, **L** is the inductance in nH (10^{-9} henry), ***l*** is the length and ***d*** is the diameter of the wire/rod (both in cm). **μ** is the permeability of the material (=1.0, except for iron and other ferromagnetic materials).

Wire Diameter (***d***) = [ ] cm

Wire Length (***l***) = [ ] cm

Permeability (**μ**) = [1.0] **(1.0 EXCEPT for IRON)**

The calculator, above, actually uses a slightly more complicated form of the equation (ref 2). The differences are small, even for fairly "squat" electrodes with ***d*** / ***l*** of 0.2 (x~1.005).

$$x = \sqrt{1 + (d/2l)^2}$$

$$L = 2l\left[\ln\left[(2l/d)(1+x)\right] - x + \mu\delta + d/2l\right]$$

Dielectric Constant Reference Guide

Dielectric Constant (k) is a number relating the ability of a material to carry alternating current to the ability of vacuum to carry alternating current. The capacitance created by the presence of the material is directly related to the Dielectric Constant of the material.

Knowing the Dielectric Constant (k) of a material is needed to properly design and apply instruments such as level controls using radar, RF admittance, or capacitance technologies. There are also analytical reasons to know the (k) of a material.

How to use this guide

CLIPPER CONTROLS has compiled an extensive list of products with Dielectric Constants. Many of these Dielectric Constants are given at specific temperatures. If your product's temperature is significantly different from those listed there is a good chance that the Dielectric Constant may be different from the values listed.

The products in this reference are listed in alphabetical order and are grouped in sections by the first letter of their name. Proper chemical names were used, and any trade names are the trademark of their respective owners. If you know the correct spelling of the name of the product you wish to review then use the "Search" feature on the web browser to locate the name in the list. You may also click on the letter from the alphabetical table to go directly to the beginning of that alphabetic section.

Mastering engineers discuss compression in mixing

Part I
Technical Guidelines for Use of Compressors

Here's an E-mail discussion I had with a U.K. engineer who discovered our web site.

> *I had a look at your web page and what a page! Exactly a page I have been looking for! I can't wait until you get it ready. I may say, could you add something about using compression, like how much to do by yourself and how much to leave to the mastering lab?*

First, let's define:

Com-pres'-sion

Email to Friend

1) Reduction of audio dynamic range, so that the louder passages are made softer, or the softer passages are made louder, or both. Examples include the limiters used in broadcasting, or the compressor/limiters used in recording studios.
2) Digital Coding systems which employ data rate reduction, so that the bit rate (measured in kilobits per second) is less. Examples include the MPEG (MP3) or Dolby AC-3 (now called *Dolby Digital)* systems.

This article is about *compression,* using concept #1 above. It's not good to refer to two different concepts with the same word, so please encourage people to use the term "Data Reduction System" or "Coding system" when referring to concept #2.

Now, for the basic two rules:

Rule #1: **There are no rules.** If you want to use a compressor/limiter of any type, shape and size in your music, then go ahead and use it.

Rule #2: **When in doubt, don't use it!**

How can you tell when you have *enough* compression*?*

- Discussing sound in print is like describing colors to a blind person, but let me try. Here's a simplistic example... supposing there are two sonic qualities of music, one called *punchy,* the other *smooth*... Let's say that some music sounds better *punchy*, other music sounds better *smooth.* Let's also assume for this example that you can achieve *punchy* or *smooth* sound through different amounts and types of compression, or not using compression at all.
- In general, *try to avoid overall compression in the mix stage if:*
  - you're mixing *punchy* music (the type of music that needs *punch*), perhaps using some individual compression on certain instruments or singers--and the mix already sounds *punchy* (good) to you.
  - you're mixing *smooth* music, and your mix already sounds *smooth.*
  - you play a well-recorded CD of similar music, and your CD in the making already sounds good (or better than) the CD in the player.
  - your music already seems to accomplish the sound you are looking for.

We'll discuss compression *esthetics* in more detail in Part II.

Technical reasons to avoid overall compression on your album
Save decisions on overall compression and individual tune equalization for an expert CD mastering house because:

1. The mastering house will have a more appropriate compressor with the proper attack, ratio, and release times exactlyright for your music. If you mixed to digital tape, they will probably use a 24-bit digital compressor for the purpose.
2. They will likely be more experienced than you about the compromises, advantages and disadvantages of applying overall compression.
3. The mastering house can program that compressor with precision, adjusting it optimally for each tune in question. You're working out of context (without having the perspective of the entire album) by attempting these sorts of decisions during mixing.
4. The mastering house will be able to monitor your "CD in the making" using a calibrated monitoring system so that they know exactly how loud your "CD in the making" is compared to other CDs of similar music. For more information on *loudness,* see my article Level Practices in Digital Audio.
5. A good mastering house will be able to do all of this in a non-destructive, non-cumulative manner. In other words, after making a reference CD, they will be able to undo anything you are unhappy with, whether it be compression, EQ or levels. Whereas, most digital audio editing stations can only perform destructive EQ or compression, only with 16-bit word length, with a consequent loss of resolution as long internal words are either dithered (resulting in a veil if further processed), rounded (slightly better than truncated), or truncated to 16 bit. For further information,see my article The Secrets of Dither.
6. For the same technical reasons, it is not a good idea to use a digital compressor (or any digital processor) on your material before sending it for mastering. If you do feel the need to nsert one of these boxes, for example, to give a demo CD to your client, be sure to also make a non-processed version to prepare for the mastering house. It is likely that the mastering house will have a fresher-sounding, more effective approach at polishing your material, and it's self-defeating if they have to try to undo what was done.
7. If you apply overall compression to your music, and your choice of compressor was wrong (e.g., the compressor you chose caused subtle pumping or breathing, loss of transients, loss of life or liveliness, etc. These are typical symptoms of "compressor misuse" on tapes I have received), the mastering house will have a difficult or impossible time attempting to undo the damage. As I've mentioned, mastering is like whittling soap; it is hard to undo compression. However, I do have some tricks up my sleeve (grin) that can restore some life to squashed tapes.

Part II
The Perils of Compression
or
The Ghost of CD Past

Introduction

24-bits, 96kHz, multichannel sound. These are some of the exciting features of the upcoming super audio disc. Before we can use these new capabilities to their fullest, we must learn not torepeat our past mistakes. Some of our engineering practices with the CD have done a serious disservice to the consumer. This article looks at one of those practices--overcompression of dynamics, and makes some recommendations that will turn the DVD (and new 16-bit CDs) into the true media of the future.

Dynamic Range - The Ups and Downs of Music

Before we can study the art of compression, we must learn to appreciate the power of music's dynamic range. How does music grab our interest? For short periods (about the length of a "single" played on the radio or in the disco), power and loudness can grab our initial attention. But at home, *variety of dynamics maintains our interest* for long periods of time. Good music written for a long-term musical experience contains a judicious mixture of variety and similarity in dynamics. A production which is relentlessly loud (or relentless in its sameness) can become boring very fast. At the age of 10, I learned the lesson of Franz Joseph Haydn's *Surprise Symphony,* the first composition to teach the importance of dynamic contrast. Musical genres that depend on constant sameness become old very fast. Disco died because it became boring, and I'm convinced that overcompression (which eliminates dynamic contrast) contributed to its death, by creating a continuously loud, boring dynamic. I wonder if the current slack in music sales is related to overcompression and its tendency to give everything a monotonous loudness--is the public voting against compression with its pocketbook?

Any genre that does not grow in musicality will quickly die, and dynamic contrast plays a big role in musicality. Today's Rap music has taken a 250-year-old lesson from classical composition, by beginning to incorporate a melodic and harmonic structure. The genre can further grow and avoid sounding tiresome by expanding its dynamic range, adding surprises. Silence and low level material creates suspense that makes the loud parts sound even more exciting. Five big firecrackers in a row just don't sound as exciting as four little cherry bombs followed by an M80. This is what we mean by dynamic range. Radio, TV and Internet distribution are currently too compressed to transmit the joy of wide dynamic range, but it sure turns people on at home, and also in the movie theater.

Films provide an ideal framework to study the creative use of dynamic range. The public is not consciously aware of the effect of sound, but it plays a role in a film's success. I think the movie *The Fugitive* succeeded because of its drama, but despite an aggressive, compressed, fatiguing sound mix. From the beginning bus ride, with its super-hot dialog and effects, all the crashes were constantly loud and overstated, completely destroying the impact of the big train crash. I can hear the director shouting, "more more more" to the mix engineers. Haven't

they heard of the term "suspense?" In contrast, the sound mix of *Titanic*, is a masterpiece of natural dynamic range. The dialog and effects at the beginning of the movie are played at natural levels, truly enhancing the beauty, drama and suspense for the big thrills at the end. Kudos to director James Cameron and the Skywalker Sound mix team for their restraint and incredible use of dynamic range. That's where the excitement lies for me.

Compressors as Tools To Manipulate Dynamic Range

Compression is a tool; when used by skilled hands, it has produced some of the most beautiful recordings in the world.A lot of music genres are based on the sound of compression, from Disco to Rap to Heavy Metal. And a skilled engineer may intentionally use creative compression to paint a mix and form new special effects; this *intended distortion* has been used in every style of modern music. This is analogous to the work of the greatest visual artists; many painters are quite capable of producing a natural-looking landscape, but have abandoned that medium to create abstractions which at first glance look like the fingerpaint work of a six-year-old. But a skilled observer realizes what the master artist is communicating. The keys here are *intent and skill.* Too often, in music, unskilled *compression* can *squash* sound, remove the life, vigor and impact, and replace it with boring mush. Many engineers don't know what uncompressed, natural-sounding audio sounds like. It actually takes more work and skill to make a natural-sounding recording than an artificial one. In audio as in the visual arts, first learn to paint naturally; then and only then can you truly understand the art of creating distortion. Learn where compression is useful, and where it does a disservice to the music. A compressed production may sound good on a boombox, but when reproduced on a high-fidelity system, it can sound overbearing and ultimately lifeless. That's why we may need to separately mix "single" and album cuts.

Compressors are commonly used in recording (tracking), mixdown, and in mastering. Everyone has his own style of working with compressors and there are no rules. However, before you make *your* rules, start by working *without any* compressors! This learning process will teach you to make better-sounding music later on; the compressor becomes a tool to handle problems, not a crutch or substitute for good recording techniques. First, learn about the natural dynamics and impact of musical instruments, then begin to alter them with compressors (which can include using compression to create special effects). Every 5 years or so, give yourself a reality check...try making a recording or mix with little or no compression. You'll rediscover what I call the *microdynamics* of music. It's a real challenge, but a refresher course may point out that *less compression* will buy you a more open, more musical sound than you've previously been getting.

Watch For These Compression-related Pitfalls

Tracking

When tracking vocalists (who have a habit of belting now and then), a well-adjusted compressor can sound reasonably transparent, and most engineers agree the cure is better than the disease. But watch out for a "closed-in" sound, "clamping down" when the vocalist gets loud, or loss of clarity or transparency. Compare IN versus BYPASS before committing to tape. Match levels to make a fair comparison. If you notice too much degradation, maybe it's time to consider a different compressor or change the settings you are using. The sound should be open and clear... remember that no amount of equalization in the mixdown can substitutefor capturing a clear sound quality in the first place. This is true for all the lead instruments, including trumpets and electric guitars. If possible, put the uncompressed sound on a spare track--it may save your life. If there's any "rule," most engineers would agree to save the decision on drum and percussion compression until mixing. There are always exceptions--every piece of music is unique. Just remember, you cannot undo the damage of overcompression, so be careful about compression during tracking.

Mixdown

There are two possible places to apply compressors during mixdown. The first is on individual instruments or stereo pairs; the other is on the console mix buss.

For individual tracks: The same precautions apply to the use of compressors in mixing as in tracking. Start fresh each time--free yourself of preconceptions. Although you compressed the bass on 9 out of the last 10 albums, maybe this time you won't need a compressor. Each musician is an individual. In general, the better the bass player, the less compression you will need to use, and the greater the chance that compression will "choke up" his sound. Get to know the sound of your instrumentalists. What is your mixing philosophy? Are you trying to capture the sound of your instrumentalists or intentionally creating a new sound? While more and more music is created in the control room, it's good practice to know the real sound of instruments; learn how to capture natural sound before moving into the abstract.

In pop music, compressors are often used to create a tighter band sound, making the rhythm instruments sit in a good, constant place in the mix. But when misused or overused, compressors can take away the sense of natural breathing and openness that makes music swing and sway. Thus, I recommend that during mixing, after you've inserted a few compressors on certain instruments (e.g., the bass, rhythm guitar, vocal) and listened for a while, try comparing with the compressors bypassed (automation makes that process easy; store two fader snapshots so you can switch between them). Many times you'll find the compression was hurting the mix, and not helping the sound, by losing the subtleties of the musician's performance. Learn the negative as well as the positive effects of compressors by proving to yourself that you really needed the compressor, or that degree or type of compression. The process of refining a mix should always include revisiting your compression (and EQ) settings and questioning your work. Most music these days is recorded in

overdubbed sections, but some performances are still captured at once. An engineer once told me that the best sound he got was the monitor mix on the recording day. By the time he got through slicing and dicing and remixing, all the life was taken out of it (what I call *the loss of microdynamics)*. So remember the sound you got during the recording...did you lose the magic in the mix?

Avoid Wimpy Loud Sound

Some of you may say that my conservative advice only applies to acoustic genres like country music or jazz. However, Rock and Roll music is often a casualty of compressor abuse. I receive rock mixes from well-meaning engineers that should be getting louder and louder and reach a climax, but which have lost their intensity, producing *wimpy loud sound*. The dynamics of choruses and verses are reversed. Instead of the chorus sounding lively and dramatic, it's been pulled back. When you go against the natural dynamics of the music, the results are less pleasant, and *less exciting.* I strive to put that kind of life back into sound during the mastering, and my clients are delighted by the results. You can make the mastering engineer's job easier. When you mix rock, listen closely to the climaxes; is it possible that you are killing the music with your compressor? This is a very common problem and only the most skilled mix engineers are able to overcome it, maintaining excitement all the way to the highest peaks. Many mix engineers have trouble handling the duality of rock; they find compressors give them power at mid levels, but they have trouble handling the climaxes; they want them to be loud, but can't seem to do it without overload or overcompression. If you're having those kinds of troubles, don't despair. Mastering engineers dislike getting squashed material, because the damage is really hard to fix (though some of the tools I apply are pretty darn effective). Better to send material that's mixed well and powerfully at the mid levels but at the high levels is not squashed. Even if the climaxes don't sound loud enough, consider it a "work in progress." Let the mastering engineer take it to the next level of performance. Using specialized and unique tools, I can remix your material, giving it the punch it needs at mid levels and strength and volume at high levels.

Buss processors

Let me be a bit dogmatic. Reserve "buss compression" or "overall compression" for the mastering stage. As a mastering engineer, I can unequivocally say that the most frequently abused compressor is in the console mix buss. Lately I've been receiving a lot of mixes that have been squashed to death by unintentional misuse or overuse of buss compression.

Overuse of buss compression

Properly-used buss compressors *can* make music sound louder and more powerful, possibly without deteriorating its character, but is the console mix buss the right place to be working on the loudness character of your music? *Absolutely not.* If you already have a great-sounding mix without buss compression, then don't add buss compression just to "beef it up." More often

than not, the buss compressor you have available will *take away the life of* your music. Turn up the monitor level if the music doesn't sound loud enough! By all means, leave questions of loudness character out of the mixing process and save them for the mastering stage, where they can be dealt with correctly and effectively (more about that in a moment).

Recently a potential client told me that he was using a little bus compression on his mix. I asked him why he wasd oing that. He said, "because I think the levels are a little too low." Please don't compress for that reason; if the "levels are too low," then turn them up! The only possible reason to bus compress during a mix is because "it sounds better" to you. I hope that in this article I have provided some useful ways of how you can judge that the mix really "sounds better" before you overall compress. Mixing "to the compressor" is also a bit like cheating. Your whole judgment becomes geared to what the compressor is doing rather than the act of mixing itself. When in doubt (and even when not in doubt), mix two versions, one with and one without bus compression, and send both to the mastering house. You may be surprised which version the mastering engineer chooses, and which one sounds better after mastering. Also remember, that not all compressors sound that good. The mastering house might be able to employ a digital compressor like the Weiss, which uses 40 bit floating point internal processing, double sampling, has extraordinary attack and release time flexibility. Or an analog compressor, like the Manley Vari-Mu. Both of these are examples of specialized mastering compressors with extraordinary sound.

One possible proper use of a buss compressor is to "tighten" a mix when individual compressors couldn't do the job. However, be careful not to squash the mix. Tuning a buss compressor is an art born of technical knowledge and experience. As always, compare IN and OUT very carefully, and don't be afraid to patch it OUT if that sounds better. Buss compression causes all the instruments to be modulated by the attack and transients of the loudest instrument. A rim shot or cymbal crash can take down the reverberation and the sound of all the other instruments. There are very few console compressors that are capable of doing buss compression without screwing up transparency, transient response or musical dynamics. Excellent circuit design is required, as well as attack and release characteristics idealized for the job of buss compression. Very few outboard compressors can handle that job. If you want to tighten the mix, first try using submix compression on the rhythm section alone. That way you won't abuse the clarity of the drums and vocal.

Stop Emulating Squashed CDs

Many mixing engineers compare their mixes against already-pressed CDs, but becareful what you choose as a standard. Ironically, mastered CDs often do not sound like what comes out of the mix, so how can you emulate something which can only be done post-mix? What you really need is to hear the sound of a good mix *before* it was sent for mastering. But since that's not available, choose from the plenitude of pop records that have been well-mixed and mastered, as listed

in the CD Honor Roll. When choosing a reference album, don't pick it because it's "hotter" than everyone else; instead, listen for impact, clarity, transparency, ambience, warmth, space, depth, beauty, openness, naturalness, and (sometimes) punch. But "punch" is an ambiguous term; any so-called "mastering engineer" with a $2000 processor can give an album a kind of "punchy" sound, but often sacrificing all the other character that makes music worth listening to. Remember this: when two CDs are presented at equal loudness, nine out of ten musicians prefer the sound of an uncompressed presentation to a compressed one. For the first few seconds, a louder presentation may grab you, but relentless sound quickly becomes fatiguing. Many of today's compact discs have already exceeded the loudness limit--the level above which the sound quality goes down hill while the sound "quantity" goes up. You can't get something for nothing.

If You Can't Make It Sound Good, Make it Loud?

Contrary to some people's beliefs, mastering is *not* supposed to be the process of making a record hotter than the competition. Mastering should be the process of making a record *better* than the competition. Currently there is a lot of pressure on mastering engineers to make a record hotter than its neighbor. I'm really surprised that more recording engineers are not up in arms about how mastering engineers (on producer's orders?) are ruining their recordings. I'm quite flattered that one recording engineer called me the first mastering engineer to make his recordings sound *better.* If you're a mastering engineer, wear the red badge of courage; strive for good sound, even if you have to sacrifice a few dB of loudness.

Clients often complain when they haveto turn the volume control up when switching CDs. Why aren't they complaining that they have to turn the volume down when a hot disc comes on? One client told me that she loved the sound of her master, but her test CDR was not hot enough when played in rotation on the CD changer in a local bar. This upset me, because it turned out she was comparing her CD against rather trashy-sounding competition and I didn't want to trash up her sound. In the bar, you can't tell the difference in sound quality, but we're making CDs to sound good at home. I told her that she would sacrifice quality if I made her CD any hotter. Ironically, it was already a hot CD, by the standards of last year and the year before, but obviously not this year! Oh, by the way, eventually I compromised, using my best skills to raise the volume on her CD slightly without sacrificing too much in sound quality, but it saddened me that this had to occur. Her CD would have sounded better if it were not as compressed.

The PARTY Button

CD changers present a real problem in client education. I had to tailor the apparent loudness of this client's CD to work with 5 other hand-picked CDs, but I could pick dozens more that are much louder or softer than hers. We have to teach clients that CDs will always differ in volume and that a CD changer is not a

radio station. The restaurant CD changer really needs a live DJ, but that's not practical. The solution: put a compressor in the restaurant, the car, and the jukebox, and reserve quality listening for the home, without compression. We should lobby manufacturers to put a compressor button on receivers and future DVD players; with DSP technology this is a snap. They could label it the **Party Button**! There should be three compression settings--for background listening at low levels, for moderate listening in a noisy environment, and for parties, whereyou want to switch discs without adjusting the volume control. Panasonic and Sony will sell a million of them, and we engineers will be eternally grateful! The button may be misused by ignorant consumers, but no more than the loudness button I find permanently pushed in 6 out of 10 homes.

Save it for the Mastering

When you're through mixing, your recordingis a diamond in the rough, it's not supposed to sound like a "record" until it is mastered. Just make sure the mixes sound great and wait for mastering to add any post-mix processes. When you make copies for your clients, if they have any problems, tell them to turn up their monitors and wait for the mastering. Don't be tempted to use so-called "mastering processors" ("maximizers")before the mastering begins. As mastering engineers, we want to receive the cleanest, highest resolution, unprocessed, original mix tape or disc. In mastering, the individual songs will be levelled (not "normalized"), and elements of your music defined and clarified, turning your record into a work of art. The mastering engineer objectively looks at every song in context in a controlled, familiar acoustic environment, using superior tools, monitoring, experience, and artistry.

The Vicious Circle of Loudness Envy

The practice of overcompression is partof a vicious circle of loudness envy. Sadly, the current crop of CDs is louder and even more squashed than its predecessors because few people have stood up to fight the problem. Participants in this unwitting vicious circle include mix engineers, musicians, producers, mastering engineers, and radio program directors, but the problem is introduced during the mastering process. Many people blame the program director for the problem, but I think we're all partly at fault. Regardless of the cause, we all have to participate in a solution before our music turns into mush.

Program directors should realize that the sound on their office CD player has little to do with the disc's on-air quality. PD's may think the loudest record they hear is the best, but they forget that when it gets to the air, on-air processors will squash it (drop the volume) more than other records. Producers are afraid that the PD will reject their record if they have to turn up the volume. But by now, hot CDs have put the PD's volume control at the bottom of its travel, so where dowe go from here? Well, let's get the program directors to make decisions on the merits of the music, not on its loudness character. One way to solve that is to install a compressor in the PD's audition system, one that'll squash music as much as his radio station does. We could call it **The**

Ecumenical Button. Send me suggestions to see how we can get this one done (no kidnapping, please).

From The Sublime to the Ridiculous

roducers don't seem to like making a CD that's even a little softer than the competition, so each succeeding CD is often a little bit hotter. Just how much hotter can CDs get? I can cut a CD that's **16 dB louder** than the ones we made in the early 90's, before digital limiters became popular, but it'll look like a square wave and soundlike audio cream of wheat! Imagine the consumer problems caused by large variations in loudness--switching CDs has literally become Russian Roulette, shooting out our speakers and ears! But ultimately, your hot CD doesn't get any louder for the public; they just turn their monitor down, and scream in disgust at the increasing range they have to move the knob when they change CDs. In addition, sound quality is suffering by an unjustifiable demand for hotter CDs. A fellow mastering engineer reminds me that in the early days of CDs, we didn't have any pressure to make them hotter (because there was little competition), and early pop CDs had good, open sound. They're much softer than current CDs, but if you turn up your volume control you'll see their dynamics are much better-sounding. Why do we have to go backwards in sound quality? We mustn't repeat this mistake with the DVD. Part II of my article on Levels discusses 21st century solutions to this problem.

Let's review the basics. The loudness war may have begun with analog records, but the current problem is many decibels worse than it was in analog. LPs were mixed largely with VU meters, which created a degree of monitoring consistency, but today's peak level meters give entirely too much more room for mischief, and today's digital limiters provide the tools to do the mischief. The net result: great consistency problems in CD level. The peak meter is currently being seriously misused. Remember that *the upper ranges of the peak meter were designed for headroom, not for level.* A compressed piece of music peaking to -6 dBFS can sound much louder than an uncompressed work peaking to 0. Mixing and mastering engineers, use compression for creative purposes, but why not master the CD at a lower peak level, and monitor at the same gain you used for your last CD? There's no reason to fill up all those bits if the CD sounds loud enough. Or, useless limiting if you insist on peaking to 0 dBFS. Too many producers are unskilled meter readers; they seem to need all those lights flashing. Try working at a fixed monitor level, with the meter hidden from view. It'll be a very educational experience.

It's come to the point where mastering engineers should think about working differently. In Part II of my article on Levels, I discuss the 21st century solution to this problem, because the future of our DVD Audio is at stake. Only education can stop this vicious spiral. It's time to fight for quality, not quantity. Sound lower than XYZ hit record?Turn up the monitor!

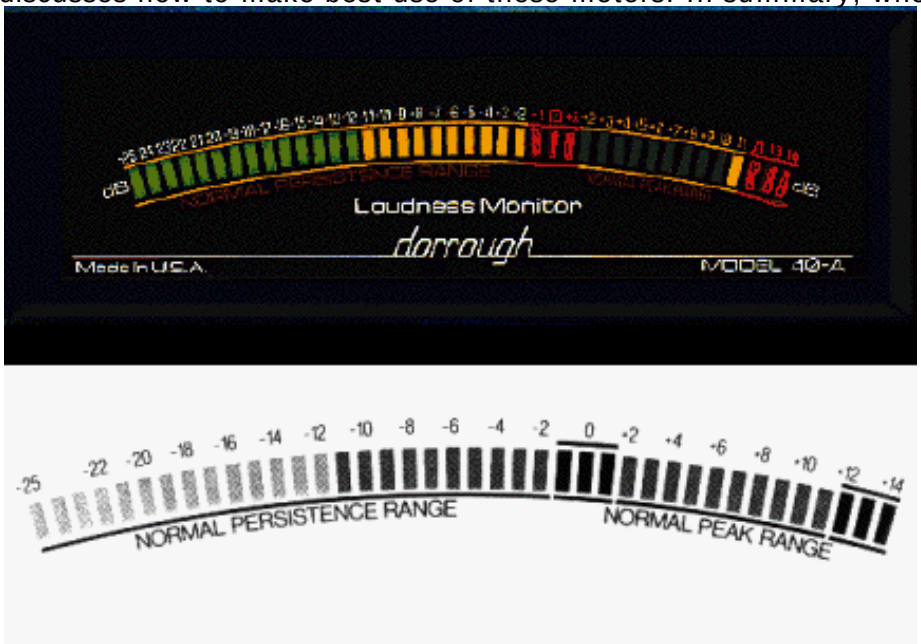
Part III
Tools To Help Keep Us From Overcompressing

How can you tell when *proper compression* is becoming *overcompression?* If you don't have good monitors, it's not easy to know when you've crossed the line. The first sign that you're probably going too far is if you start playing with the compressors simply to achieve overall program "loudness" rather than to help you make a great sound. Remember, the mix room is for mixing. If you know you've got a great sound when the monitor is turned up, then all is ok, the mastering engineer can do the rest. The second sign you're probably overcompressing is if you find you're leaning too much on the compressors to make your mix. A program shouldn't mix itself. It takes a lot of work to mix, and depending on the compressors to do that work for you will probably result in a squashed, lifeless sound.

Here are some practical tools you can use to make better-sounding recordings to send to the mastering studio.

1) As mentioned above, install a *Dolby-level-calibrated monitor control, connected via a single, high-quality D/A converter.* Visit Part II of my article on Levels for more details.

2) *Metering*. Meters with combined peak and average readings are some of the best protections against overcompression. The Dorrough meter is a good example, as are meters from DK and Pinguin. Part II of my article on Levels discusses how to make best use of these meters. In summary, when mastering, try to keep the "average level" on this meter's average scale from exceeding 0, with occasional "high average levels" to +3 (equivalent to +3 on a VU meter). If you do, you will have obtained approximately a 14dB peak



to average ratio. (Peak to average ratio is also known as *Crest Factor).* The meter is also a good visual aid for visiting producers.

3) *Monitoring.* A clean, high-headroom monitor system is essential. If your monitor speakers or amplifier saturate, how can you possibly tell if your material is saturating?

Recording and Measurement Microphones

Rod Elliott (ESP)

PCBs for the discrete mic preamp and a complete housing are available - click on the image for details

Introduction

The purpose of this article and small group of projects is firstly to introduce the electret microphone into the ESP projects lineup, and secondly to allow the reader to build a microphone that although uncalibrated, can be used to great effect as a measurement mic with any loudspeaker project, or for very high quality recordings.

Traditionally, measurement microphones are calibrated, so that the exact output level for a given SPL is known, and so that the frequency response is predictable and accurate. These are fine goals, but few hobby speaker builders can afford (or can justify) the expense of a fully calibrated measuring set, or even the microphone by itself.

The measurement mic project here is not calibrated for level or response, but relies on the reasonably predictable performance of electret microphone units. These are readily available, very cheap (less than $5.00 in any currency), and are usually surprisingly good.

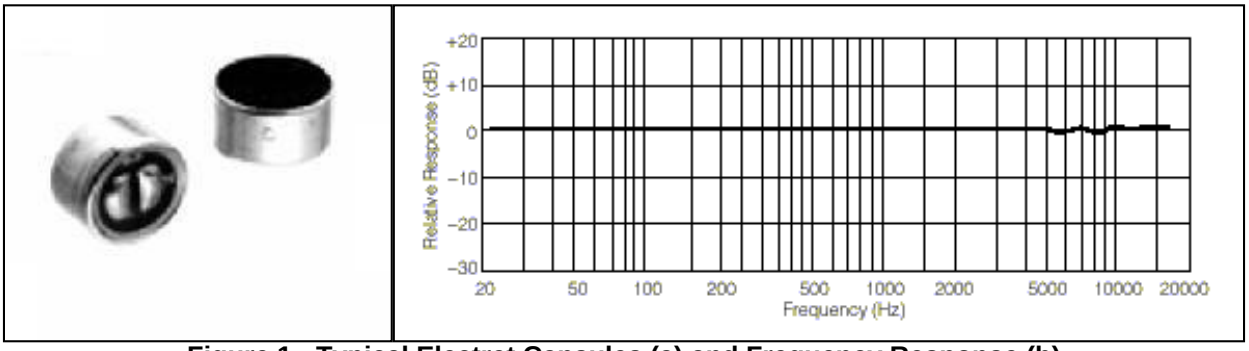

Figure 1 - Typical Electret Capsules (a) and Frequency Response (b)

Figure 1 shows what they look like, and a typical frequency response (Panasonic capsules and response are shown - but this is also typical of many others). This is extremely good performance, and is fairly close to what you can expect.

Additional microphone projects will be presented when I get the opportunity, with some hopefully interesting variations to the concept of a basic microphone as described here. Most applications will require a directional mic, and these will be discussed in the next article. Unfortunately, the casing is much more complex and critical for a directional mic than for an omnidirectional version - fortunately, measurement mics need to be omnidirectional, so that limitation is not a problem ... yet.

Powering

Traditionally, electret mics are powered from a 1.5V cell, in a very simple circuit as shown in Figure 2. Shown is the schematic for a Radio Shack "Boundary" microphone, and this is actually more complex than most - the inductor is not usually used. Like all such simple circuits, this has some very real disadvantages.

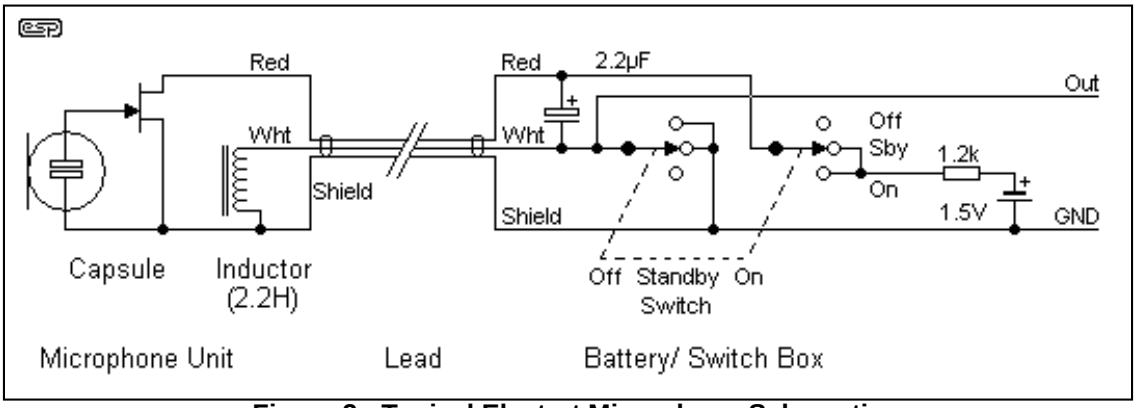

Figure 2 - Typical Electret Microphone Schematic

The disadvantages of the standard method (and commercial electret microphones in general) are ...

1 Output impedance is relatively high (typically about 1k to 5k)
2 Signal output is limited (relatively low sensitivity)
3 Noise is relatively high
4 Sound level handling ability is low (typically <90dB SPL)
5 They are normally available from retail outlets very cheaply

These have caused such mics to have a poor reputation, however, with some additional work excellent results can be achieved. The first objection is easily resolved with an opamp to buffer the output, making sure that the output impedance is kept low. It is easy to achieve an impedance of 100 ohms or so, and this will drive any mixer.

The second objection is resolved by increasing the supply voltage. 1.5V is simply too low to be useful, and a supply of 9V or more is recommended. This in turn solves the next two problems as well, since with more signal from the mic the noise contribution is lower, and a higher supply voltage allows much more output voltage before distortion.

The final objection remains, and we can't change that, but we can use it to our advantage. The idea that something so cheap is capable of excellent performance is somewhat disconcerting - the expectation is that if it is very cheap, it cannot have high performance. This is actually not the case at all.

I have used a modified hyper-cardioid electret mic (which cost less than $50 at the time) and achieved excellent results for recording voice announcements. In many cases, the quality was better than that from a professional studio, even though the recordings were done in an ordinary (but reasonably quiet) room, and having no acoustic treatment whatsoever.

The original mic was housed in a plastic case, with zero shielding (so it picked up lots of electrical noise), and used a 1.5V cell as its power source. After modification, the case was fully shielded, and it used a modified power feed directly from the mixer - not 48V phantom power, just the 15V supply from the mixer itself. Output level and signal handling ability were increased dramatically, and the results were very impressive indeed - all for $50 or so, and a bit of modification.

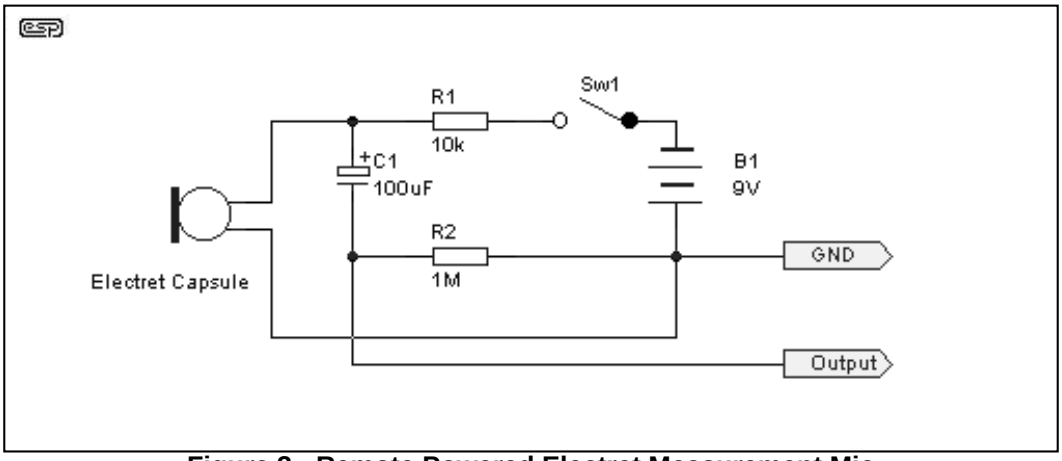

Figure 3 - Remote Powered Electret Measurement Mic

Figure 3 shows a simple remote powered microphone schematic - this can be used directly as a measurement mic with a 9V battery, and will give very good results as long as lead lengths are kept short. Generally, a circuit such as that shown should only be used with a maximum of a metre or so of low capacitance cable. If this is not enough (and it usually won't be), it is necessary to use an amplifier to reduce the output impedance. It is usually worthwhile to include some extra gain as well as shown in the schematics below.

The standard "off the shelf" electret mic may not be calibrated, but typical inserts will be acceptably flat from 20Hz to 10kHz, often with a 3dB rise at 18kHz before rolling off again. A typical response graph is shown above in Figure 1b. While it is obviously impossible to guarantee that the one you get will be the same, it is unlikely that it will be wildly different.

I have included a photo of my prototype probe, and based on initial tests, seems to be remarkably close to a Behringer measurement mic that I have performance wise, but a great deal cheaper. The output is very high with either of the amplifiers shown below - I have measured about 50mV at 70dB SPL, and it has a clean undistorted output at 100dB SPL of almost 1.6V RMS. Based on this, it is obviously not suited to measuring extreme SPLs, but as a measurement mic it is perfect.

Figure 4a - Behringer Measurement Microphone

Figure 4b - My Prototype Measurement Mic Probe

The long tube ensures that there is minimal diffraction interference from the casing, and the final unit has a turned aluminium casing, and is phantom powered. Since the PCB needs to be very small, it was not possible to finish the unit until I had PCBs made - these are approximately 12.5 x 50mm (or 0.5" x 2"), and are now available. The prototype amp was built first, and works extremely well (see Project Proper, below), but alas is too big to fit into the casing.

Figure 4c - Photo of Completed Preamp

Figure 4c above shows what the preamp looks like. I attached mine directly to the modified XLR connector, using PCB pins carefully bent to fit the receptacles of the XLR. The connections on the board are designed to align with the XLR connections for exactly this purpose. Despite the use of standard (as opposed to miniature) 100uF/16V caps throughout, the completed assembly does fit into the casing perfectly - there is not a lot of room for error, but it does fit. This was my intention from the outset, and the idea is to be able to use a standard 19mm (3/4") inside diameter tube to match the connector diameter.

Note: I have produced a small number of housings, and the "exploded" photos are shown below. These are available now, and include the XLR connector (machined to fit the housing), a PCB and PCB pins, copper tape, and two ferrite beads - all basic hardware. You will need to supply the microphone and the components for the PCB, as well as some insulation and a short length of heatshrink tubing (and/ or a suitable adhesive) to secure the mic element to the end of the tube.

The main housing is machined from a solid aluminium bar, and is 25mm (1") in diameter. Photos of the component parts are shown below. Pricing is available on the Purchase PCBs page, and covers the basic hardware set as shown - the remaining components should cost you less than AU$10, to make a complete phantom powered microphone.

Mic Casing Detail

The Other Parts

In case you were wondering, the steel rule is not part of the deal :-) It is shown so that you can see the relative size. The copper strip is used to wrap around the XLR, so that the case is properly earthed via pin 1. The complete assembly details are available in the secure section, and has step by step photos. Such photos are normally needed, but with a mechanical assembly it is essential. The screws are to secure the mic tube and the XLR connector via the recessed holes visible in the upper photo. The final assembly has a nice solid feel, and is extremely easy to put together. Not shown (but included) are the ferrite beads for the mic's outputs.

Pressure Zone Microphones® (PZM®)

The original Pressure Zone Mic was developed quite some time ago, and I have one of the very first ones that were available (manufactured by Wahrenbrock). Crown Audio has been making these since 1980, and Radio Shack (known as Tandy in Australia) also makes one (now called a boundary microphone) that is easily modified to be of near studio quality. Again, all it needs is a decent power supply, and a buffer or amplifier to ensure that the output impedance is kept low (and balanced) to match up with professional mixing desks. The original Radio Shack unit was a true PZM microphone, but it must be noted that the new ones are not - similar, but not the same. See Figure 2 for the schematic of the standard unit.

To make the modifications, the case does not even need to be undone. If you want to see what's inside, the latest ones have 4 screws under the rubber pad on the bottom, and this must be removed. It is attached with double sided tape (such as carpet tape or similar, which can be used to re-attach it when you are done playing). There is a small PCB inside amongst some medium density foam. The top piece can be removed, and the mic terminals are then accessible. The 2.2H iron cored choke (of rather dubious quality) is simply left disconnected, by not using the white wire in the shielded pair to the switch unit and battery holder (these will be discarded). The inner wiring from the mic unit is connected to the new preamp board using a suitable connector on the existing cable from the mic. A fixed lead is not recommended, but you don't have much choice at the mic end unless you really do want to dismantle it. The shield is the mic negative terminal (and also the case), and the red lead carries the signal.

Figure 5 - Radio Shack (Tandy) Boundary Microphone

Using only the shield and red lead (microphone connection - see Figure 2, above for internal schematic), this mic unit can be connected to the preamp shown below. It can then be phantom powered for theatre or other performance recording or sound reinforcement, and gives a very good account of itself indeed.

The Project Proper

Figure 6 shows the project preamp - a balanced mic line driver. This is suitable for use with phantom or battery power, and is easily adapted for either (as described below). This preamp has a PCB which is available, and is suitable for use with any of the microphones shown in this article. Suitable for measurement or recording, it has high output, low noise, and may be powered from a 9V battery or phantom power from 30V to 48V. The load resistance/ impedance should be at least 1k, but this is actually considerably lower than most preamps, so will not cause a problem.

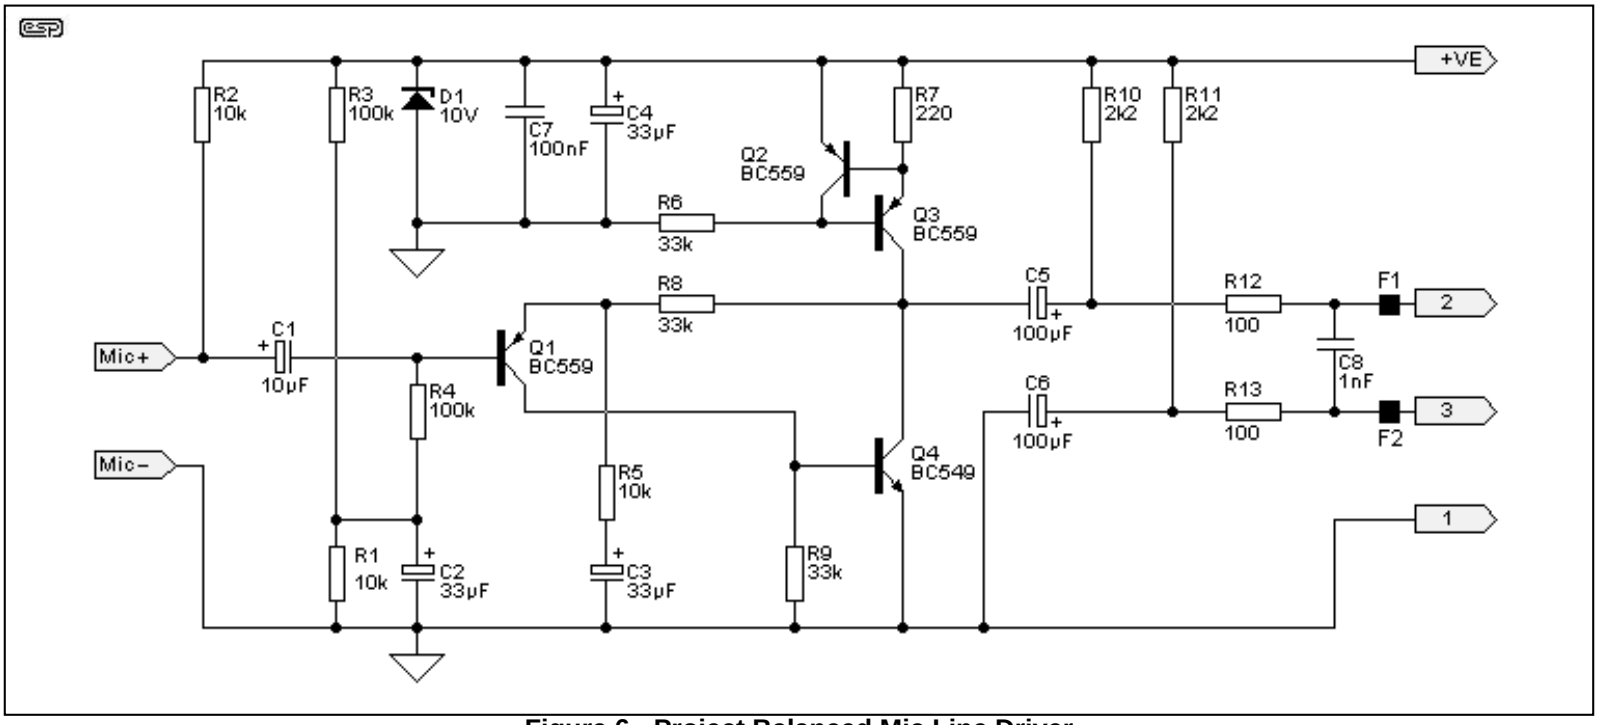

Figure 6 - Project Balanced Mic Line Driver

The preamp is very similar to the DoZ preamp - the topology is identical, but it has been modified to use a lower

supply voltage. The amplifier is a single ended Class-A, current feedback circuit, which has extremely good linearity, wide bandwidth and is unconditionally stable. Ferrite beads (F1 and F2) are recommended at the outputs. The output pins shown are the normal connections to an XLR audio connector, with Pin 1 as ground, Pin 2 is "hot", and Pin 3 is audio return ("cold"). The output actually is balanced, but is asymmetrical - this is very common, and the same basic idea is used by many premium studio microphones.

All resistors should be metal film, and electrolytic caps need to be rated at 16V. The 100uF units shown for C5 and C6 may be reduced to 33uF for recording use, but to maintain response down to 10Hz for measurement, use 100uF as shown.

To use the preamp on battery power, simply leave out R10 and R11, and connect the battery to the +VE terminal. Note that C5 and C6 *must* be reversed if you plan on using battery power, and D1 may also be omitted. Current drain is quite low (about 5mA maximum), so a 9V battery should last quite well. As noted above, PCBs are available for this version - they are tiny, and will fit easily into even small microphone housings.

This preamp can be used for a modified "boundary" mic, to make a high performance measurement mic, or to convert a cheap directional mic into something of near professional quality. It won't be the equal of a Neumann or other expensive studio microphone, but it won't set you back over $1,000 either :-)

Opamp Version

Getting enough current from the phantom supply of a mixer is not a trivial task. If the two 6.8k feed resistors are shorted to ground, the maximum available current is only 14mA, but with no voltage at all. For a workable current of (say) 10mA, the maximum available supply voltage is 14V DC. Getting the current as low as possible is a fine goal, but all opamps need some current to operate, and the powering circuit shown in Figure 7 is a relatively simple way to achieve the desired results.

This is the receiving end of the phantom supply, and it powers the microphone and opamp line driver. This circuit can be expected to handle sound levels up to about 110dB, and possibly more - this is more than sufficient for any microphone that is not used in close proximity to loud vocals or instruments.

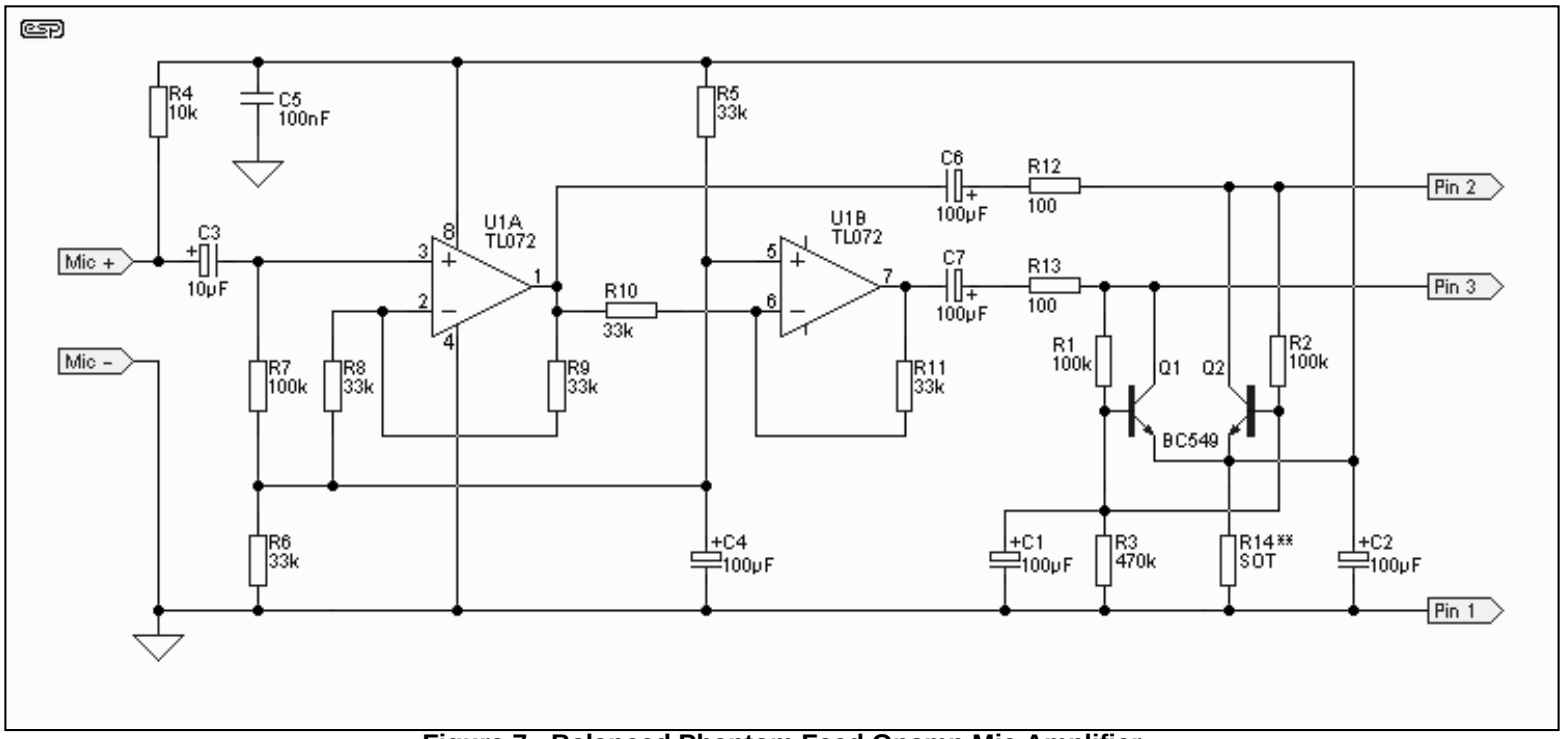

Figure 7 - Balanced Phantom Feed Opamp Mic Amplifier

A similar (but slightly more complex) method for deriving the DC from the signal lines is used by Crown in their PZM microphones, and similar circuits are also used in other (similar) mics. How does it work? It is actually quite simple. Q1 and Q2 are operated as current sinks, and the load is connected to the emitters. Because a current sink (or source) has an extremely high impedance on the collector, there is minimal loading of the signal lines. The DC appearing at the bases is filtered by C1, so the collectors only "see" the DC - the AC signal is left untouched except at extremely low frequencies (less than 1 Hz for the circuit shown above). R14 (marked **) is described as "S.O.T", or select on test. This resistor needs to be chosen so that the DC is about 10V with a normal phantom supply of 48V. A zener may be used instead, which will give a little more voltage range - depending on the opamp used.

R3 is used to ensure that there is some voltage across the transistors, and the differential must be greater than the expected peak output. As shown, the differential is about 3V, so a 6V peak to peak signal can be accommodated - this is equivalent to an output level from the microphone of almost +10dBm! This circuit has been built and tested, and works extremely well. Output level is about the same as the discrete version shown in Figure 6, but it is more complex, and a board cannot be made small enough to fit inside a slim microphone housing. No PCB will be offered for this version unless there is considerable demand.

The most common variant of my simplified DC "extraction" circuit uses a transistor as a capacitance multiplier instead of just a capacitor. This has not been found to be necessary in practice for the schematic as shown, and I have found that it works exceptionally well without the extra complications.

My prototype preamp uses a OPA2134 (a relatively high current opamp), and gets a working voltage of a little over 10V with 48V, 6.8k phantom feed. The output level is extremely high - 2V RMS can be achieved quite easily by speaking directly into the mic ... LOUDLY! In all, this is an extremely capable preamp, with excellent specifications and performance. If demand warrants it, a surface mount version of this preamp may be made available at a later stage, as this is the only way to get the size down so it could be used in a slim microphone housing.

Sound Pressure Level

It must be realised that all electret mics have one limitation we cannot readily change, and that is maximum SPL. Because they have an integral amplifier, there will always be a level where they will distort. A capsule having a 10k feed resistor and supplied from a 15V supply will output well over 1V RMS quite easily, simply by having it close enough to your mouth as you speak loudly. Even professional microphones (including dynamic types) are quite capable of 0dBm in close proximity to a floor tom or a loud singer. As a result, close vocal work, drums and brass instruments (trumpet, sax, etc) are capable of extremely high SPL, and are not really suitable candidates for electret mics. It is possible to get good performance at up to 110dB SPL quite easily, however - possibly more.

The sensitivity can be reduced, simply by reducing the value of the feed resistor. Again, there is a limit, as the internal FET amplifier can be driven into distortion regardless of what you do on the outside of the capsule. It is feasible to modify the capsule itself - but this is only possible with some models unless you are willing to make a few sacrifices (you can guarantee that you will ruin a couple in the process).

This I shall leave to the individual constructor. One possibility if using a Panasonic mic insert, is that the external track on the PCB can be cut, and this gives access to the source of the internal FET. As shown in Figure 6, this little track can be cut, and the mic is then rewired with the FET as a source follower. I do not know what the maximum SPL that a mic modified in this way will take, but it is considerably higher than an unmodified electret capsule. Expect the microphone polarity to be reversed if you do this. The standard insert produces a positive voltage for an air compression because the electret is wired to do so.

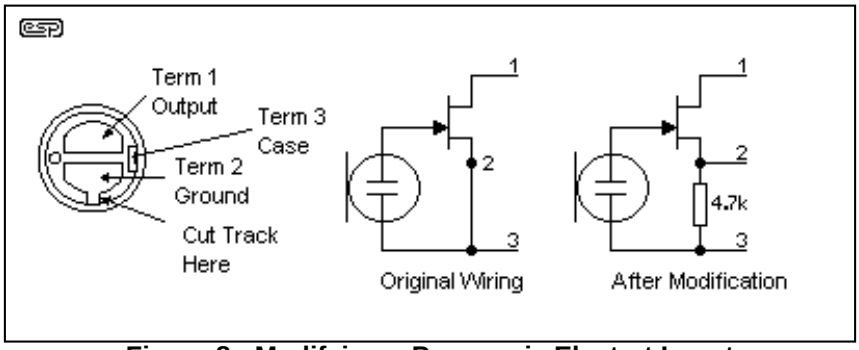

Figure 8 - Modifying a Panasonic Electret Insert

This modification was originally suggested by Siegfried Linkwitz for his cosine burst generator (see Project 58). Note that this is only known to work with the Panasonic capsule, but others may be able to be adapted in a similar manner.

The drain connection is connected to the power source with no series resistor, and the output now comes from the source (Terminal 2). There is no amplification, so expect the output level to be quite a bit lower than normal. Output impedance with a 4.7k source resistor is somewhat less than 4.7k, but it still requires an opamp (or transistor) buffer to prevent current saturation in the FET if connected to any typical mic preamp.

48V Phantom Feed Supply for Microphones

Rod Elliott (ESP)

Introduction

For reasons that I find somewhat puzzling, there are very few decent 48V phantom power supply schematics available on the Net. Those that I have seen are either very crude, or require the use of a special transformer that (naturally) is all but unobtainable (or both). In contrast, a 15-0-15V transformer can be obtained almost anywhere, but alas, does not have enough voltage after rectification and filtering.

Fortunately, this is not a problem, as a voltage doubler supply will give more than enough voltage, and is easy to build. The design featured here uses just that, and allows the use of a readily available transformer and other low-cost parts, to give a supply with extremely good performance. As shown, there is no short circuit protection, but a phantom supply is unlikely to be shorted anyway, so this is not a limitation.

Of the designs that *are* available on the Net, there *is* the supply shown in the P30 mixer (see Figure 3), which is similar to the design shown here, but is not as refined.

Another version of phantom supply (reasonably common) uses an oscillator and voltage multiplier to provide the 48V (or thereabouts) supply, but these are not suitable (IMO) due to very poor regulation and an inherent inability to provide enough current. The maximum current that can be drawn from a standard phantom circuit (using 6.81k resistors) is 14mA into a short circuit. Since all phantom powered systems need some operating voltage (a typical value being around 10V), the maximum practical current drawn by each powered circuit is around 11mA. Naturally, some will draw less than this. The voltage multiplier supply will be struggling tosupply even this meagre current, and will have high battery drain as well.

There are also quite a few suggestions that you can use as little as 18V for phantom powering (using a pair of 9V batteries), but unless the microphone or DI box (for example) is specified to

operate at such a low voltage, then I would not recommend it - headroom will be reduced dramatically, and distortion will be a problem at even relatively low levels. Some equipment will not work at all. The lowest recommended phantom supply voltage is 30V, and I consider even that to be too low for most things.

Output current of this design is rated at 100mA at 48V, although you will be able to get more - 200mA is not unreasonable, and even then, output ripple can be expected to be well below 1mV. Simulation gives a figure of 10uV peak to peak at 200mA, but this is likely to be rather optimistic.

It is probable that few people will ever need the maximum suggested output current, since 200mA is capable of supplying up to 20 phantom powered microphones at once.

Description

The circuit is shown in Figure 1, and as described avove, uses a voltage doubler rectifier. From there, a pair of resistors provide additional smoothing to the secondary filter caps. R3 is used to balance the voltage across C3 and C4, and must not be omitted.

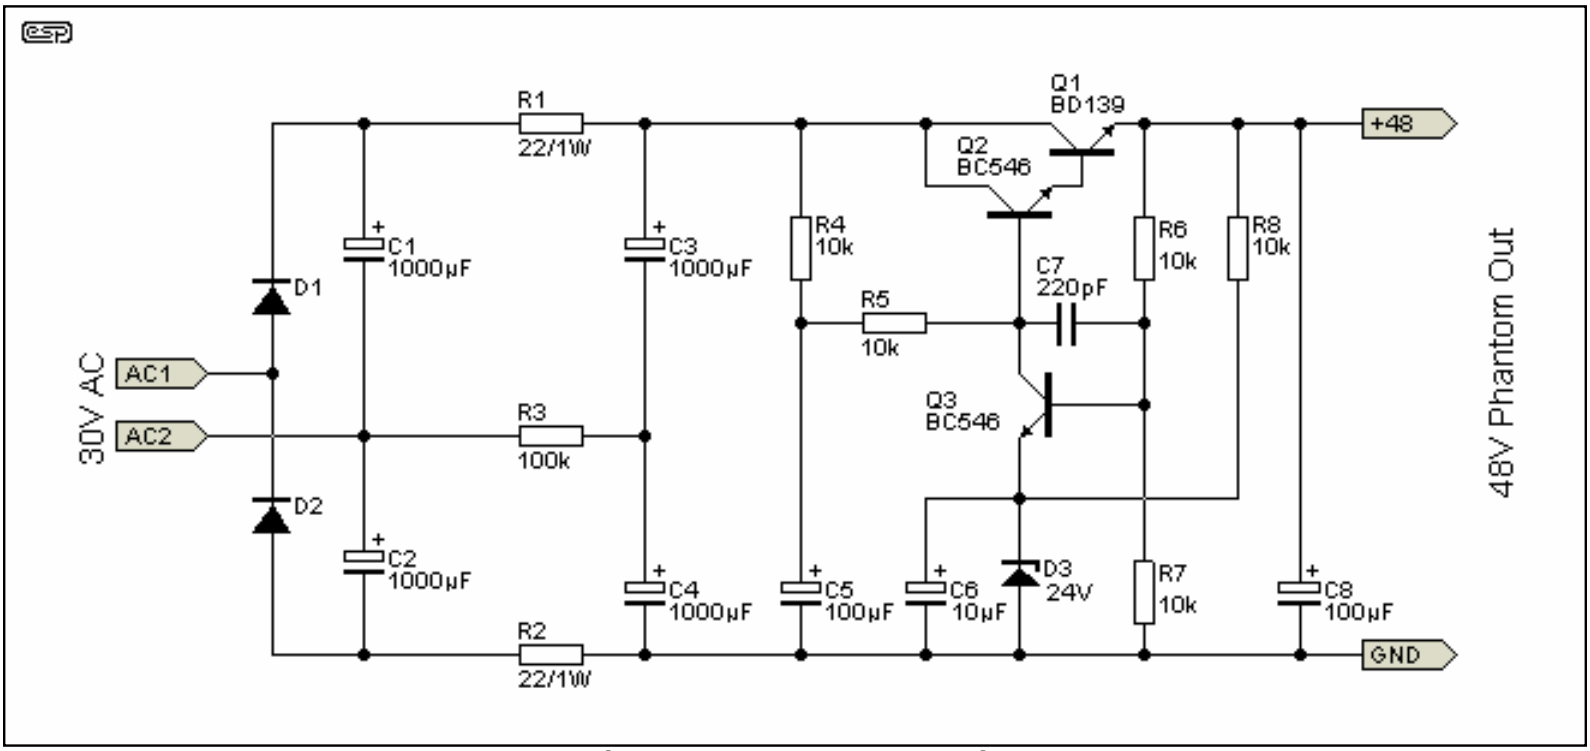

Figure 1 - 48V Power Supply

The regulator was a very common topology prior to the introduction of 3-terminal regulator ICs, and is used here so that high voltage regulators are not needed. These are much harder to get than the standard versions, and still require additional circuitry because 48V versions are not made. Although the circuit looks complex, it is very easy to build (especially if the PCB is used).

The zener diode is the reference voltage, and 1/2 the output voltage is compared to the zener voltage by Q3 (the error amplifier). If output voltage increases, Q3 is turned on harder, removing

base drive from Q1 (and hence Q2), reducing the output voltage to the preset value.

As can be seen, there are no adjustments, and this means that the 48V may be a little higher (or lower) than rated. This is not a problem however, and all phantom feed microphones will handle the variation without any problems at all.

Load regulation is far better than you might expect, with typically 100mV variation between full load (100mA) and no load. At 200mA load, the voltage falls by less than 150mV compared to the no-load voltage. Line (input) regulation is also quite good, with less than 200mV output change with +20% and -20% input voltage, with a load of 100mA.

The next problem is how to actually send the phantom power to the microphone and not the mixer input circuits. The latter will not be impressed with 48V DC applied, and will most likely voice their displeasure by failing instantly. The standard value of 6.81k (0.1% tolerance) for phantom feed circuits can be reduced to 6.8k (a standard E12 series resistor value), and I suggest that using a multimeter to match the resistors to at least 0.1% is the easiest and cheapest alternative. Each pair of resistors should be matched to within 10 ohms (or less if possible) of each other for best results. This is better than 0.1%, and ensures that common mode performance is not compromised.

In case you were wondering about my claim that 10 ohms is better than 0.1%, a worst case pair of 0.1% 6.81k resistors could have a difference of 13.62 ohms - one resistor at the maximum positive tolerance, and the other at maximum negative tolerance. Fairly obviously, the closer the match the better, and the multimeter used does not have to be absolutely accurate, since you are measuring for a difference rather than an absolute resistance value. If your multimeter refuses to measure to the number of digits needed, see the appendix for an alternative method you can use.

Figure 2 shows the basic phantom powering scheme. Only one channel is shown - subsequent channels are identical, up to a typical maximum of 10 (20 at a pinch) for a single supply module.

Although shown using bipolar electrolytic caps, some constructors will no doubt want to use something 'better', but polyester or similar caps at those values will be very large! Assuming a mic circuit input impedance of 1.2k (fairly typical), the two 22uF caps as shown will give a -3dB frequency of 12Hz - this is needed to get flat response to 20Hz. Naturally, if the lowest frequency you need is higher, then lower capacitance is acceptable. Likewise, if the mic preamp input impedance is higher than 1.2k, less capacitance can also be used.

It is worth noting that many mixers use polarised electrolytics at the inputs of phantom power circuits. While this is quite ok while phantom power is applied, the caps will be unbiased when phantom power is not being used. This is not a good idea (IMO), and can lead to audible distortion or colouration. For a "cost no object" design, use 10uF/50V (or higher) polyester caps, enclosed in their own shielding can. These can be wired into the PCB without too much difficulty. Keep wires tightly twisted for maximum noise rejection.

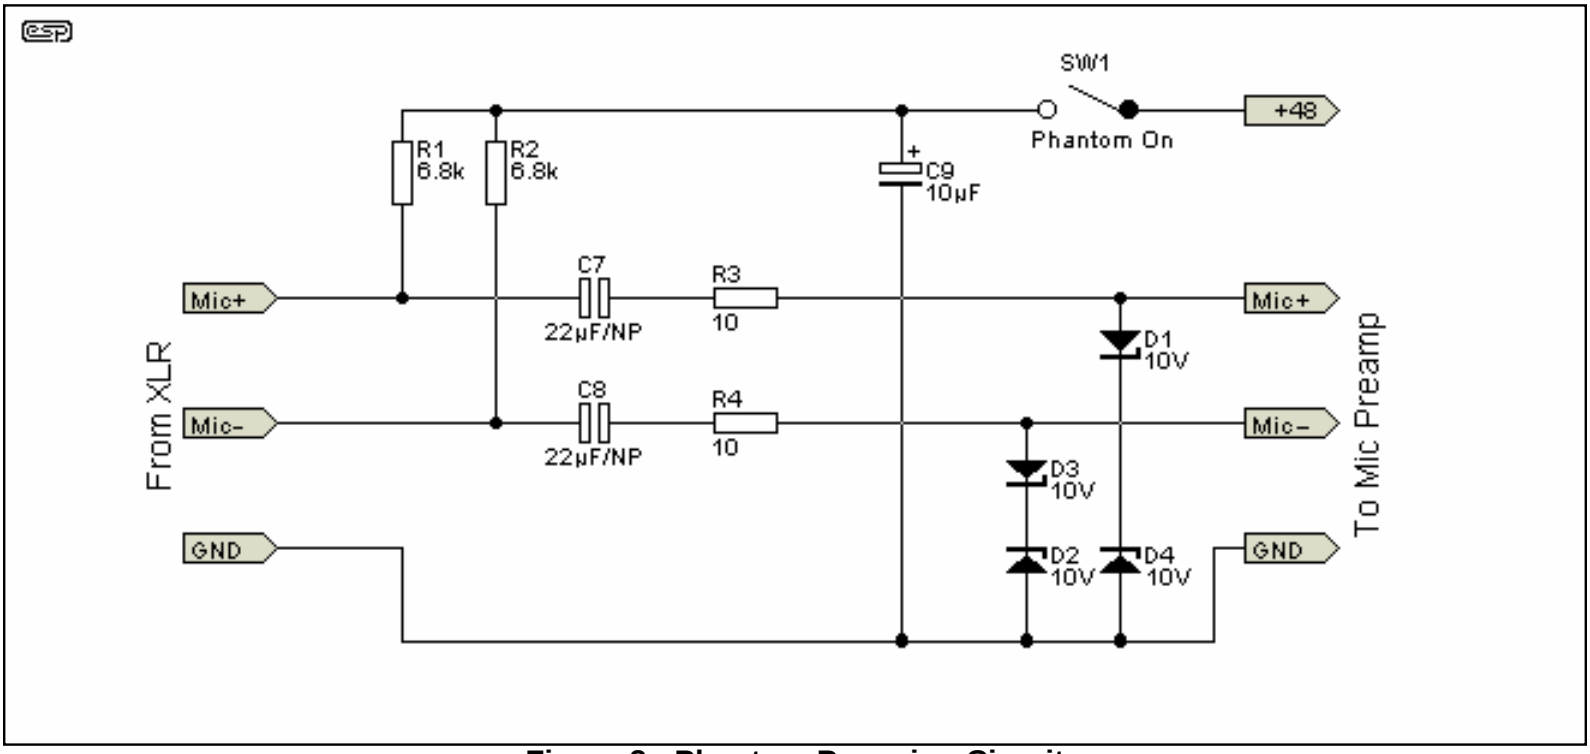

Figure 2 - Phantom Powering Circuit

Zener diodes must be used as shown to limit the maximum voltage applied to the mic input circuits. The worst possible scenario is when a mic lead is connected to a mic while phantom power is on. The cable is effectively a capacitor, and the sudden discharge of the cable and coupling caps can create a high current through the zeners, which must be capable of withstanding the surge without failure. Fortunately, 1W zeners are rugged enough to take it, and this is almost an industry standard circuit. Maximum surge current for 1W 10V zeners is typically around 450mA, and this is unlikely to be exceeded in practice. 10V zeners are specified because it is virtually impossible for any microphone to exceed that level, and the mic preamp will clip well before you achieve the 7V RMS input voltage limit imposed by the zeners. In addition, 10V zeners have a higher current capacity than higher voltages for an additional safety margin. The 10 ohm series resistors will have little or no influence on input level or noise, and help to limit the peak zener current.

Some mixers boast a "silent" phantom switch to alleviate the typical loud BANG through the mixer when phantom power is turned on or off. The phantom distribution PCB (2 channels) has this feature, but it is not shown here.

Construction

Somewhat naturally, I suggest the PCBs be used, as this makes construction very easy. The PCBs both measure only 64mm x 38mm (2.5" x 1.5"), so will be easy to retrofit into all but the most compact mixer. Where there is just no space at all, an external box can house the regulator and distribution board(s).

If you don't wish to buy the PCBs, you may use Veroboard, but unless great care is taken with the

earthing arrangements, noise will almost certainly be worse than quoted. All electrolytic caps should be rated at 50V or higher (**NOTE:** C5 in Figure 1 *must* be rated at 63V!). A standard 50V ceramic is recommended for C7, which is used to ensure that the regulator does not oscillate. Not shown (or needed) are film caps in parallel with the electrolytics - if you wanted to, these may be added, but with the filtering shown high frequency noise should be non-existent.

The power transformer does not need to be anything too fancy, but I suggest a separate box for it to minimise hum and noise. Typically, a 20VA 15-0-15V (or a multitap transformer with a 30V connection) will be more than enough. These are available readily in Australia, but I can't speak for the rest of the world. If the worst comes to the worst, you can use a pair of single winding 15V transformers, with the windings in series to give 30V. I recommend a conventional 'EI' transformer if possible, as these have less capacitance between primary and secondary, and will allow less HF mains noise through.

It is extermely important that the transformer is not used to power other supplies or equipment. The centre-tap *must* not be connected to anything, and needs to be insulated to prevent contact. The supply circuit uses the full 30V AC in a floating configuration, and connection to another supply or rectifier will cause a short on the winding.

Q1 on the supply must be fitted with a heatsink, and worst case power dissipation will be around 5W. This may not seem like a great deal, but a 10°C/W heatsink (typical of a large PCB mount type) will get to 50°C above ambient temperature (i.e. too hot!) at 200mA output.

At 100mA load, this is reduced to about 3W, which is a little more manageable. Even so, there is no such thing as a heatsink that is too big, so I suggest that you use the largest one that you can. Forced air (fan) cooling will not be necessary.

The PCB is laid out such that the power transistor can be attached directly to the chassis if desired (using insulating washers and heatsink compound, of course), and this alleviates the need for a separate heatsink. For only one or two phantom powered mics, a heatsink is not essential, but a small one is cheap insurance. In this case, R1 and R2 in Figure 1 may be increased in value, and this will provide even better filtering. 100 ohms will be more than satisfactory for a two microphone system.

Appendix - Resistor Matching

The age old methods are sometimes the best. A Wheatstone Bridge used to be the standard method of accurately measuring resistance, inductance and capacitance, but new digital instruments have taken over. This is a shame (I think), because the old methods actually taught you something as you used them - not the case with any digital instrument.

A Wheatstone Bridge is easy to set up, and while it is not especially accurate in absolute terms, it

can be made extremely sensitive to *variations* between components. Using a power supply, 9V battery (or even a small AC voltage from a transformer), the circuit shown in Figure 3 will resolve a difference of 1 ohm easily with a suitable test setup. A difference of 10 ohms will give a 4.38mV output signal from a 12V input.

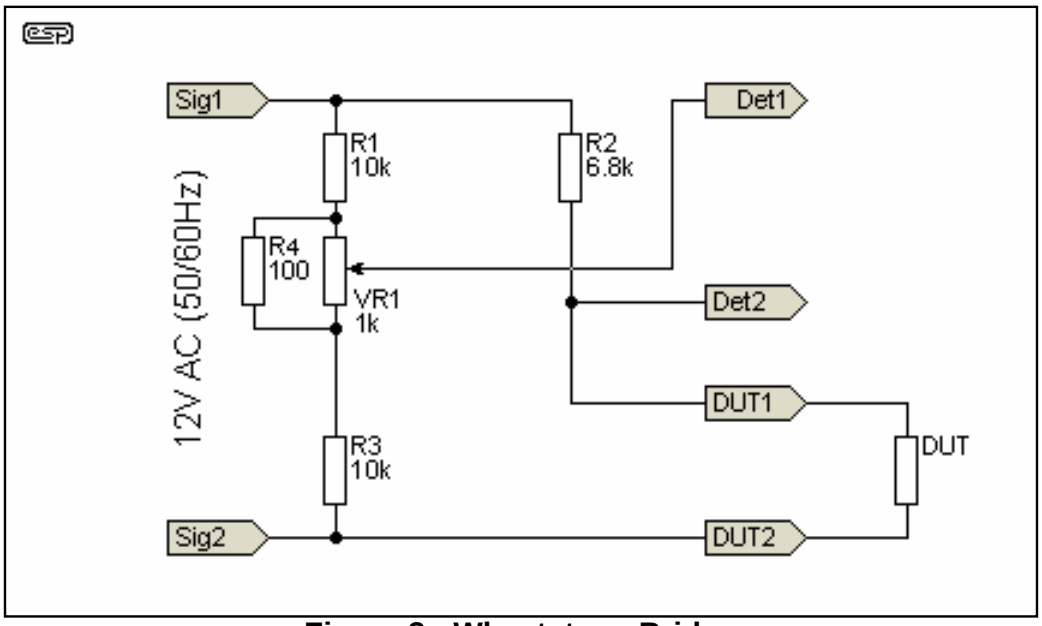

Figure 3 - Wheatstone Bridge

Because the bridge circuit does not care if you use AC or DC, an amplifier can be used to detect the null, and it can be made almost unbelievably sensitive. In use, wire up the circuit as shown, and use a meter or amplifier and headphones (or speaker) to monitor the difference signal. **Be warned** - the amp input signal will be 6V RMS (for a 12V input) with the DUT (Device Under Test) removed! Install a test resistor, and adjust VR1 for a complete null (no signal). That is now your reference resistor. Connect the remaining resistors into the circuit, and aim for an output signal of less than 4mV - do not re-adjust VR1.

The signal input (applied unsurprisingly to Sig1 and Sig2) *must* be floating if you use an amp for monitoring, since one side of the amp input will be earthed. A 50 or 60Hz 12V transformer is fine for this. Press the TEST button only when the DUT is securely attached, or the output will be very loud indeed. You can connected a pair of diodes across the Monitor terminals - in parallel and opposite polarity. This will keep the maximum level down to something more sensible.

The Wheatstone Bridge is such a useful device that you can soon expect to see a complete article describing its use for comparing resistors, capacitors and inductors - actually, you can match any passive components and even complete networks by this means. Wheatstone bridges are also used for precision temperature measurement, strain gauges (use to test mechanical movement in structures) and has many other uses.

Yorick - A Dummy Head Recording Microphone

Rod Elliott (ESP)

PCBs are available for this project. Click the PCB image for details, or select P93 or P88.

Introduction

"Alas Poor Yorick ..." Well, there's not a lot of alas in this - indeed a lack of alas, one might say. Yorick just happens to be the name I chose for my dummy head recording microphone for reasons that shall remain obscure Using a pair of P93 electret microphone amps, this dummy head can be phantom powered or you can use batteries. It will run happily on a standard 9V alkaline battery.

> Speaking of Shakespeare, something that is not at all well understood is this snippet ... While writing 'King Richard III', poor Bill's word processor had a hard drive failure, and the actual quote (lament, more like it) was "Now is the winter of our disk content." - having just lost everything, I know how he must have felt. This was utterly misconstrued over the years, until we now have the mangled version that everyone seems to think is correct. Of course this is true - would I lie? To *you* ?

The project came about when I came across a polystyrene foam wig holder (replete with wig), and its final use was sealed on the spot. It still took me a year to get around to it, but hey, these things take time. With the addition of a pair of electret mics and a couple of RCA sockets, the dummy head was complete, just needing a suitable mic amplifier to finish it off. P93 was an immediate candidate, although for my application I used P88.

More than anything else, this is intended to be a fun project. While those who are especially interested in making recordings of <*insert favourite application here*> will find it very useful, the project also shows how powerful our auditory processing really is. To be able to listen to a recording made in natural surroundings with almost no reverb - which we normally do not hear in most rooms, even though it's there all the time - is remarkable. To hear the difference, simply mono the signal, and suddenly the reverb and general background noise becomes most intrusive.

Figures 1 & 2 - The Completed Dummy Head Recording System, Front and Rear Views

The completed dummy head unit is shown above. The details are given below. He's not particularly handsome by any stretch of the imagination, but that's not really a requirement for the application. The control box is shown below.

Figure 3 - Prototype Control Box

The prototype shown is based on the Project 88 hi-fi preamp (details shown below). It can run from a pair of 9V batteries, or an external DC source may be used. Any external supply needs to be (electrically) very quiet. Any hum or noise from the supply will have some impact on overall noise performance. I used NE5532 opamps in mine, but be aware that these (as well as many other high quality audio opamps) draw considerable current - around 20mA in total for two dual opamps. This means that battery life is fairly limited. Expect no more than about 10 hours continuous operation from alkaline batteries, less from zinc-carbon or re-chargeable types. As you can see, I added a pair of XLR connectors for flexibility, but this is completely optional.

Description

There's not really very much to it. Simply take a suitable head such as the one shown, and make a couple of ear holes using a long, thin screwdriver as a boring tool. These should be located in approximately the position of real ear holes, but if you plan to add a wig for added realism (oh, really?) then make sure the wig doesn't cover the holes. The outer ends of the holes need to be enlarged so the mic inserts are a snug fit.

Figure 4 - Side View (Sans Wig) Showing Microphone Insert

Most of the expanded polystyrene foam heads are reasonably solid, and have a hollowed out section up the inside. This allows us to run the cables through easily. A rotary tool is useful for making neat cut-outs for the microphone connectors, and for enlarging the ear holes to accept the inserts. Overall insulation is not needed because polystyrene is an excellent insulator, so you only have to make sure that the mic leads (inner cable and shield) can't short together.

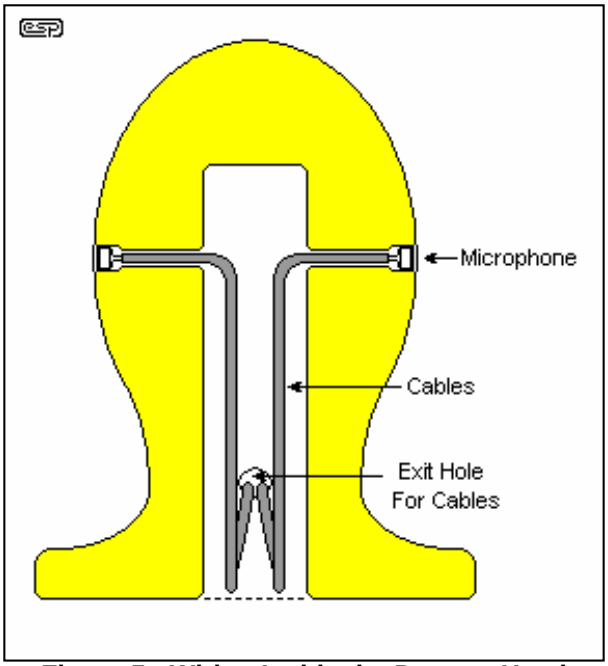

Figure 5 - Wiring Inside the Dummy Head

Getting the cables through the small holes from the mic locations, down the hollow centre and out through the opening for the connectors can be a challenge. You may find it easier to use a thin draw-wire that can be fed through the holes and hooked out with a stiff wire hook. Ultimately, I have to leave that part to you, as the best

method will depend on what you have available. Because the hollow section is a reasonable size (at least in the heads I've seen), you have plenty of room to stash any excess cable.

Mounting the mic connectors may be easy or hard, depending on the connectors you have, and what you can find in your junk box. In my case, I have a large bag of the RCA connectors you see in the photos above, and it was possible to just screw them directly into the polystyrene. No, this is not the most secure fastening, but I don't plan to hang heavy cables from them, and tests so far seem to indicate that they'll be fine for as long as I need. Some care is needed, but that's not an issue.

I do recommend that the two connectors are electrically isolated from each other. Because of the small signal level, a ground loop will be created if the leads join at more than one place, and this will create hum. If you plan on gluing anything, remember that solvent glues will dissolve polystyrene foam (it just vanishes!), so only use adhesives that are designed for such applications (I don't actually know of any, which is why I tried the screws). PVA wood glue will work and does not dissolve polystyrene, but it probably won't bond very well either. The connectors could be attached to a strip of plastic and attached with cable ties. There are many possibilities, so see what works best for you.

Control Box Construction

There are actually two equally valid possibilities for the control box. As mentioned above, the P93 mic amp is ideally suited, and for reference this is shown below.

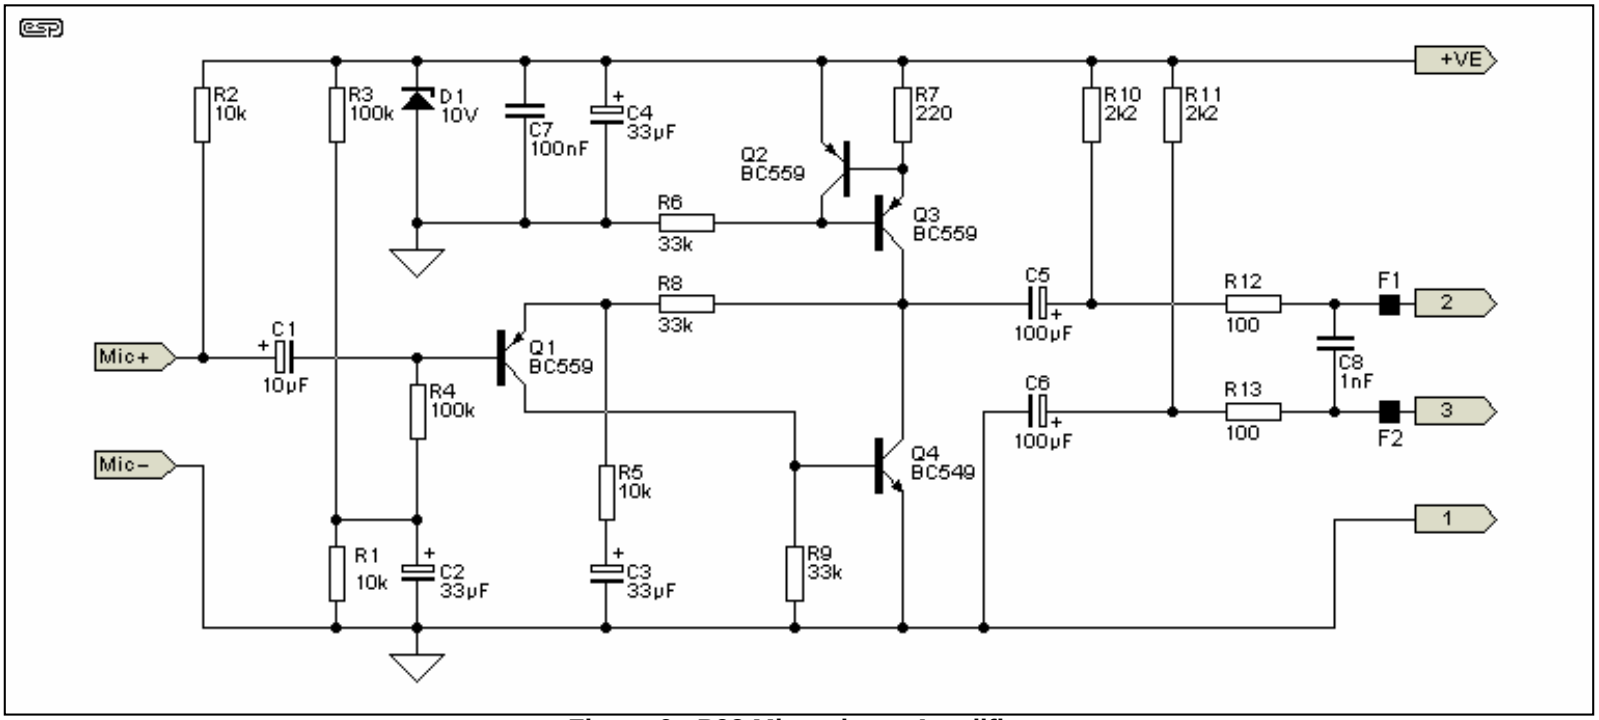

Figure 6 - P93 Microphone Amplifier

This is unchanged from the original project. The only difference is that the P93 board is not installed close to the mic capsules. Although it would be possible to do so, having XLR connectors on the dummy head would mean a substantial mounting because of the force needed to connect and disconnect. RCA connectors require very little force, making mounting easier.

Another method is to use the P88 preamp, and this is ideal if you don't need the balanced output and phantom feed capability. The gain needs to be increased, but it is a very flexible alternative.

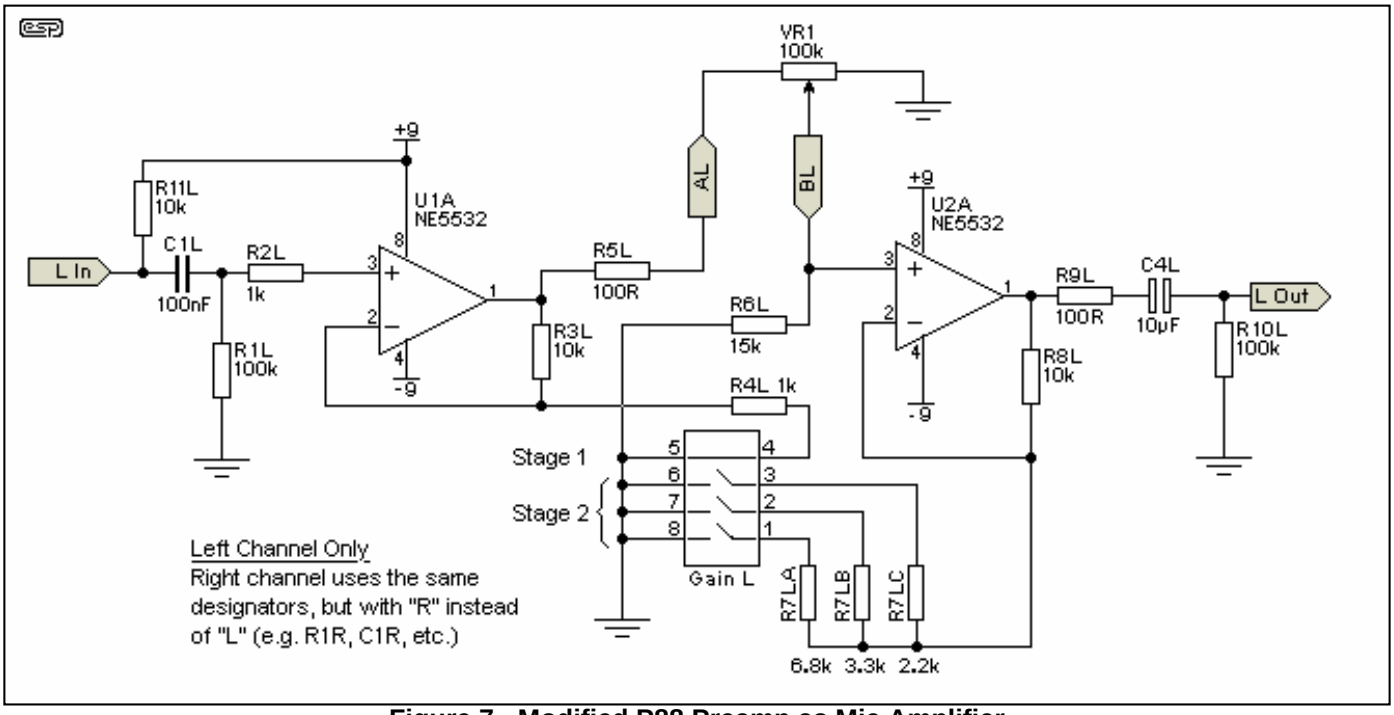

Figure 7 - Modified P88 Preamp as Mic Amplifier

The use of low noise opamps is highly recommended, but be warned that devices like the OPA2134 and NE5532 draw about 5mA per opamp (20mA per package for dual opamps), so you will be looking at close to 20mA for the amp. While 9V batteries can supply this easily enough, you will only get about 10 hours of use from a set. TL072s will give much longer battery life, but at the expense of noise.

As shown, the first stage gain is increased to 11, so a typical 20mV signal level will give you 220mV across the level pot. The gain of the second stage is also increased, and like the P88 can be made switchable to accommodate different recording systems. With the values shown, you can get the following ...

Switch	Stage 2 Gain	Total Gain	dB (Total)
1	2.47	27	29
2	4.03	44	33
3	5.54	61	36
2+3	8.57	94	39
1+2+3	10.05	110	41

The above is with the volume control at maximum. Switch #4 should be closed at all times for this application. You can experiment with the resistor values if you need more or less gain. The level control (VR1) can be a stereo (dual gang) pot, since in most cases you will not need to adjust the levels independently. Remember that the opamps are DC coupled, so expect to get some DC offset at the output pins. A 10uF bipolar cap may be used from the AL (and AR) terminals leading to the pot. This will prevent DC induced pot noise as the level is adjusted.

Note that R11 is not provided for on the PCB, but it is an easy matter to add it. Details will be included shortly in the P88 construction guide to make it a simple matter to adapt the preamp.

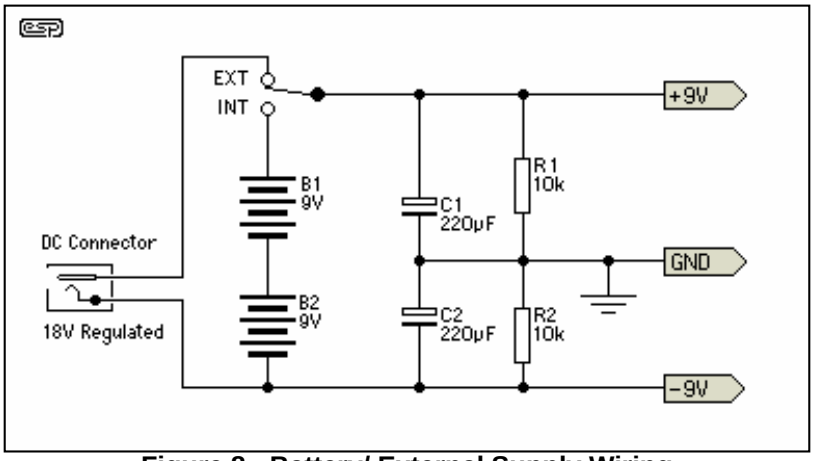

Figure 8 - Battery/ External Supply Wiring

The above is a suggested wiring scheme for the supply for the modified P88 board. While the battery centre tap could be earthed, then you would need a double pole switch to change from battery to external power. Feel free to do so if it makes you feel any better.

The supply will not be completely symmetrical because of the mic feed resistor. You can change R2 in the supply above to 5.6k or thereabouts to make the supplies equal, but the opamps don't really care that much.

Testing

Connect to a suitable power supply - remember that the supply earth (ground) must be connected! When powering up for the first time, use 100 ohm safety resisors in series with each supply to limit the current if you have made a mistake in the wiring. Refer to the individual project pages (P88 or P93, depending on which you used) for full test procedures.

Once the preamps are working, connect the complete recorder system to a tape machine or a computer sound card (via a mixer in most cases). It is quite uncanny to listen to the normal sounds around you via headphones from the dummy head.

Phantom Powering for Condenser Microphones

History

Condenser (capacitor) microphones differ from dynamic and ribbon microphones because they are not self-generating. That is, they cannot generate electricity in response to an impinging sound wave. A condenser microphone modifies an external source of electricity to reflect the effects of a sound wave striking its diaphragm. Dynamic and ribbon microphones use magnetism to generate electricity in response to a sound wave: they are self-generating. Furthermore, both of these types of microphones are inherently low impedance devices. It is possible to connect a dynamic microphone element directly to a balanced, low-impedance mixer input. Many commercially made dynamic microphones do just that.

On the other hand, a condenser micorphone is an inherently high-impedance device. How high? Verrrrrrry high. On the order of a billion ohms (1 Gigaohm). This is high enough that the inherent capacitance of a foot of shielded cable would audibly reduce the output of the microphone. All condenser microphones have an impedance converter, in the form of a vacuum tube or field-effect transistor (FET), built into the microphone, and located extremely close to the microphone element. The impedance converter and the microphone element itself require an external power source. <To be strictly correct, electret condenser microphones are a bit different as the microhone element does not require a power source for operation (it is more or less permanently self polarized). Regardless, the impedance converter still requires an external source of power.>

What is it, exactly?

The obvious external power source for any modern microphone is a battery. About the only electronic advantage that a battery has is that its output is pure DC. The only other advantage (to the battery company) is that you have to keep on buying them.

Tube microphones require several different voltages for operation. This invariably means a multi-conductor cable and non-standard (not XLR) connectors. A tube microphone will always have an associated external power supply.

In the late 1960’s, Neumann (you know, the folks that brought you the U47 and U87 microphones) converted its microphones to solid-state, adopting a system of remote powering that they called, and trademarked, Phantom Powering. Because of the trademark, some manufacturers use terms like Simplex Powering, etc. Over the years, the trademark has become genericized and now refers to any device that

is powered according to DIN standard 45 596.

So, where is the Phantom of Phantom Powering? Because (like the Phantom in the old comic strip) it's there when you need it, and invisible when you don't. This technology is not new, it actually predates rocket science. Like so many other things in audio, it was brought to you by the telephone company, who used it to get an extra circuit from a pair of wires. In effect, so does your phantom powered microphone.

What is important is: phantom powering is a compatible system. Your dynamic/ribbon microphones as well as your condenser microphones work side-by-side, from the same microphone inputs, without further thought on your part.

Technically speaking, phantom powering refers to a system where the audio signal is applied to the balanced line in differential-mode <across pins 2 and 3>, and the DC power is applied common-mode <pins 2 and 3 plus pin 1>. The audio travels via pins 2 and 3 differentially, and the power travels between pins 2 and 3 simultaneously and pin 1. Microphones that do not require power simply ignore the DC present between pin 2, pin 3, and pin 1. If you measure with a voltmeter between pin 2 and pin 3, you will read 0 Volts DC. This is what your dynamic microphone sees. Measuring between pin 2 and pin 1, or between pin 3 and pin 1, you will read the phantom power voltage, usually 48V, without a microphone connected. The dynamic microphone, as well as your balanced mixer input, ignores this voltage.

Lately, the term phantom power has been perverted to refer to any remote powering system. In the strict sense of the DIN standard, this is not true. Furthermore, microphones or transducers that claim to use this system are not compatible with the DIN standard and will almost certainly be damanged if connected into such a system. Fortunately, these systems use tip-ring-sleeve phone plugs or miniature XLR connectors and they are usually associated with instrument pickup applications.

Phantom powering is defined in DIN standard 45 596 or IEC standard 268-15A..

What works?

To be compatible in a phantom powered system, a device (microphone, preamp with a microphone-style output, or direct box) must have a balanced and floating, low-impedance output. This includes all microphones commonly used for sound reinforcement and recording such as the Shure SM-58, SM57, Electro-Voice RE-15, RE-16, RE-20, ND series, Beyer M88, M160, M500, AKG D224, D12, D112, and MANY others.

If you are fortunate enough to own any tube condenser microphones, such as the AKG C12, Neumann U47 or U67, these microphones may be connected in a phantom powered system and will operate without regard to the presence or absence of phantom power. They will always require their external power supply (which must be plugged in and turned on).

Older condenser microphones (Sony C22, EV 1777, PL76, etc.) that were either made before the adoption of phantom power, had the phantom power feature omitted as a cost savings measure, or omitted it for product differentiation reasons (stupid, really stupid). These microphones will operate, but they will always require their own batteries. Consider them a battery-powered dynamic microphone. There is one tube condenser microphone that can operate using phantom powering. It is the Microtech Gefell UM900. For further information, consult their website

What doesn't work?

The list is short:

1. Microphones with unbalanced outputs.
2. Microphones with grounded center-tapped outputs. Many old ribbon microphones were supplied connected this way. Have a technician lift the ground from the center tap. The microphone is now phantom-power compatible. Connecting a microphone with a grounded center-tap, when phantom power is present, could damage the microphone. Connecting the microphone first, and applying phantom power second is permissible and will not harm the microphone. We recommend the latter (connect first, then apply power) as a safety measure if you don't know for sure that the microphone has a grounded center-tap.
3. High-impedance microphones.
4. Microphones that exhibit leakage between either pin 2 or pin 3 and pin 1. These microphones will sputter and crackle when phantom power is applied and will work fine when you turn off the phantom power. Get the microphone repaired.
5. Musical Instrument Stuff with Direct Outputs. Sometimes they work, sometimes they don't. It's a crapshoot at best.

Many pieces of electronic equipment aimed at the musician marketplace have direct outputs intended to make connection into a professional sound system easier. In theory at least, you eliminate needing a direct box. The problem is that many of these manufacturers apparently haven't heard of phantom power.

The problem is that their balanced output is transformerless, and (worse) can't tolerate the 48V power present. Usually, the output coupling capacitors are 25V parts, and most often connected so that their + terminal goes to the opamp that drives the output connector. When connected into a phantom powered system, the 48V reverse biases the capacitor and causes trouble. This trouble can be temporary and sometimes it can be permanent.

If you're a musician and this scares you, it should. What can you do? Call the manufacturer and ask. Have a service tech who understands the problem check the schematic. A really bright service tech can study the circuitry without a schematic by looking at the unit and figuring out what the manufacturer did circuit-wise.

I have seen at least one brand of amplifier (G-K) with outputs that are supposedly phantom power proof that aren't. In this case, I spoke to their chief engineer, and we both agreed that what he was doing should work, but in practice it doesn't. If you are connecting to a G-K/Gallien-Kruger amplifier, you should use a direct box.

Electronic keyboards are also suspect. I've had other musicians tell horror stories of blown instruments caused by assuming that the balanced outputs on the instrument were phantom power proof. When in doubt (and that's my usual state), use a direct box.

A Simple Modification

This modification makes a balanced transformerless output phantom power proof. I came up with this idea when I worked at Mackie Designs. It works. It has been incorporated into all of their mixers that have XLR connectors for their outputs. I'll describe the mod in words. This should be crystal clear to a competent service tech.

I'm assuming that the circuitry of the balanced output is driven by a pair of opamps, with their outputs arranged to be out-of-phase with each other. It doesn't matter if the output is cross-coupled or not.

Find the output coupling capacitors. They need to be at least 25V units, polarized so that the plus side connects to the XLR connector.

There should be a resistor on the XLR side of the coupling capacitor going to ground. There should be one for pin 2 and one for pin 3. If not, add them. The value needs to be 10k or lower (equal value).

The resistors put enough of a load on the phantom power coming from the mic preamp to reduce the phantom voltage to something that the capacitor can withstand.

What about T-Powering?

T-powering is another remote powering system. It is sometimes known as A-B powering or as "Modulation Lead Powering." It uses pins 2 and 3 to carry both power and audio. It is NOT compatible with dynamic, ribbon, or phantom powered microphones. For further information, please refer to my article about T-powering.

Do/Don't Chart

Do	Don't

If you are plugging in a condenser microphone, do verify that your microphone can be phantom powered.	Worry about your other microphones as long as their outputs are balanced and floating.
Ensure that the microphone's output is low impedance, balanced and floating. This is especially important for vintage ribbon microphones like the RCA 44BX and 77DX.	Connect microphones or devices that do not conform to the DIN 45 596 standard.
Mute the sound system when turning the phantom power on or off, or when connecting or disconnecting microphones. Lest you forget, the resulting loud, nasty POP may be your last.	Don't connect A-B or T-system microphones (another remote powering system) without suitable adaptors.
Turn the phantom power off when connecting ribbon microphones (cheap insurance). It's OK to turn it back on after making the connection. Be sure that there is some way to bleed the charge off of the power supply if you chose to do this. See the discussion on patch bays, below.	Worry about your tube condenser microphones. They're compatible; they just can't be phantom powered.
Do read the discussion about phantom powering causing magnetized transformer cores.	Put your microphone lines thru a TT or TRS patch bay. See further discussion, below.

Phantom Power and TT/TRS Patch Bays

If you're building a studio, this is a bad idea. Avoid it.

Use XLR connectors instead. Yes, they're not as high density as a TT bay. Don't hot patch microphones when the phantom powering is turned on. Turn the phantom power off first. Even this may not be sufficient.

The problem is that the tip of the plug can contact ground as the plug is being inserted. With a transformerless input, this can discharge/charge the input blocking capacitors thru the microphone's output transformer. This could magnetize the core of the transformer, zap a ribbon microphone, or (remote possibility) damage a dynamic microphone.

With a transformer coupled input, you risk magnetizing the core of the console's input transformer, ruining its distortion characteristics.

If the microphone's output is transformer coupled, the microphone's output transformer could also have its core magnetized, ruining its distortion characteristics.

This is not good.

There are several ways to disable or turn off the phantom power in a mixer.

Disconnect the input to the rectifier/filter system in the phantom power supply. Mackie mixers with a global phantom power switch use this method. There should be a bleeder resistor somewhere within the supply to discharge the filter capacitors.

Break the feed to the 6k81 phantom feed resistors, either individually or in groups. In transformerless consoles, there should be a discharge path for the input coupling capacitors.

Using a voltmeter, or the console schematics, determine which method your console uses and how long it takes for the voltage at the microphone inputs to fall to zero volts after the phantom power has been switched off. If you can't do this yourself, get someone who can and have them explain it to you until you understand it. Have them read this article.

When patching microphones through a patchbay, either turn off the phantom powering first, and/or unplug the sensitive microphones (ribbons) before repatching any of these lines.

Phantom Power and Magnetized Transformer Cores

A discussion on the Ampex listserve led to some further thought *vis a vis* the issue of hot patching (connecting or disconnecting a microphone without first turning off the phantom powering). Although the theory says that you can do this, practice says that you need a few more details before deciding what the practice shall be in your own facility.

This issue at hand is the magnetization of the transformer core caused by unbalanced current pulses through one of its windings. Once this occurs, it is quite difficult (although not impossible) to undo. Once the core has been magnetized, the transformer's low distortion characteristics go by the wayside.

First, let's look at the different ways that this can happen:

1. Hot patch a phantom powered microphone. If you can guarantee that both pin 2 and pin 3 make at *exactly* the same time, then this is not a problem. Problem is, you can't. This likely isn't as bad as #2 or #4. If the phantom feed system uses a resistor bridge across pins 2 and 3 of the XLR, then this cause is pretty much a non-issue.
2. Using a shorted mike cord with phantom power turned on. Varying degrees of problem result depending on the nature of the short and what happens at the instant of plug insertion.
3. A dufus with an ohmmeter
4. Plug in a mike having a grounded center tapped output with phantom power turned on. This is the same mechanism as #1.

So, if your board has input transformers, and/or if the mike has an output transformer, then it's good medicine to turn that phantom power off and wait a bit before plugging things in. If you know for sure that both the board and mike use resistor bridges to apply and get powering to/from the line, then it doesn't matter if you turn the phantom powering off first or not. If this isn't the case, it would be worth the piece of mind to modify the phantom power switching to ensure that there was a discharge path for the input stuff, and/or monitor it with a meter to see how long it takes things to die.

I guess there IS a GOOD reason to have phantom power switches on every input!

Phantom Power and Mic Splitters

There are several ways to split a microphone's output. They range from cheap (wye-cord or paralleled inputs) to expensive (BSS active mic splitter). Somewhere in the middle there is the venerable old transformer coupled splitter.

For sure, the active splitter is the best solution. The microphone only sees one load, which is the splitter's input impedance. Each of the outputs is buffered from the rest. The only rub is that the splitter's sonics are imposed on everyone that takes one of the split outputs.

In this case, the splitter supplies phantom power to the microphone and could care less what the mixers are doing.

Transformers are the next-best solution. Unfortunately the usual 1:1:1 transformer still parallels the input impedances of the two consoles. From a microphone loading perspective, this is no better than simply paralleling the mixer inputs. If you run into a nasty grounding situation, the transformer coupled

splitter will save your bacon. For phantom power purposes, what usually happens is that the FOH mixer gets a direct feed from the microphone and the monitor mixer gets a transformer-isolated split (in reality, a parallel feed) from the mic. The FOH mixer supplies phantom and everyone is happy. In a really nasty scene, both mixers might get transformer splits, and the splitter itself has phantom feed resistors and a 48V DC source.

In many instances, simply connecting the mixers in parallel works just fine. You can get into trouble if you aren't really careful about how things get grounded, especially with regard to the FOH console's ground system and the monitor console's ground system. If either of the boards has pin-1 trouble, this may be exacerbated. I've used this method myself for over 30 years and only occasionally had problems. In each instance, I can trace the source of trouble back to not following the rules. The big rub with parallel connected mixers is the old question: "Who supplies phantom?"

Some consoles don't like having phantom power applied via their microphone inputs when their internal supply is not switched on.

This is especially true of mixers that don't have individual phantom on/off switches or at least switches for groups of inputs. What happens here is that the manufacturer took the easy way out to turn the phantom power supply on and off: they switched the AC feed to the phantom supply rectifier. The voltage regulator that supplies 48V to all of the phantom feed resistors is always connected. When the mixer that isn't supplying phantom has it's inputs 'backwashed' with phantom power, the regulator doesn't quite know how to deal with this voltage coming at it from what it thought was its output.

The cure here is a simple series diode connected at the output of the regulator, and a large electrolytic capacitor to ensure that the output impedance of the regulator stays low in spite of the series diode.

The Mackie SR series mixers that I had a hand in have this series diode. Other mixers may, and it pays to check the schematic for this feature.

Now, having said that, let's explore the situation when both mixers supply phantom.

Quite simply, we have two 48V supplies driving the mic through 6800 ohm resistors on each leg. As far as the microphone is concerned, it's no different than if we halved the value of the feed resistors to 3400 ohms each. So, again from the microphone's perspective, the mic is seeing 48V thru 3400 ohms in parallel with 3400 ohms. This means that twice the current is available to every microphone. Looking inside the microphone, we typically have a zener diode with or without some extra current limiting resistance. So, the effect of the extra current is that the zener diode works a bit harder.

I have used sound systems where both the monitor and FOH boards supplied phantom powering to the microphones. I've done this with just about everything from cheap electrets to Neumanns and AKGs. It works, and the microphones have all said, "so what." The Neumanns are especially immune to this. The 9-52V AKGs (old C451's, C414's) have to work their zeners a bit harder, but it's no big deal. They're a

worst case example. My C451's and C414's still work just fine, thank you.

Model SM58 Dynamic Microphone Specification Sheet

MODEL SM58®
UNIDIRECTIONAL DYNAMIC MICROPHONE

OVERVIEW

The Shure SM58® is a unidirectional (cardioid) dynamic vocal microphone designed for professonal vocal use in sound reinforcement and studio recording. A highly effective, built-in, spherical filter minimizes wind and breath “pop” noise. A cardioid pickup pattern isolates the main sound source while minimizing unwanted background noise. The SM58 has a tailored vocal response for a sound which is a world standard. Rugged construction, a proven shock mount system, and a steel mesh grille ensure that even with rough handling, the SM58 will perform consistently. Outdoors or indoors, singing or speech—the SM58 is the overwhelming choice of professionals worldwide.

FEATURES

- *Frequency response tailored for vocals, with brightened midrange and bass rolloff*
- *Uniform cardioid pickup pattern isolates the main sound source and minimizes background noise*
- *Pneumatic shock-mount system cuts down handling noise*
- *Effective, built-in spherical wind and pop filter*
- *Supplied with break-resistant stand adapter which rotates 180°*
- *Legendary Shure quality, ruggedness, and reliability*

- Part 1 - Valves (Vacuum Tubes)
  - Valve Characteristics
  - Valve Current Amplifier
  - Valve Power Amplifiers
  - Summary

Part 1 - The Valve (Vacuum or Thermionic Tube)

In the beginning the vacuum tube was the only way to amplify, and valves (or "tubes") survive to this day, with a dedicated following of "believers" who are convinced that the development of the transistor (or indeed, any semiconductor) was fundamentally a bad idea. This is not a discussion I intend to follow - I intend simply to state how these devices amplify a signal, and the factors that determine voltage and current gain.

The basic amplifying valve (there are many different types) has three elements. These are

- The anode (Plate) - Collects the electrons released by the cathode
- Cathode (indirectly or directly heated) - The source of the electron flow
- Control Grid (Grid) - controls the flow of electrons

When a positive voltage is applied to the anode with respect to the cathode, an electron stream

is emitted from the cathode and flows to the anode, completing the circuit. The grid is a fine coil of wire, suspended between the other two elements. A negative voltage on the grid (with respect to the cathode) will repel some of the electron stream, causing the current to be reduced. If the voltage on the grid were to be varied, then the cathode to anode current must also vary, and an amplifier is born. Figure 1.1 shows the basic circuit of a valve voltage amplifier.

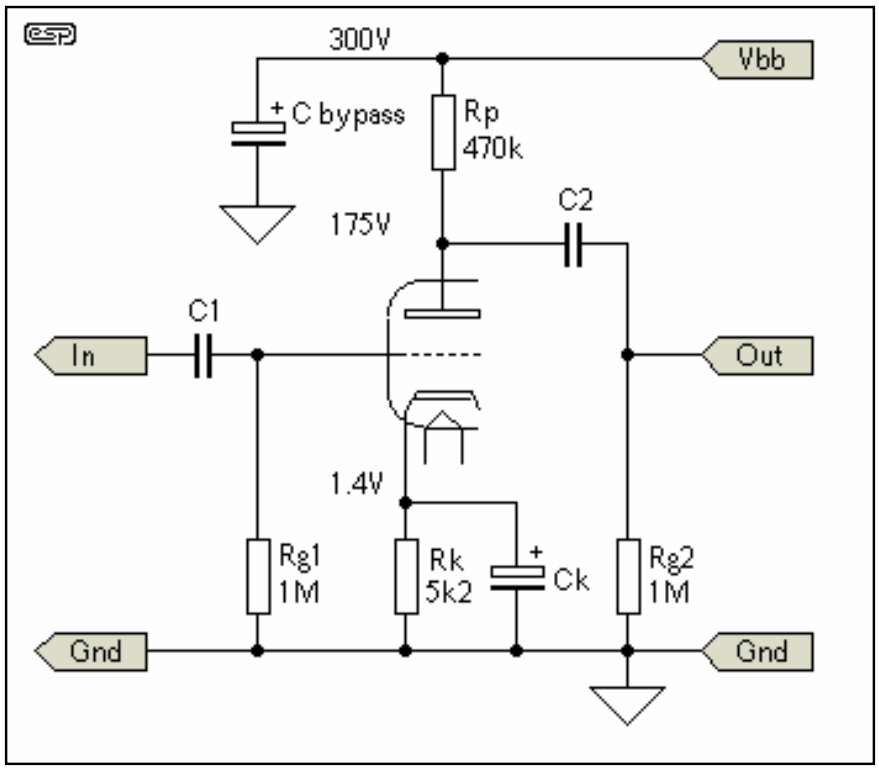

Figure 1.1 - A Basic Valve Voltage Amplifier

This circuit configuration is known as "common cathode", because the cathode reference point (earth) is common to both input and output. By placing a resistor "Rk" in the cathode circuit, a voltage is developed because of the current flow. If the grid is referenced to earth (ground), then the grid is negative with respect to the cathode. The voltages shown on the circuit are typical of a single element of a 12AX7 twin triode. Note that the two valve pins that are not connected are for the heater. This is used to heat the cathode so that it emits electrons more readily.

The cathode resistor will cause the circuit to reach a stable current, where any attempt at increasing the cathode current will cause a greater voltage across the resistor, making the grid effectively more negative and reducing the current. A point of equilibrium is quickly reached, where the circuit operates in a stable manner. This is known as cathode biasing, and is most common with signal level and very low power amps.

By applying a varying voltage (the signal) to the grid, the current between cathode and anode will vary too. Since the anode load is a resistance, a varying voltage will be developed which will (hopefully) be greater than the voltage applied to the grid. The input voltage has been amplified.

Because the signal voltage on the grid is "fighting" the attempt of the cathode resistor to maintain the current through the valve at a constant value, this is a form of feedback. It is also known as cathode degeneration. The name is of no consequence, because as local feedback, it will improve the linearity of the stage but reduce the gain. In reality, the improvement in linearity is only minor, and leaving out the capacitor can increase noise in sensitive circuits - especially hum that is induced into the cathode from the heater, which was nearly always operated from AC in the past, but DC heater supplies are now common.

Where the cathode is directly heated (the filament has the oxide coatings directly applied), DC operation is mandatory, or hum would be inevitable. Directly heated cathodes will always emit electrons unevenly, because of the voltage gradient across the filament. The most postive end will have the greatest emission, since the negative voltage between cathode and grid is lowest.

Note that for indirectly heated cathodes, the heating element is called the heater, but for directly heated cathodes it is more commonly referred to as the filament (as in the heated filament of a light bulb).

Because valves have a relatively low voltage gain, it is common to bypass the cathode resistor with a capacitor to defeat the local feedback and extract as much gain as possible, as is shown in Figure 1.1. The gain (or more correctly, the transfer characteristic) of a valve is sometimes measured in mA/V - which tells us how many milliamps change in anode current will occur with a grid voltage change of 1 Volt. Another common way to describe this is "mu" or amplification factor. Yet another value is common with valves - the "conductance" (A.K.A. mutual conductance or transconductance), which is the opposite of resistance, and is expressed in Mhos (Ohms backwards - seriously!).

One problem with valves has always been the number of different methods used to describe what is essentially the same thing. Depending entirely which book you happen to be reading, you will see the effective gain quoted as mA/V, mutual conductance ("g_m", in Mhos or more commonly uMhos), or the equally obscure term "Amplification Factor", none of which has any direct relevance to the gain you can expect without further calculation.

The output impedance of the circuit of Figure 1.1 is 470k - the same as the plate resistor. Rg2 is the grid resistor for the following stage, and at 1M, loads the output and reduces gain.

Valve Characteristics

There are three main characteristics that are quoted for any given valve. These are:

- Amplification Factor (mu) - This parameter compares the effectiveness of the control grid voltage to the plate voltage in changing the plate current
- Plate Resistance - This is the equivalent resistance of the internal cathode to plate circuit,

since the plate voltage is applied across the valve, and the current flows through it
- Mutual Conductance (AKA Transconductance) in uMhos - This shows how effective the grid is in controlling the plate current.

One important thing to realise about valves is that everything changes. The characteristics vary widely with plate voltage, load resistance, bias current and just about everything else you can think of. Despite this, it is still possible to design a circuit using valves that will be repeatable from one unit to the next, provided the designer knows what s/he is doing.

A typical signal valve (such as the 12AX7 high mu dual triode) has a plate resistance of 2k5, an amplification factor (mu) of 100, and a g_m (using the circuit of Figure 1.1) of about 1600uMhos, which can (by simple mathematics) be converted into a figure of 1.6mA/V, meaning that a change of 1V on the grid will cause a change of 1.6mA in the anode current. This does not actually mean what it says, since the valve might be quite incapable of sustaining an anode current of 1.6mA under all circumstances. However, a change of 0.1V at the grid *can* cause a change in plate current of 0.16mA - the measurement is typically "normalised" to make comparison easier (just like they don't in the supermarket).

Let us now have a look at how the valve amplifies the signal. The transfer curve in Figure 1.2 shows the input waveform applied to the grid, at any convenient frequency. As the signal becomes more positive, the valve draws more current, until at the peak of the waveform, the grid voltage has been made 0.1V more positive than it was before. Therefore, the anode current is 0.16mA greater that it was before. Using Ohm's Law, 0.16mA with a resistance of 470k means that the anode voltage is 75 Volts lower than when in the idle (or quiescent) state.

This would seem to indicate that the valve has a gain of (75 / 0.1) 750 - not a chance! The circuit of Figure 1 will have a typical voltage gain (Av) of around 75. As I said - everything changes. The only way to be certain what a valve will actually do is consult the manufacturer's data, and refer to the transfer curves for the mode of operation you wish to use. Supply voltage, plate current, plate voltage and the impedance of the next stage all have a profound effect on the performance of a valve.

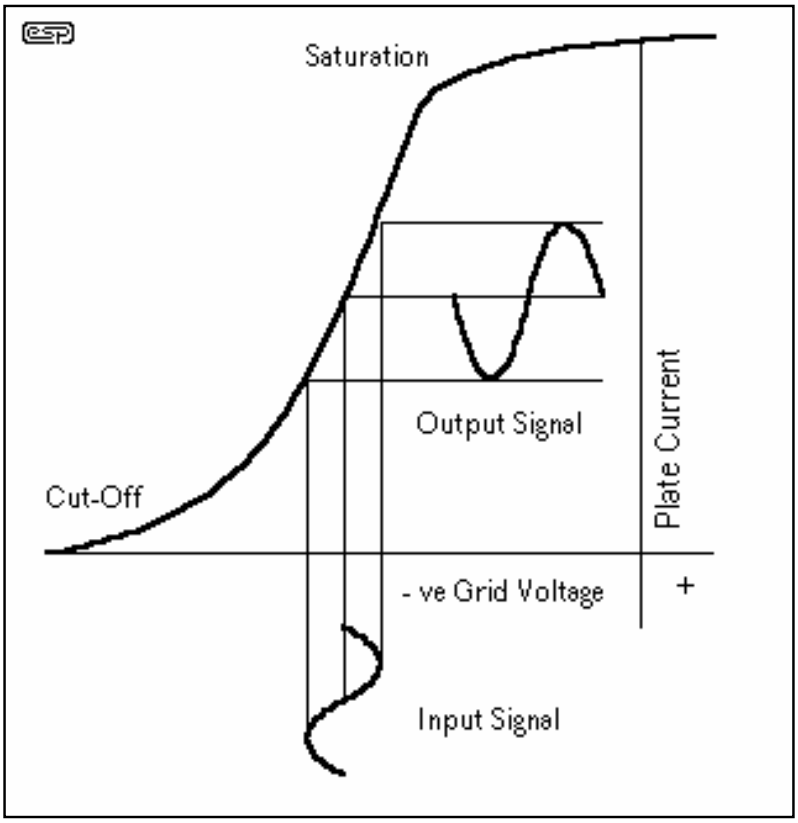

Figure 1.2 - Typical Valve Transfer Curve

As can be seen from Figure 1.2, the transfer curve is not linear, which means that as the valve approaches cut-off (turned off completely) or saturation (turned on completely) the characteristics change, and distortion is introduced. A (very) rough estimation of maximum rms output voltage to keep distortion below 1% is about 0.1 of the quiescent plate voltage. Thus, with a plate voltage of 150V at idle, the maximum output voltage will be 15V RMS. This assumes that the valve has been biased correctly in the first place. From the graph we can see that at high values of negative grid voltage the valve will cut off, while at low (or positive) grid voltage, the valve is turned on as hard as it can.

A valve can be thought of as having an infinite input impedance (although this is never realised in practice). The input impedance is approximately equal to the value of the grid resistor for audio frequencies. The output current is therefore controlled by a voltage at the grid, so the valve migh be considered a voltage controlled current source (or VCCS).

Valve Current Amplifier

Figure 1.3 shows a valve current amplifier, commonly known as a cathode follower, or common plate (because the plate circuit is common to both input and output - for AC signals only). Although this circuit can provide a useful increase of current, and an equally useful decrease in output impedance, it has a voltage gain that is less than unity. Typically, this will be about 0.8 to 0.9, so for every volt of signal applied to the input, we only get about 850mV output.

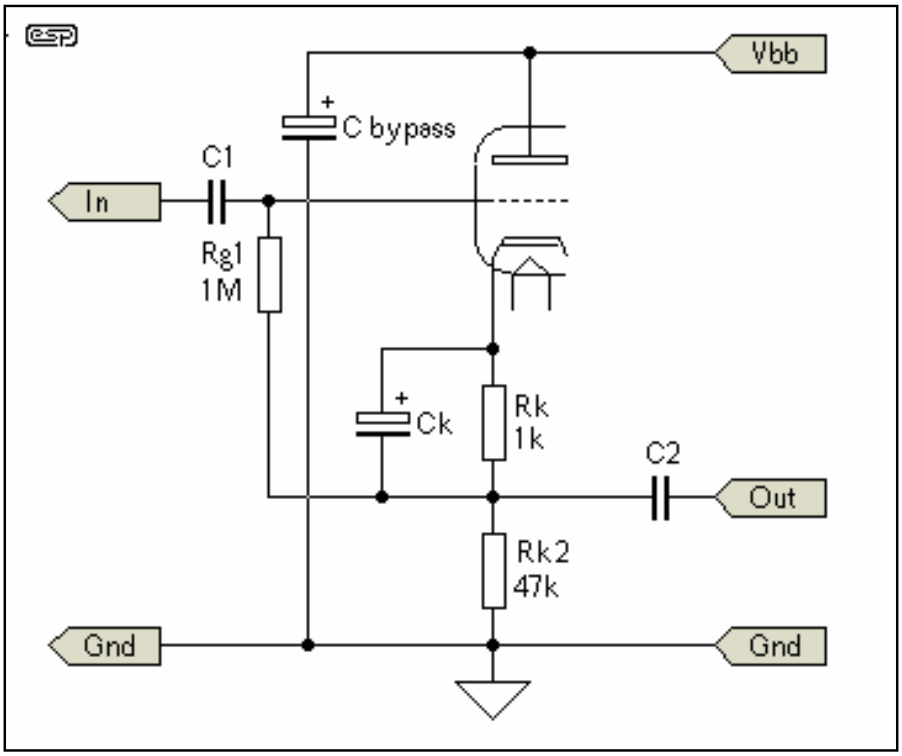

Figure 1.3 - Cathode Follower Current Amplifier

The cathode follower is typically used where a low impedance output is desired, since the output impedance of most valve circuits is rather high (equal to the value of the plate load resistor). Simply attaching a low impedance load to a voltage amplifier stage will cause the output level to be dramatically reduced, so the current amplifier (cathode follower) is a useful stage. The output impedance of the circuit of Figure 1.3 can be expected to be about 1/10th the value of the cathode resistance Rk2 - but this is highly dependent on the valve itself, and its operating current. The available current is very low, so the circuit will not be able to drive a load much less than Rk2, or 47k. Remember that output impedance and drive capability are not related.

Note that the grid must still be biased to an appropriate voltage negative with respect to the cathode. The bypassed cathode resistor is used as before, but the grid is connected to the bottom of this resistor, and not ground. If it were connected to ground, the circuit would be capable of only very small signal levels before it distorted.

Valve Power Amplifier

Finally, we can combine a voltage amplifier stage and a current amplifier stage, and get a power amplifier. Cathode followers are very unusual in the valve amplifier, and it is more common to use a "push-pull" output stage, generally using a transformer to match the high voltage and relatively high impedance of the output valves to the impedance of the speaker.

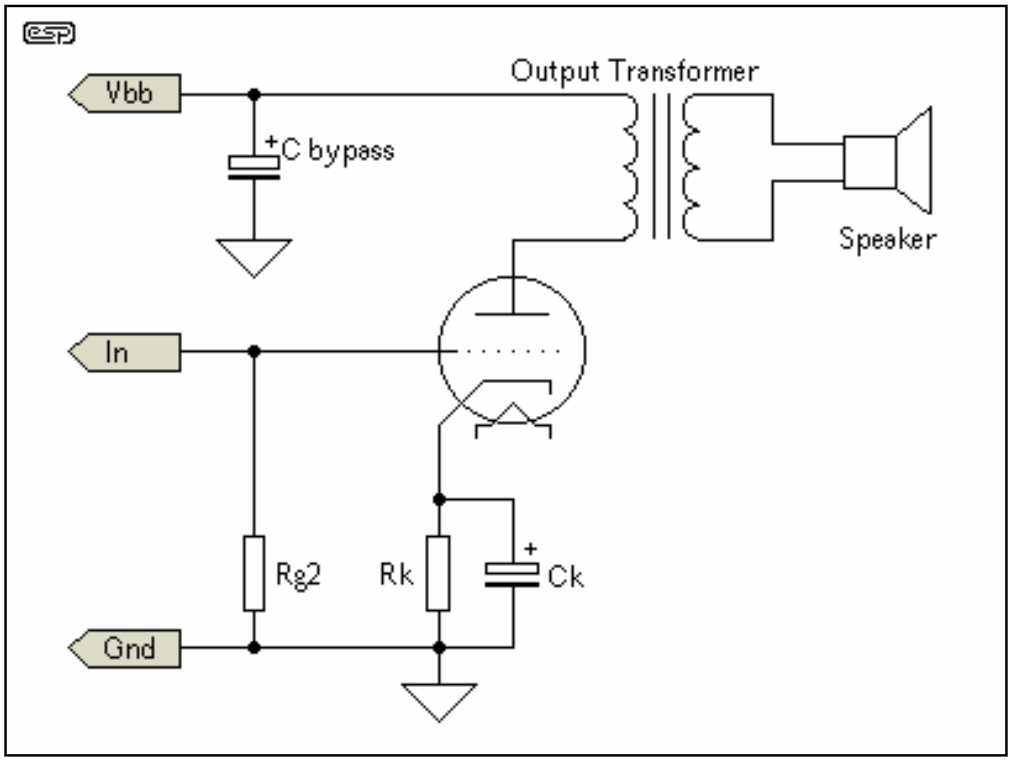

Figure 1.4 - Basic Valve Power Amplifier

Figure 1.4 shows a very basic valve power amplifier, using a triode in "single-ended" mode. The output transformer converts the high voltage, high impedance plate circuit of the valve to a low voltage, low impedance signal for the loudspeaker. Because the primary of the output transformer must carry the full DC quiescent current of the valve (which will be a large, high current unit), it needs a very large core of laminated steel.

Interestingly, these inefficient and high distortion amplifiers have made a comeback in recent years. However in the heyday of the valve, the efficiency and distortion of these circuits was such that they were replaced in nearly all installations by more efficient and lower distortion circuits, such as that shown in Figure 1.5.

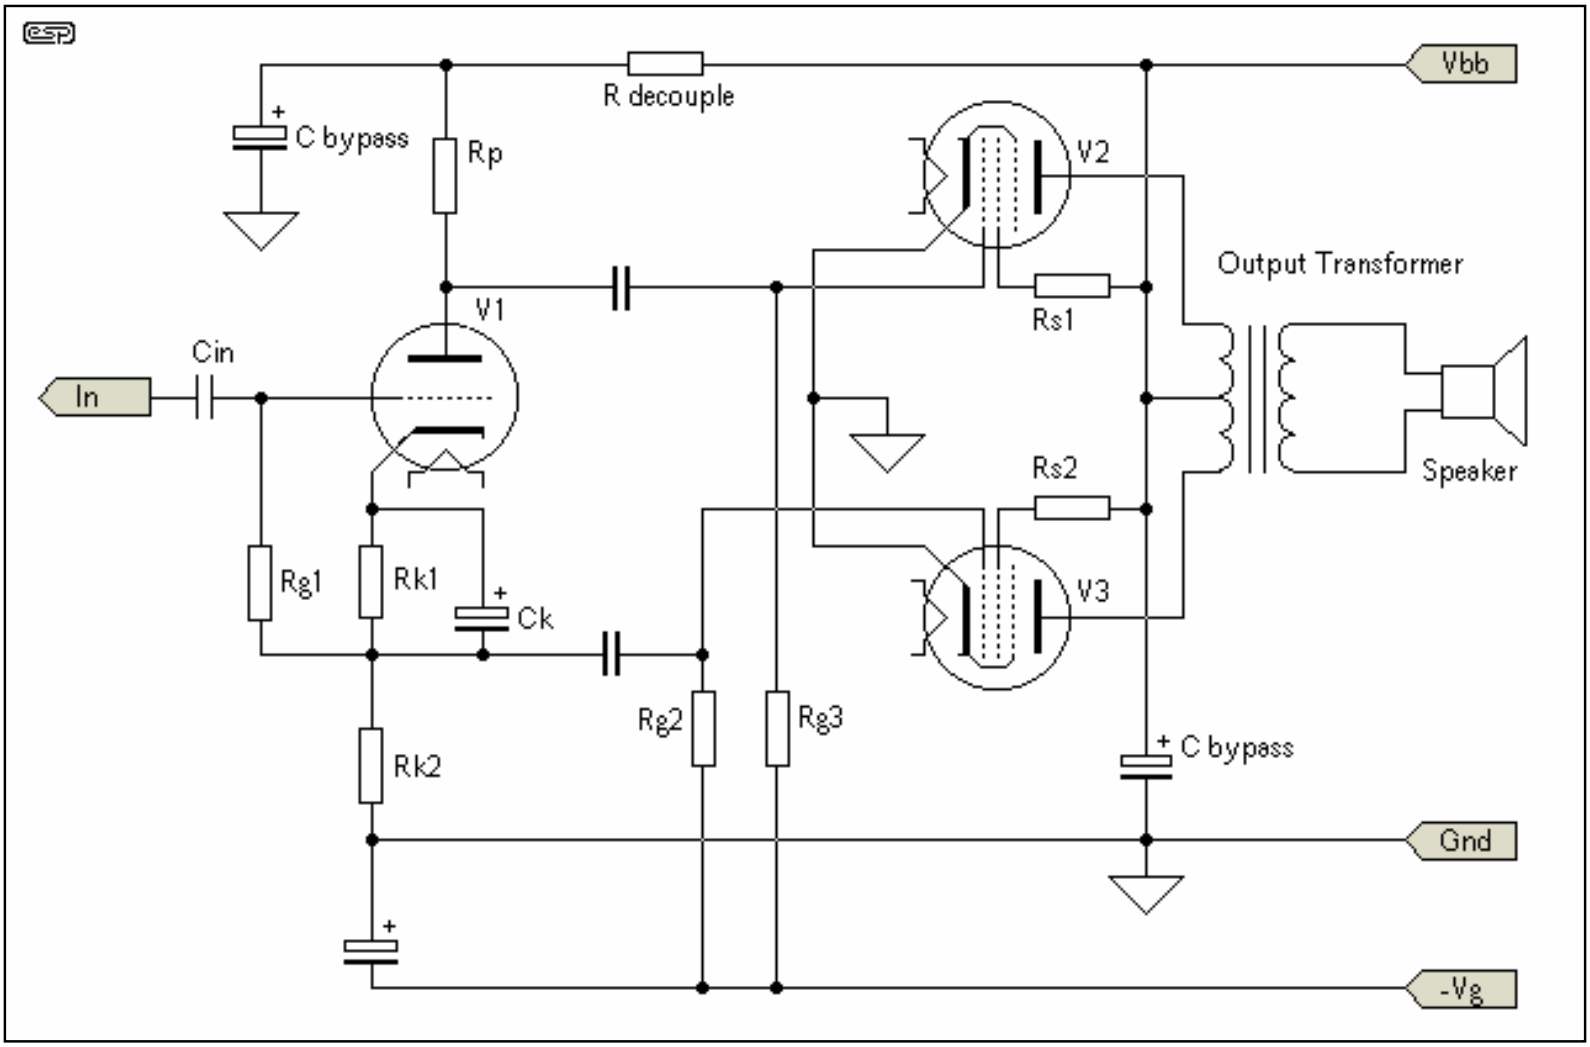

Figure 1.5 - Push-Pull Valve Power Amplifier

The valves shown for the output are called pentodes (from penta - five), having 5 electrodes instead of the three for a triode. The second grid (called the screen grid, or just screen) increases the gain of the valve dramatically, while the third grid, the suppressor, prevents what is called "secondary emission" from the plate. The screen accelerates the electron flow so much that electrons bounce off the plate, or dislodge others. The addition of the screen gives the valve some nice characteristics, such as much higher gain, but also some nasty ones (lower linearity, more distortion), which the suppressor counteracts to some degree. The suppressor grid is almost always connected internally to the cathode. It is not uncommon for designers to connect pentodes as triodes, by connecting the screen and plate together.

The first stage of the circuit is interesting, and is called a phase splitter. It is a combination of a voltage amplifier and a current amplifier, having equal values of resistance in each circuit (i.e. Rp = Rk2). Because all valves have the same "polarity", they cannot be used like transistors or MOSFETs, but must be driven with their own signal of the correct polarity.

The incoming signal is therefore sent "as is" to one valve (from the cathode circuit), and is inverted for the other - hence the term push-pull. As one valve "pushes" the anode current lower, the other simultaneously "pulls" it higher. In a properly designed circuit, the two output

valves will pass the signal between them with little disturbance. Any disturbance in this region is called crossover distortion, because it happens as the signal crosses over from one valve to the other.

Notice something else quite different. The cathodes of the output valves are connected directly to earth, and the grids are supplied with a negative bias from a separate -ve power supply. This is the most common method of biasing output valves in high power circuits, having a much greater efficiency than cathode biasing.

For many large output valves, it is not even considered a good idea to use cathode biasing, because the amount of negative grid voltage required is too high. Voltages of up to -60V are not uncommon with high power pentodes or another common type, beam power tetrodes (I will not cover these in more detail, but there is much information to be found on the web). Using cathode bias for this sort of voltage is inefficient and reduces the output power dramatically.

Valves - A Summary

The above is but a very small offering from the world of the vacuum tube. As I said in the introduction, this is not designed to be a complete electronics training course. The circuits presented are basic only, which is to say that they will all work, but are not optimised in any way.

For further reading, the most highly recommended work is the rather old (but still considered *the* reference manual) "Radiotron Designer's Handbook", by F. Langford-Smith and originally published by Amalgamated Wireless Valve Co. Pty. Ltd. in Australia. My copy is dated 1957, but it has recently been republished (although I think it is quite expensive, unfortunately).

Overall, the valve is still an almost mystical thing, but in all honesty, modern amplifiers using transistors or MOSFETs are so vastly superior in terms of fidelity, efficiency and reliability, that I really don't see what all the fuss is about. Having said this, I was using a valve preamplifier on my own system until recently.

There is no doubt that valves do have some very nice characteristics, and for guitar amplifiers there are few guitarists who would argue otherwise. A soft overload behaviour means that a valve amp does not sound as harsh as a transistor amp when it is overdriven - which is great for guitar, but a hi-fi should never be overdriven anyway, so the point is moot.

The problems that befall valves are many, and include

- **Fragile** - The glass envelopes are very thin, and are easily broken.
- **Limited Life** - Even if a valve is operated well within its ratings, it still has a finite life. The main causes of valve failure are cathode emission degradation (happening all the time),

and gas, when small amounts of air "break" the full vacuum.

- **Microphonics** - All valves tend to be slightly microphonic, which is to say that they act as a microphone. This can cause additional colouration to the signal if the sound from speakers vibrates the amplifier.
- **High Voltage** - Having to ensure that the 600V DC typical of a high power amp does not "flash over" valve bases is a constant headache, and ensuring that these voltages are kept well away from small fingers is mandatory. High voltage capacitors are also more expensive than lower voltage ones.
- **Heaters** - Valve cathodes must be operated at the correct temperature so they emit electrons properly, and "boil off" contaminants. If the heater voltage is too low, the cathode will become poisoned, and the valve is useless. The heater power used is all wasted, in that none of it is turned into sound.
- **Output Transformers** - The output transformer for a valve amp is expensive, bulky and heavy. It introduces its own distortion components, which are difficult (or impossible) to eliminate completely.
- **Heat** - All valve amps run hot. The valve will not work unless it is hot, and the heat causes problems for other components, shortening their life. The heat is all wasted energy.
- **Damping** - Valve amplifiers nearly all have a low damping factor, caused by a relatively high output impedance. Speakers must be very well damped indeed to work well with any valve amp, or the bass will become poorly defined, and crossover networks (which rely on a very low amp impedance) may not work as well as intended.

On the positive side, valve amplifiers have a "warm" sound, partly because of the low order harmonic distortion introduced. A good valve amp will also have a very wide bandwidth, and will have an easy job driving loads that cause solid-state equipment to have severe heartburn (or just blow up on the spot).

At low levels, valve equipment has vanishingly small distortion levels, and when all is said and done, there is something nice about little glass tubes, with little lights inside, making your music.

Part 2 - Bipolar Transistors

Since it was invented, the transistor (from "transfer resistor") has come a long way. Early transistors were made from germanuim, which was "doped" with other materials to give the desired properties required for a semiconductor. In the beginnings of the transistor era, nearly all devices were PNP (Positive Negative Positive), and it was very difficult to make the opposite (NPN) polarity. The NPN transistors that were available at that time were low power and did not work as well as their PNP counterparts.

When silicon was first used, the opposite was the case, and for quite some time the only really high power devices available were all of silicon NPN construction. More recently, it has become possible to make NPN and PNP transistors that are almost identical in performance. Germanium is rarely used, although some examples are still available.

All transistors have three "elements":

- Emitter - analogous to the cathode of a valve. The emitter only emits electrons in an NPN device, but this is of no consequence
- Base - the controlling terminal. A current at the base controls the current through the transistor
- Collector - basically, collects the emitted electrons. Somewhat analogous to the plate of a valve

A transistor can be represented as two diodes, with a junction in the middle. This is shown for both polarities in Figure 2.1. This is only an analogy, and connecting two discrete diodes in this manner will not produce a transistor, because the point where they meet must be a common junction on the same piece of silicon (or germanium) - hence (in part) the term Bipolar Junction Transistor. The "bipolar" term means that transistors use "charge carriers" of both polarities - positive and negative, or minority and majority.

Since the base to collector junction is reverse biased in normal operation, there will be no current flow. It is the action of injecting current into the base that causes current flow in the collector circuit. I do not intend to explain the exact conduction mechanism, as it is somewhat outside the scope of this article.

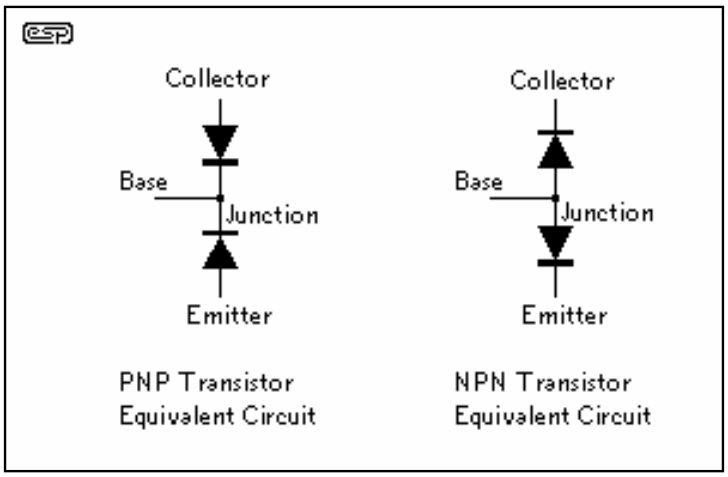

Figure 2.1 - Analogous Depiction of Transistors

This is very convenient, because it gives us an easy way to check if a transistor is likely to be good or bad, simply by measuring the "diodes". Early PNP germanium devices would actually work equally well if the emitter and collector were reversed, but devices are now optimised to maximum performance, so this trick is not as successful (it does still work, but the device gain is *much* lower when the terminals are reversed).

To make the transistor actually do something useful, it is necessary to bias it correctly. This is done (having selected a suitable collector resistance) simply by applying enough base current to ensure that the collector is at 1/2 the supply voltage. In the same way that the plate load resistor determines the output impedance of a valve amplifier, the collector resistor determines the output impedance of a transistor amplifier. Unlike a valve, the transistor is not said to have a "collector resistance" as in the equivalent resistance between emitter and collector, because this is not relevant to the operation of a transistor.

Figure 2.2 shows three methods of biasing a transistor. Of these Figure 2.2a is the least usable, because there is no mechanism to ensure that the circuit will be repeatable with different devices or with temperature. Variations caused by temperature are (and always have been) a real problem, and it is necessary always to ensure that the circuit has some feedback mechanism for DC operating conditions to ensure stability. Different transistors (of the same type and even from the same manufacturing run) will have different gains, and this, too, must be compensated for.

Assume that the gain of the transistor is 100 (exactly). This means that for 1mA of base current, 100mA of collector current will flow. The emitter current is the sum of the base and collector currents. To bias the transistor we need only meet this criterion (in theory), and everything will be well. With a Supply voltage (Vcc) of 20V, we want to have 10V at the collector, to allow maximum voltage swing. This will allow the voltage to go to +20V or to 0V, however the signal will be badly distorted by then.

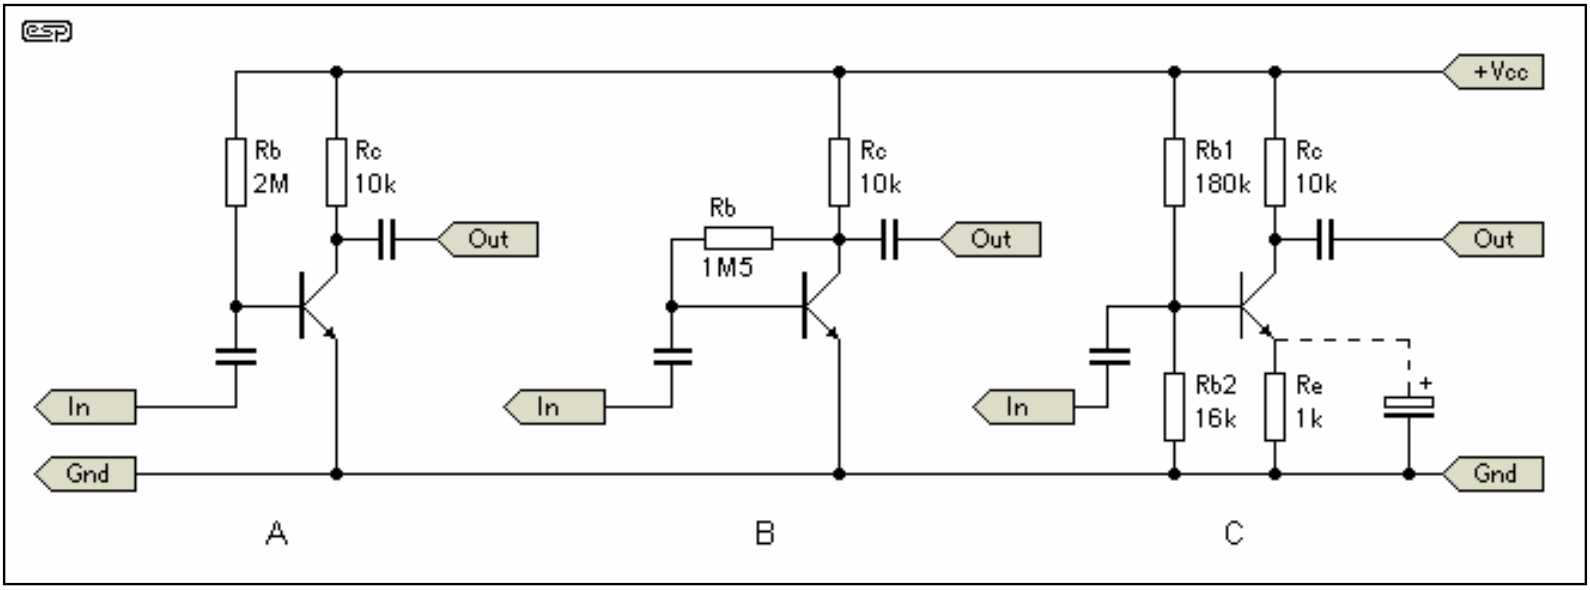

Figure 2.2 - Biasing a Transistor Voltage Amplifier, Three Methods

Figure 2.2b is a simple way to achieve this, but has some drawbacks. Because the bias resistor (Rb) is supplied from the collector circuit, it will have some of the collector current flowing in it. This will introduce negative current feedback, which at DC stabilises the circuit, but with the AC signal makes the input impedance very low, as well as reducing gain for any finite value of source impedance. This is not necessarily a drawback, however, as the feedback also reduces the distortion components.

This problem is overcome with the circuit in Figure 2.2c, with a bias divider providing a fixed voltage reference, and the emitter resistor (Re) providing stabilising feedback as we saw with the valve voltage amplifier. In the same way as with a valve, this also provides feedback, increasing linearity and reducing gain. With a transistor we get one additional effect - the input impedance is increased (more on this subject later). Again, to achieve maximum gain, it is common to place a capacitor in parallel with Re to defeat the feedback for AC signals, allowing maximum gain.

To bias a PNP device, we use exactly the same circuitry, but the supply polarity is reversed, so the collector (and base) will have a negative voltage with respect to the emitter.

One of the major differences between valves and transistors is that once we have decided on a suitable biasing circuit (or specified a gain from the amplifier), we can make device substitutions with little or no change in performance, provided the transistors have similar basic parameters. Often the same circuit will work just as well with perhaps 10 or 20 different devices, all from different manufacturers.

Transistor Characteristics

I shall only discuss the basic characteristics of transistors (as with valves), and there is really only one variable parameter and two fixed parameters (which are the same for every silicon transistor) to deal with. With transistors, the parameters are not as interactive as with valves, and the circuit gain is not as reliant on the device gain as with valves. In the same way as with valves, there are small signal devices (low power), working all the way up to power devices, which can have collector current ratings of 50 to over 100A for some of the very large power transistors.

- Gain - (AKA DC Current Gain, h_{FE}, beta) - the measure of the base current versus the collector current. This figure is only slightly dependent on the collector voltage, but can be affected considerably by collector current.
- re - Internal emitter resistance. With silicon transistors this is **26 / Ie** (in mA). Ie is the emitter current.
- Thermal coefficient - the diode junction voltage of a silicon transistor is nominally 0.65V, and falls by 2.0mV / degree C (this applies equally to diodes and transistors)

As stated before, the gain of a transistor is dependent on collector current, but will normally be applicable over a fairly wide range. The gain normally falls at very low currents (compared to the device maximum), and again at high current (approaching the maximum rated collector current for a given device).

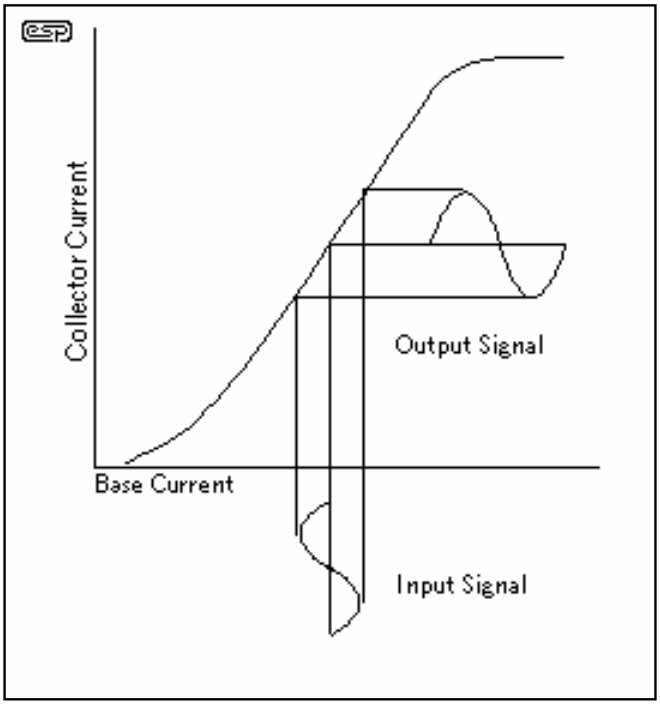

Figure 2.3 - Transistor Transfer Characteristics

The signal transfer curve is similar to that of a valve, and is shown in Figure 2.3. There is generally less distortion in the linear part of the curve, but because of the lower operating voltage, a transistor amp must work closer to the supply rail and earth, so distortion is often much higher with simple circuits such as those in Figure 2.2 than with an equivalent valve amplifier.

The major cause of distortion in small signal transistor amplifiers is the variation in the internal emitter resistance (re). Because transistors can tolerate a wider range of supply voltage and operating current than valves, it was common (when transistors were new and frightfully expensive) to try to extract as much voltage gain as possible from each device. This is no longer an issue, but the problem is still there, and it is necessary to take steps to prevent distortion. Very high gain circuits with global feedback are extremely common with transistor circuits, which renders the circuit immune from almost any variation of the device parameters, whether intrinsic (internal fixed) or manufacture dependent.

The gain of a transistor stage is approximately equal to the collector resistance divided by the emitter resistance (including the internal resistance re). So for the circuit of Figure 2.2c, the gain will be 9.75 without the emitter bypass capacitor, or about 384 with it installed. The distortion will be much higher with the emitter bypass in place, and it is uncommon to see these circuits any more.

The input impedance of a transistor voltage amplifier is low, and the output impedance is determined by the collector resistance (ignoring any feedback that may be applied from collector to base).

The input impedance is essentially determined by the gain of the device, and the value of emitter resistance (including the internal resistance), and in theory (that word again) is approximately equal to the emitter resistance multiplied by gain. The circuit of Fig 2.2a will therefore have an input impedance in the order of 2600 Ohms, Fig 2.2b will be very low because of the feedback, and 2.2c

(without the bypass capacitor) will have an input impedance of 100k - but as this is shunted by the bias resistors, the impedance will actually only be about 12k.

A transistor can be thought of as a current controlled current source (CCCS).

Transistor Current Amplifier

The current amplifier is much more common in transistor circuits than with valves, and is called an emitter follower (or occasionally common-collector). The emitter follower (like the cathode follower) has a voltage gain of less than 1 (or unity), but the difference is much less. Typically, the gain of an emitter follower circuit will be about 0.95 to 0.99 - depending on the operating current. The use of feedback to lower this further is very common, and output impedances of less than 1 Ohm are quite possible.

Figure 2.4 shows a standard configuration for an emitter follower current amplifier stage. It is common to bias the base to exactly 1/2 the supply voltage, using equal value resistors. I say "a" standard because there are many different configurations that can be (and are) used, including direct coupling, which is very common with transistor circuits.

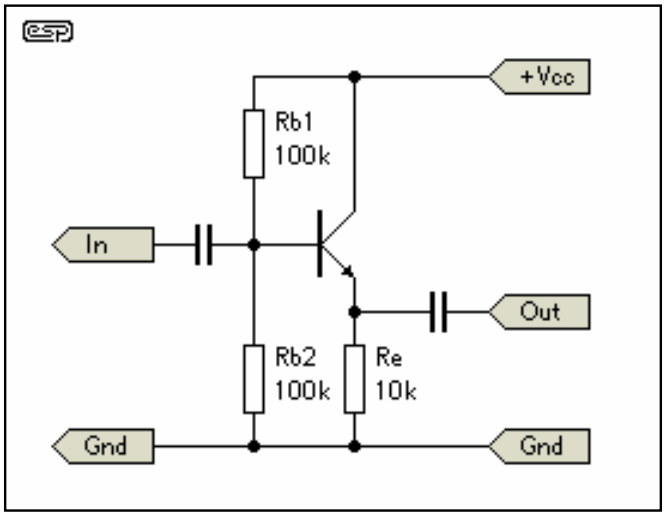

Figure 2.4 - Transistor Current Amplifier

One of the great attractions of transistors is their flexibility, which is considerably enhanced by having two polarities of device to work with. Because of this, circuits such as that shown in Figure 2.5 are common (or they were before the advent of opamps). Indeed, opamps themselves use the flexibility of transistors to the full, as can be seen if you have a look at the "simplified equivalent circuit" often published as part of the specification sheet for many opamps.

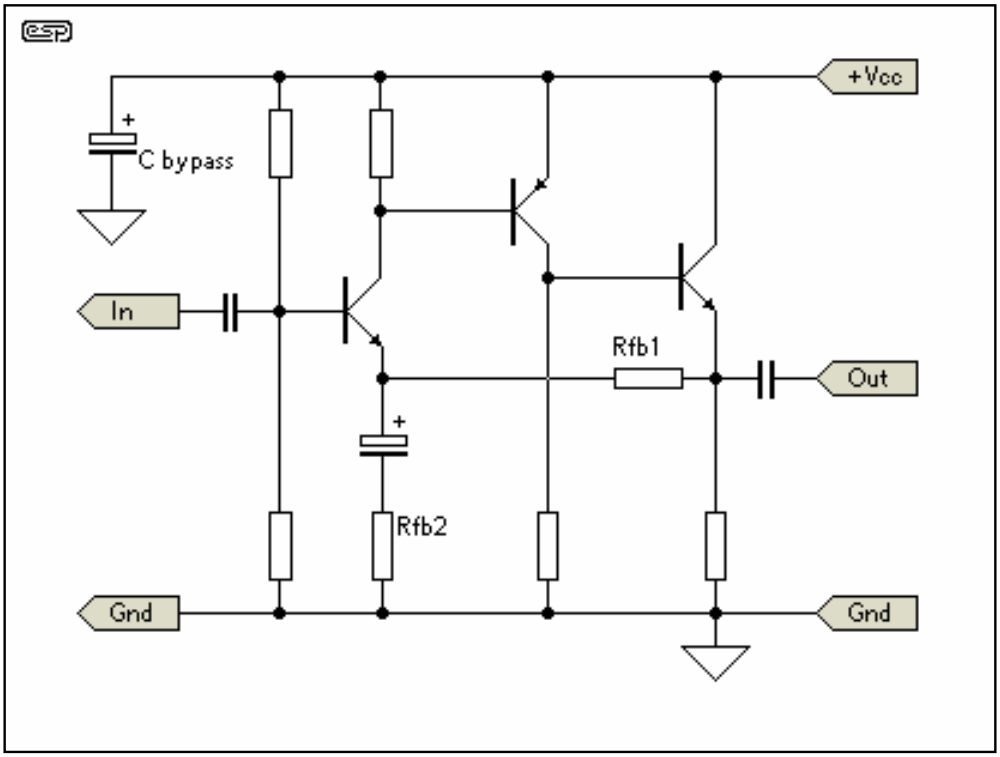

Figure 2.5 - A Typical Direct Coupled Transistor Amplifier

As can be seen, this amplifier uses an emitter follower for the output, is direct coupled within the circuit itself, uses both NPN and PNP devices, and has feedback to set a gain which is dependent only on the ratio of the two resistors Rfb1 and Rfb2. It is this sort of circuit that the opamp came from in the beginning, and there are still ICs (and small power amplifiers) that use similar circuitry internally. Regular readers may even recognise the basic circuit from the Projects Pages - essentially this is a discrete opamp, and will have a very high gain, which is brought back to something sensible by the feedback.

The actual gain is almost entirely dependent on the resistor values (for gains less than about 50 or so), and may be calculated by

Av = (Rfb1 + Rfb2) / Rfb2 where Av is voltage gain (Amplification, voltage)

So to obtain a gain of 20, Rfb1 would be 22k, and Rfb2 1k2 - this is actually a gain of 19.33, representing an error of 0.3dB. This gain is so stable that a completely different set of transistors from a different manufacturer would make no difference to measured gain performance. Other factors, such as noise or distortion must vary with the quality of the active devices, but the changes will generally be very subtle, and may not be noticeable at all, depending on the similarity of the transistors.

Transistor Power Amplifiers

A transistor power amplifier uses (typically) another configuration for the input stage. This is called a "long tailed pair", (LTP) and acts as both the input stage and error amplifier (Q1 and Q2). This

circuit operates in current mode, so there is little output voltage to be seen from its output.

The second stage (Q3) is a Class-A amplifier, and is responsible for a large proportion of the overall gain of the circuit. Notice the current sources that are typically used for the LTP and Class-A amp sections. These are commonly made using transistors and maintain a constant current regardless of the voltage at the collector. If the current were truly constant, this implies that the impedance is infinite (which means that the gain of the transistor stage is also infinite!), and although this is not the case in reality, it will still be remarkably high.

For more information on how current sources are constructed, see Section 5.1

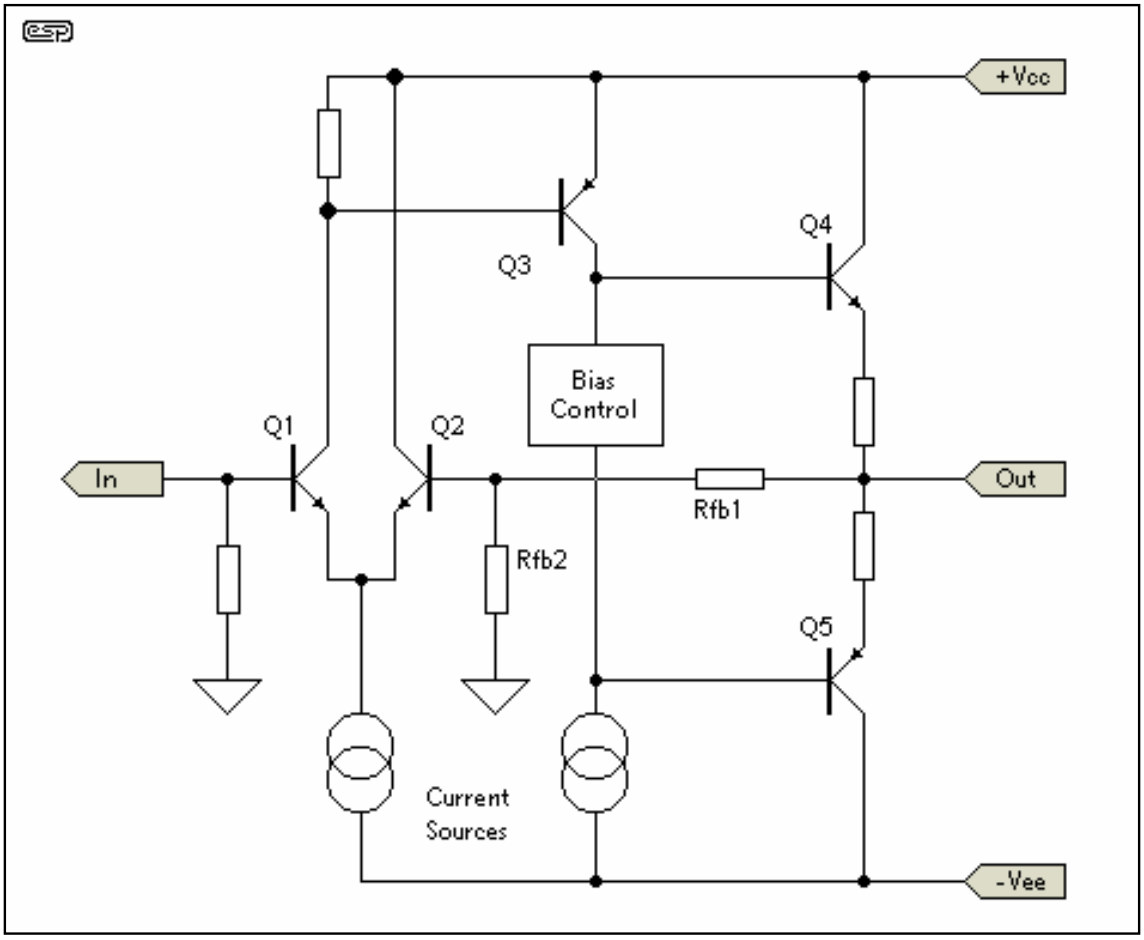

Figure 2.6 - Transistor Power Amplifier

The output stage (Q4 and Q5) typically is a pair of complementary emitter followers, which must be correctly biased to ensure that as the signal passes from one transistor to another, there is no discontinuity. This form of operation is known as Class-AB, since the amp operates in Class-A for very low level signals, then changes to Class-B at higher levels. Any discontinuity while passing the signal from one transistor to the other is the cause of crossover distortion, and for many years gave transistor amplifiers a bad name in the audio world. With proper biasing, and properly applied feedback, the crossover distortion can be made to go away - although never completely, but amplifiers with distortion levels of well below 0.01% are common.

The resistors at the emitters of the output transistors help to maintain a stable bias, and also

introduce some local feedback to linearise the output stage. This is a simplified circuit, and in reality the output stage will usually consist of multiple transistors, commonly a driver transistor followed by the output transistor itself. This does not change the operation of the circuit, but simply gives the output stage more gain, so it does not load the Class-A driver too heavily (this will result in greatly increased distortion).

Like the previous example, the gain is entirely dependent on the ratio of Rfb1 and Rfb2. As shown, the amp in Figure 2.6 is DC coupled, meaning that it will amplify any voltage from DC up to its maximum bandwidth. Not shown on this circuit are the various components needed to stabilise the circuit to prevent oscillation at high frequencies - often in the MHz range. Such oscillation is a disaster for the sound, and will quickly overheat and destroy the output transistors.

There are also transistor amplifiers that operate in Class-A, which means that the output transistors conduct all the time, and are never turned off. This can produce distortion levels that are almost impossible to measure, but this is at the expense of efficiency, and Class-A amplifiers will get very hot while doing nothing. Unlike the more common Class-AB amplifier, they will actually get slightly cooler as they reproduce a signal, since some of the input power is then diverted to the loudspeaker.

Transistors - A Summary

Just as with valve amplifiers, I have only scratched the surface. Entire books are written on the subject, and range from basic texts used in technical schools, to very advanced tomes intended for university students. Since transistors are easy to work with (and safe), there is much to be gained by experimentation, and you will have the satisfaction of having designed and built a functioning amplifier.

Transistors also have their fair share of problems, and there are some things that they are just not very good at. Some of the major failings include:

- **Low Impedance** - Bipolar transistors are inherently low impedance, and additional circuitry is needed to make them work satisfactorily in high impedance circuitry. Noise is also a problem when high impedance sources are used.
- **Heat** - Transistors dislike heat, and if it is not removed, they will destroy themselves. Most transistors can operate with junction temperatures up to about 125 degrees C, but at that temperature, can do no work at all. The life of a transistor is severely shortened by operating at high temperatures.
- **Thermal Stability** - Transistors are subject to some major changes in operation, depending on their temperature. This can make the design of high quality amplifiers difficult, because the transistor has a tendency towards "thermal runaway". This means that as the device gets hotter, it will draw more current, which makes it get hotter still. This continues until the maximum operating temperature is exceeded, and the transistor(s) fail.
- **Second Breakdown** - This is a version of thermal runaway, but at a molecular level. Parts of the internal structure become hotter than others, causing the hottest part to do the most

work. This makes it hotter still until the transistor fails. Second breakdown is the most common cause of output transistor failure in power amps. It also happens very fast, and without warning - transistors can fail from second breakdown even when at ambient temperature.

- **Short-term Overload** - Largely due to second breakdown effects, transistors do not tolerate short term overloads, and in many cases even a momentary short circuit will cause instantaneous failure. Compared to valves, transistor circuits are much less capable with difficult loads, and usually must be over-engineered to sometimes extreme levels to prevent failures.
- **Hard Overload** - when a transistor amp goes into overload, it does so with startling clarity. The harmonics produced are such that tweeters can be destroyed very easily, and the sound is altogether unpleasant

Again, there are many advantages as well. Transistor amplifiers are very reliable, and can be counted on to give many years of life without requiring even a basic service (most of the time anyway).

They are also very quiet (generally much quieter than valve amps) and do not suffer from microphony, so room vibrations are not re-introduced into the music. Efficiency is much higher, with lower voltages and no heaters (its a pity they don't look really nice, though).

Output impedances of 0.01 Ohm are achievable, so loudspeaker damping can be very high. Because transistor amps are very mechanically rugged, they can be installed in speaker boxes, so speaker lead lengths can be very short.

Typical transistor amplifiers have much wider bandwidth than valve amps, because there is no transformer, this is especially noticeable at the lowest frequencies - a transistor amp can reproduce 5Hz as easily as 500Hz.

Part 3 - Field Effect Transistors and MOSFETs

Now on to FETs and MOSFETs. FET stands for Field Effect Transistor, and MOSFET means Metal Oxide Semiconductor Field Effect Transistor. This topic is something of a can of worms, not because of some deficiency in the devices, but because of the huge array of different types. The basic FET types are

- N-Channel Junction FETs
- P-Channel Junction FETs
- N-Channel Enhancement Mode MOSFETs
- P-Channel Enhancement Mode MOSFETs
- N-Channel Depletion Mode MOSFETs
- P-Channel Depletion Mode MOSFETs

There are a couple of major sub-classes of MOSFET - lateral and vertical. Lateral MOSFETs are particularly suited to audio applications, as they are far more linear than their vertical brethren, although their gain is generally lower. Vertical MOSFETs are ideally suited to switching applications, and this includes Pulse Width Modulated (PWM) amplifiers.

The terms 'lateral' and 'vertical' refer to internal fabrication methods, so many others you may come across (such as HEXFETs ®) are essentially variations of the vertical process. This is still not all the possibilities, because there are additional sub-classes as well, particularly with switching MOSFETs. However, for the purpose of a general article on their characteristics and how they work, I will concentrate on the most commonly used versions. This narrows the field, and we are left with both polarities of junction FETs, and both polarities of enhancement mode MOSFETs. With these, we cover the major proportion of current designs, so even 'though I will be leaving out a lot, the stuff I leave out is not all that common (he says hopefully).

FETs are "unipolar" devices, in that they use only one polarity of carrier, in contrast to bipolar transistors, which use both majority and minority charge carriers (electrons or "holes", depending on the polarity). FETs are far more resistant to the effects of temperature, X-Rays and cosmic radiation - any of these can cause the production of minority carriers in bipolar transistors).

I shall concentrate only on three terminal FETS, and the terminals are

- Source - The electron "source" (for N-channel devices), and is the equivalent of the cathode of a valve or the emitter of a transistor
- Gate - Control terminal - (more or less) equivalent to the grid of a valve or base of a transistor
- Drain - The terminal from which current is "drained" - equivalent to the plate of a valve or collector of a transistor

There is no simple equivalent circuit for FETs (as there is for transistors), but this is of no consequence. The gate is the controlling element, and affects the electron flow not by amplifying a current (as in the transistor), but by the application of a voltage. The input impedance of junction FETs is very high at all usable frequencies, but MOSFETs are different. They have an almost infinite input resistance, but appreciable capacitance between the gate and the rest of the device. This can make MOSFETs hard to drive, because the capacitive loading makes most amplifier devices unhappy.

The junction FET is common in the inputs of high performance opamps, and offers extremely high input impedance. Indeed this is the case for discrete FETs as well, and a simple voltage amplifier using a junction FET and a power MOSFET are both shown in Figure 3.1. Both devices are N-Channel, and note that the arrow points in a different direction for each. The arrows point in the opposite direction for a P-Channel device, and all polarities are reversed. Vdd is +20V.

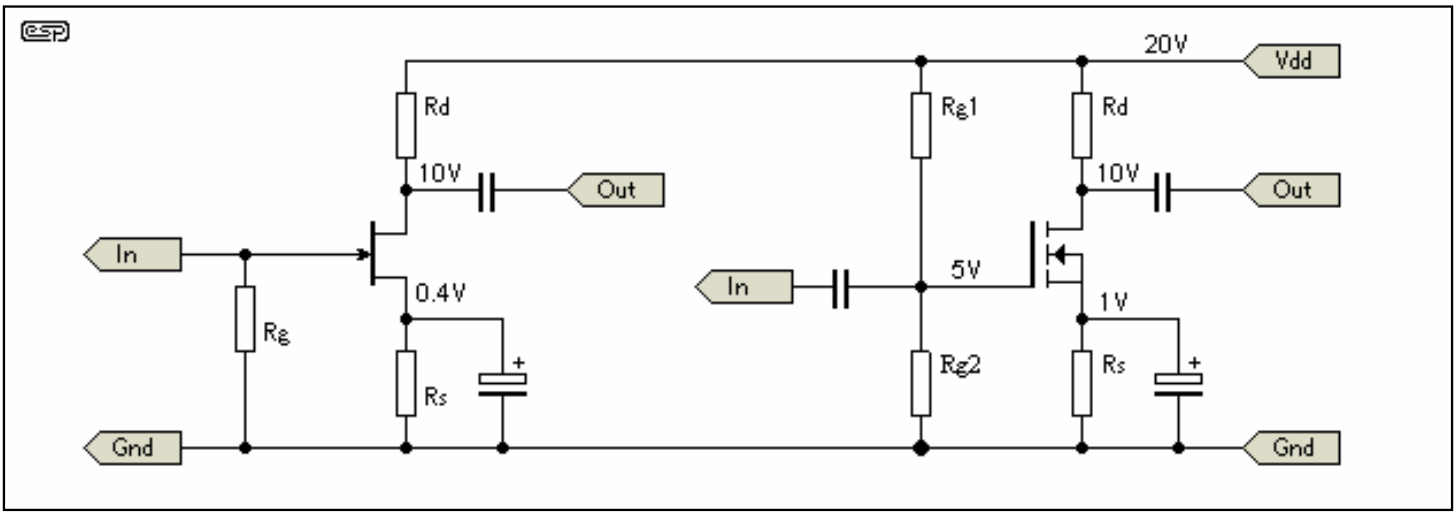

Figure 3.1 - Junction FET and Power MOSFET Voltage Amplifiers

Junction FETs are depletion mode devices, and (like all depletion mode FETs and MOSFETs) can be biased in exactly the same way as a valve. Depletion mode means that without a negative bias signal on the controlling element (the gate), there will be current flow between the drain (equivalent to plate or collector) and source (equivalent to cathode or emitter).

An enhancement mode device remains turned off until a threshold voltage is reached, after which the device conducts, passing more current as the voltage increases. Although there are MOSFETs made for low power operation, the majority (in audio, anyway) are power devices. These are almost exclusively enhancement mode, and can be capable of very high current.

In Figure 3.1, the power MOSFET is an enhancement mode device, and the junction FET is depletion mode. These are the most commonly used in audio. Enhancement mode power MOSFETs are also used in switching power supplies, and are far better than bipolar transistors in this role. They are faster, so switching losses are not as great (therefore the MOSFETs run cooler), and they are more rugged, and able to withstand abuses that would kill a bipolar transistor almost instantly.

This ruggedness (coupled with the complete freedom from second breakdown effects), means that MOSFETs are very popular as output devices for high power professional amplifiers. In this area, the MOSFET is second to none, and they are firmly entrenched as the device of choice for high power.

This is not to say that this is the only place MOSFETs are used. There are many fine audiophile power amps (and even preamps) that use power MOSFETs, and there are many claims that they are sonically superior to bipolar transistors (again, a debate that I will not discuss here).

Somewhat like valves, FETs and MOSFETs are very device dependent, and it is not normally possible to just substitute one device for a different type. Also like valves, the gain that can be expected from a voltage amplifier circuit is device dependent, and the manufacturer's data sheet (or testing) is the only way that one can be sure of obtaining the gain required in a given circuit.

FET Characteristics

The characteristics of FETs must be covered in two parts, since we are dealing with two quite different devices. The first will be the junction FET, and as with transistors, I shall only describe the N-Channel, but virtually identical P-Channel devices are available (although not as commonly used).

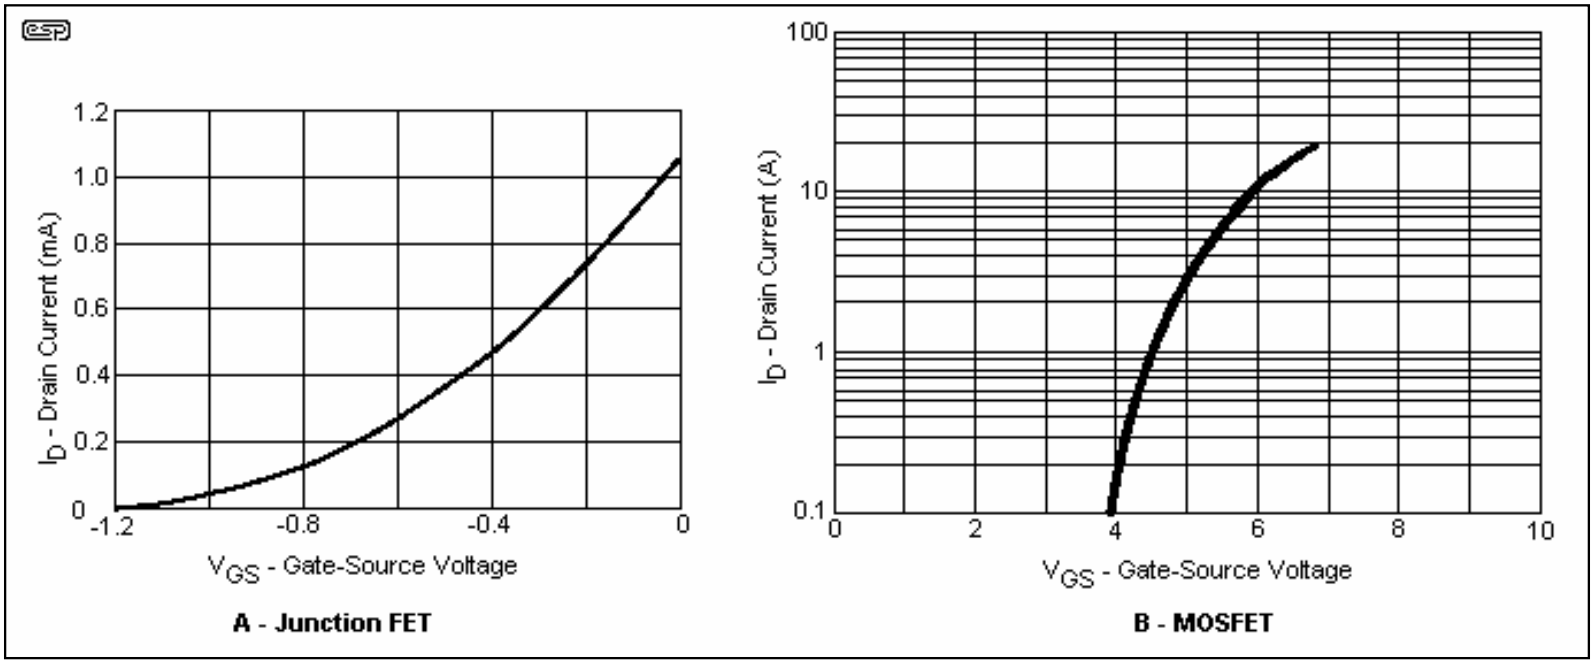

Figure 3.2 - Transfer Curves For a Junction FET and MOSFET

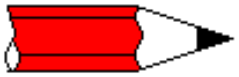
Initially, so the transfer characteristics of the two devices can be seen side by side for comparison, Figure 3.2 shows a fairly typical device from each "family" The junction FET data is from a 2N5457, and the MOSFET is an IRFP240 (a vertical MOSFET - more suited to switching applications).

Rather than show the input and output signals superimposed on a graph, this time I show only the graph itself. These are excerpts from manufacturers data, but with a small catch - Figure 3.2b has the drain current displayed on a logarithmic scale, so the linearity of the device cannot be seen properly. If this graph were redrawn as linear, it will show that linearity is best at higher currents (on the graph shown it looks the other way around), and the device becomes almost perfectly linear with drain currents above about 3A.

Note that because the junction FET is depletion mode, drain current is highest at 0V gate-source voltage. The MOSFET on the other hand is enhancement mode, so at 0V gate-source, there is no current. Conduction starts at 4V, and by 6V the drain current is 10A.



The term Siemens (S) is now replacing Mhos as the unit of transconductance in some literature: 1S = Mho (1uS=1 uMho. For the above graphs, it may be worked out that the junction FET has a transconductance of 1500uS, and for the MOSFET it is approx. 9,000uS (9,000 uMhos)

Junction FETs

Like valves, FET data sheets provide gain information as gm (mutual conductance - in uMhos). The junction FET shown has a gm of (typically) 1,500 uMhos (in the graph shown it is actually closer to 1425 uMhos in the linear section), which translates to about 1.5 mA/V.

The most common of the quoted parameters for junction FETs are

- Forward Transfer Admittance (Common Source) - Transconductance - essentially the gain of the device
- Input Capacitance - The effective capacitance of the gate terminal to the remainder of the FET
- Gate–Source Cutoff Voltage - The gate voltage at which the FET is turned off

The process of amplification is almost identical to that of a valve, except that the voltages are lower. The device is biased in the same way (although fixed bias can also be used). This means that the gate must be reverse biased with respect to the source, with the gate having the opposite polarity of the source-drain voltage.

FETs offer low noise, especially with high impedance inputs, and in this respect are the opposite of bipolar transistors, which are generally at their best with low source impedance.

Junction FETs are predominantly low power, although there are some high power devices available. These are uncommon in audio applications.

MOSFETs
Again, MOSFET data sheets also provide information similar to junction FETs, but there are more items of importance to the designer. The most useful of these are

- Forward Transconductance - The device gain characteristic
- Drain to Source On Resistance - The minimum resistance when the MOSFET is fully on
- Gate Threshold Voltage - The gate voltage at which the MOSFET will start conduction
- Gate to Source Voltage - The maximum voltage (of either polarity) that may be applied between source and gate. (This is typically in the order of +/-20V)
- Input Capacitance - The value of capacitive loading that is placed on the driving circuit

Enhancement mode MOSFETs pass virtually no current when there is no gate voltage present. To conduct, a voltage must be applied between source and gate (of the same polarity as the drain voltage). Once the threshold has been reached, the device will start to conduct between drain and source.

At increasing gate voltages, the drain current increases until either a) the maximum permissible drain current or total dissipation limit is reached, or b) the drain voltage falls to its lowest possible value. In this instance, since the source-drain channel is now fully conducting, the value of $R_{DS(on)}$ determines the voltage.

Typical power MOSFETs offer extremely low on resistance, with values of 0.2 Ohm being fairly typical. There are some devices with much lower values, but this is only important in switching circuits. In an audio amp, the MOSFETs should never be turned completely on, since this means the amplifier is clipping.

Another area that must be addressed with MOSFETs is the voltage between gate and source. Because the gate is insulated from the channel by a thin layer of metal oxide, it is susceptible to damage by

static discharge or other excessive voltage. It is common to include a zener diode between source and gate to ensure that the maximum voltage cannot be exceeded. Voltage spikes in excess of the breakdown voltage of the insulating layer will cause instantaneous failure of the device.

FET Current Amplifier

Again, I have shown both a junction FET and a MOSFET in Figure 3.3, both common-drain or source-follower circuits. As can be seen, the junction FET is biased almost identically to a valve, but all voltages are much lower. The MOSFET requires a positive voltage, and this must be greater than the source voltage, by an amount that takes the characteristics of the MOSFET into consideration. For the device characteristics shown in Figure 3.2 this means that at a current of 100mA, the gate must be 4V higher than the source.

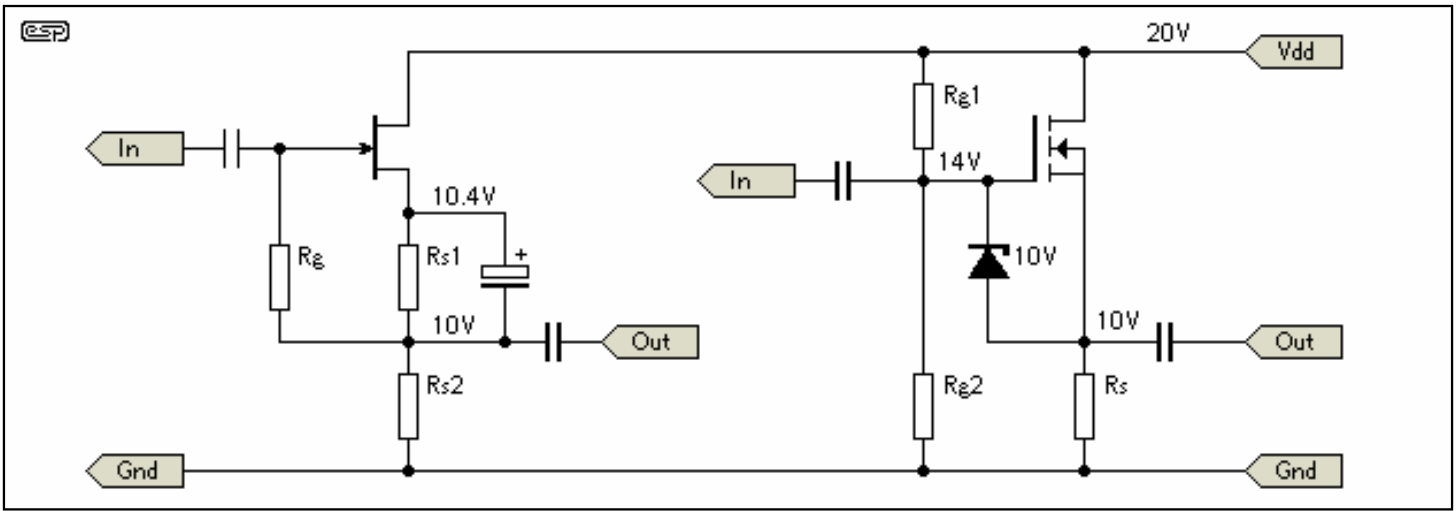


Figure 3.3 - FET Current Amplifiers

Included in the MOSFET version is a zener for protection of the gate insulation. A 10V zener is used, as this gives good protection and is still able to let the maximum possible MOSFET current flow. A 6V zener could have been used, and this would still allow current up to 10A, which is far more than can be achieved from this simple circuit.

FET Power Amplifiers

In exactly the same way as a power valve can be used in single-ended Class-A, so too can a MOSFET. A simple circuit is shown in Figure 3.4 which will provide about 10W of audio. Using a constant current source as a load (as shown) gives much better efficiency than a resistor, and improves linearity. The distortion from a circuit such as that shown will be roughly the same as that from a single ended triode valve circuit. Overall efficiency will be higher, since there is no cathode bias resistor needed, and no heaters as with a valve.

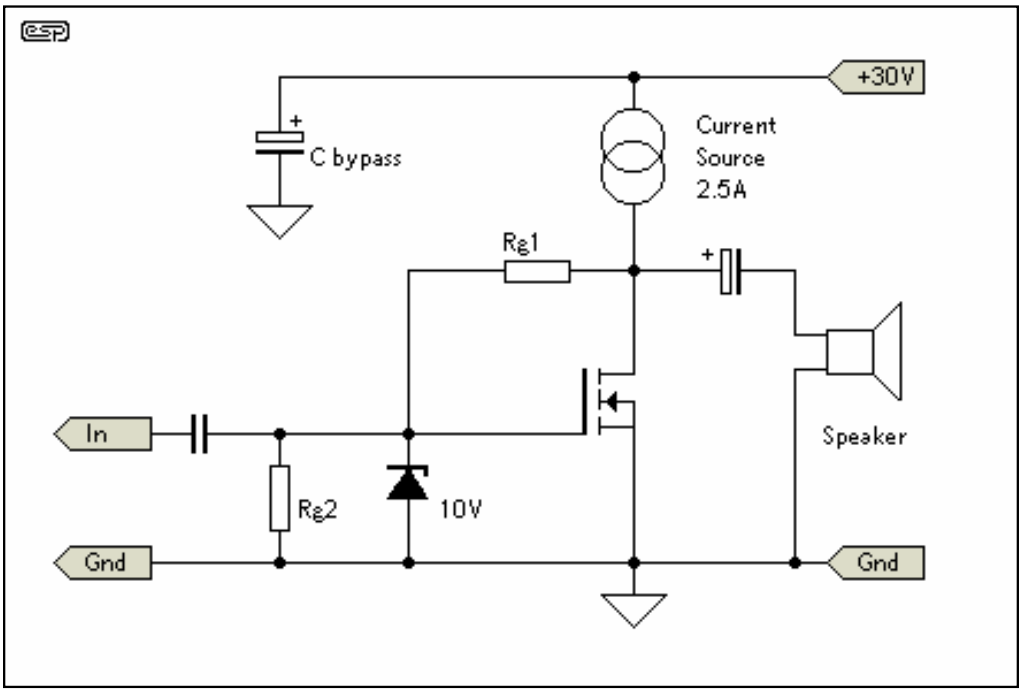

Figure 3.4 - Single Ended MOSFET Class-A Amplifier

Although there are a few, all MOSFET power amplifiers are uncommon. Most use a combination of bipolar transistors (for the input and gain stages), and MOSFETs for the output devices. This seems to be the most popular circuit arrangement, so I will concentrate on this. Figure 3.5 shows a fairly typical arrangement (in simplified form), and the operation of this is almost identical to that of an amplifier using bipolar transistors in the output. Note that emitter followers are needed to be able to provide the low impedance drive that MOSFETs need, although in some circuits they are not used. Instead, the Class-A driver stage (Q3) is operated at a higher than normal current to allow it to drive the MOSFETs properly.

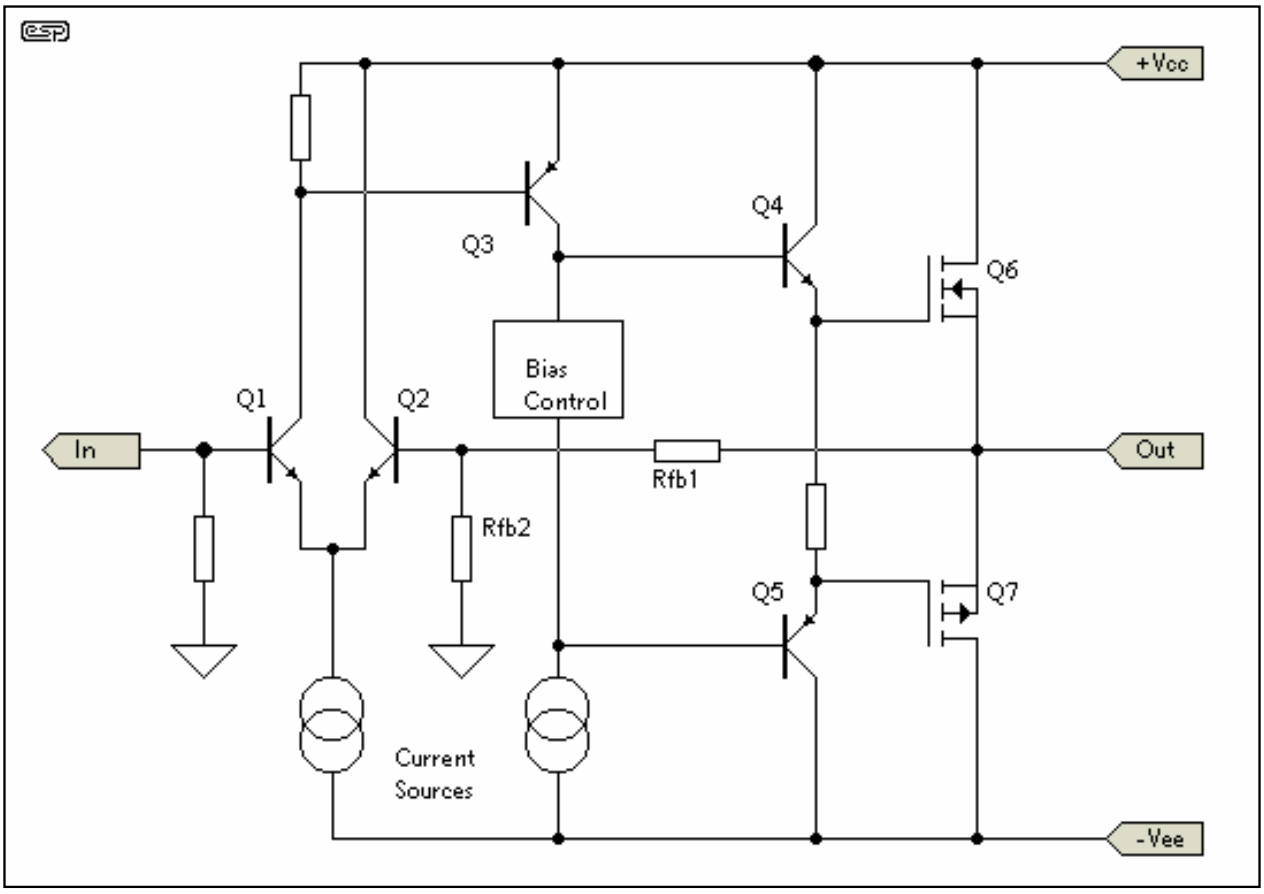

Figure 3.5 - MOSFET Output Power Amplifier

One problem with this arrangement is that the drain to source voltage represents a circuit loss, so the power supply voltage needs to be typically +/-6V higher than the required peak output voltage to the load. Although this is not a major problem, it does increase dissipation in the output stage, and the loss increases with lower impedance loads.

Some (especially very high power) amps get around this by using a low current (but higher voltage) secondary power supply for the drive circuit, and the main high current supply for the MOSFETs. In an amp using +/-50V at 20 Amp main supplies, the secondary supply might be +/-60V, but capable of perhaps 1A maximum.

As with the bipolar amp (did you notice how similar they are?), I have not included components for stability. These are typically the same as for a standard bipolar transistor amp, but will usually include "stopper" resistors in series with the gates of the MOSFETs, and sometimes additional capacitance to prevent parasitic oscillation - the need for these varies from one device type to the next.

FETs - A Summary

Junction FETs

The surface is again, only barely scratched. The junction FET (A.K.A. JFET) is ideally suited to circuits where high impedances are expected, and will give the lowest noise. They are an invaluable electronic building block when used where they excel - providing extremely high input impedance.

Like all devices so far, JFETs have their limitations ...

- **Gain** - JFETs do not have the high gain of bipolar transistors
- **High Frequency Response** - Generally, JFETs have a high frequency performance that is not as good as bipolar transistors
- **Linearity** - The linearity of JFETs is not as good as bipolar transistors (so distortion is greater), but can be improved by using current source loading or feedback.

There is generally an ideal (or close to ideal) amplifying device for every application, and when used properly, the JFET is extremely versatile and at its best when high impedances are needed. If you have a need to send an amplifier into space, then JFETs are preferred due to their greater "radiation hardness".

JFETs (in fact all FETs) are more sensible than bipolar transistors when heated, and problems of thermal runaway are not encountered with these devices.

MOSFETs
The MOSFET is one of the most powerful of all the current range of amplifying device, with extraordinary current capability. Ideally suited to very high power amplifiers, where extremes of operating conditions are regularly encountered, the MOSFET has no equal.

... And, as always, there are limitations ...

- **Gain** - Like JFETs, MOSFETs have a lower gain than bipolar transistors, which usually means that additional gain must be applied to the driving circuit to ensure that the global feedback is sufficient to maintain low distortion at low levels.
- **Gate Capacitance** - The capacitance of the gate to source can be as high as 2nF (although more typically around 1.2nF). This is not a lot at low frequencies, but makes the drive circuit work very hard at high frequencies.
- **Static Damage** - Until installed in a circuit with full protection, the MOSFET is susceptible to damage from static discharge. The voltage and current needed to destroy the device are generally below the threshold of feeling for humans. Some devices have (limited) protection built in.
- **Linearity** - Most MOSFETs are not very linear at low currents, so for low distortion higher quiescent is needed to ensure that crossover distortion is minimised.

To some extent, all the above can be forgiven when you really need the capabilities of a MOSFET. The complete freedom from second breakdown and the massive current capabilities of MOSFETs are unmatched by any other active device. With a properly designed drive circuit, MOSFETs are also very fast, capable of performance that is generally superior to that of bipolar transistors. This is not very helpful in audio, but is essential for switching circuits.

Coupled with a positive temperature coefficient that completely stops thermal runaway in a linear circuit, the MOSFET is almost indestructible, provided that precautions are taken to ensure the gate voltage is kept below the breakdown voltage.

The positive temperature coefficient is a great help in audio circuits, although it can be a problem in switching power supplies, since the "on" resistance also increases with temperature, and in a switch-mode power supply this can cause thermal runaway (exactly the reverse of bipolar transistors in this application).

Part 4 - Operational Amplifiers (Opamps)

No discussion of amplifying devices would be complete without a discussion of opamps. Although not a single device, the opamp is considered to be a building block, just like a valve or any transistor.

The format I used for the other discussions is not appropriate for this topic, so will be changed to suit this most versatile of components. I shall not be covering esoteric or special purpose types, only the basic variety, as there are too many variations to cover.

The operational amplifier was originally used for analogue computers, although at that time they were made using discrete components. Modern (good) opamps are so good, that it is difficult or impossible to achieve results even close with discrete transistors or FETs. However, there are still some instances where opamps are just not suitable, such as when high supply voltages are needed for large voltage swings.

The majority of power amplifiers (whether bipolar or MOSFET) are in fact discrete opamps, with a +ve input and a -ve input. You tend not to see this, but have a look at Figure 3.5 again. The signal is applied to the +ve input at the base of Q1. The base of Q2 is the -ve input, and is used for the feedback signal, exactly the same as you will see in Figure 4.1a below.

Unlike the other devices, opamps are primarily designed as voltage amplifiers, and their versatility comes from their input circuitry. Opamps have two inputs, designated as the non-inverting and inverting (or simply + and -).

When wired into a conventional amplifier circuit, the opamp has one major goal in its little life ...

Make both inputs the same voltage

If, because some swine of a designer has made this impossible (very common with a lot of circuits), the opamp then takes another approach ...

Make the output the same polarity as the most positive input

The latter condition needs a small explanation. If the +ve input is most positive, then the output will swing to the positive supply rail (or as close as it can get). Should the -ve input be more positive, then the output will swing to the negative supply rail. The difference between the two inputs may be less than 1mV! Simple as that.

I call these "The First and Second Laws of Opamps". These two statements describe everything an opamp does, and just by knowing this, makes the task of working out what most common circuits do a simple process. There is actually nothing especially complex about opamps, unless you look at the "simplified" circuit diagram often included in data sheets. Don't do this, as it is too depressing. (By the way, the first statement is not strictly true of real-life devices, which will always have some error, however without very specialised equipment you will be unable to measure it.)

Modern opamps (the good ones, anyway) are as close as anyone has ever got to the ideal amplifier. The bandwidth is very wide indeed, with very low distortion (0.00003% for one of the Burr Brown devices), and low noise. Although it is quite possible to obtain an output impedance of far less than 10 Ohms, the current output is usually limited to about +/-20mA or so. Supply voltage of most opamps is limited to a maximum of about +/-18V, although there are some that will take more, and others less.

Depending on the opamp used, gains of 100 with a frequency response up to 100kHz are easily achieved, with noise levels being only very marginally worse that a dedicated discrete design using all the noise reducing tricks known. The circuits shown below have frequency response down to DC, with the upper frequency limit determined by device type and gain.

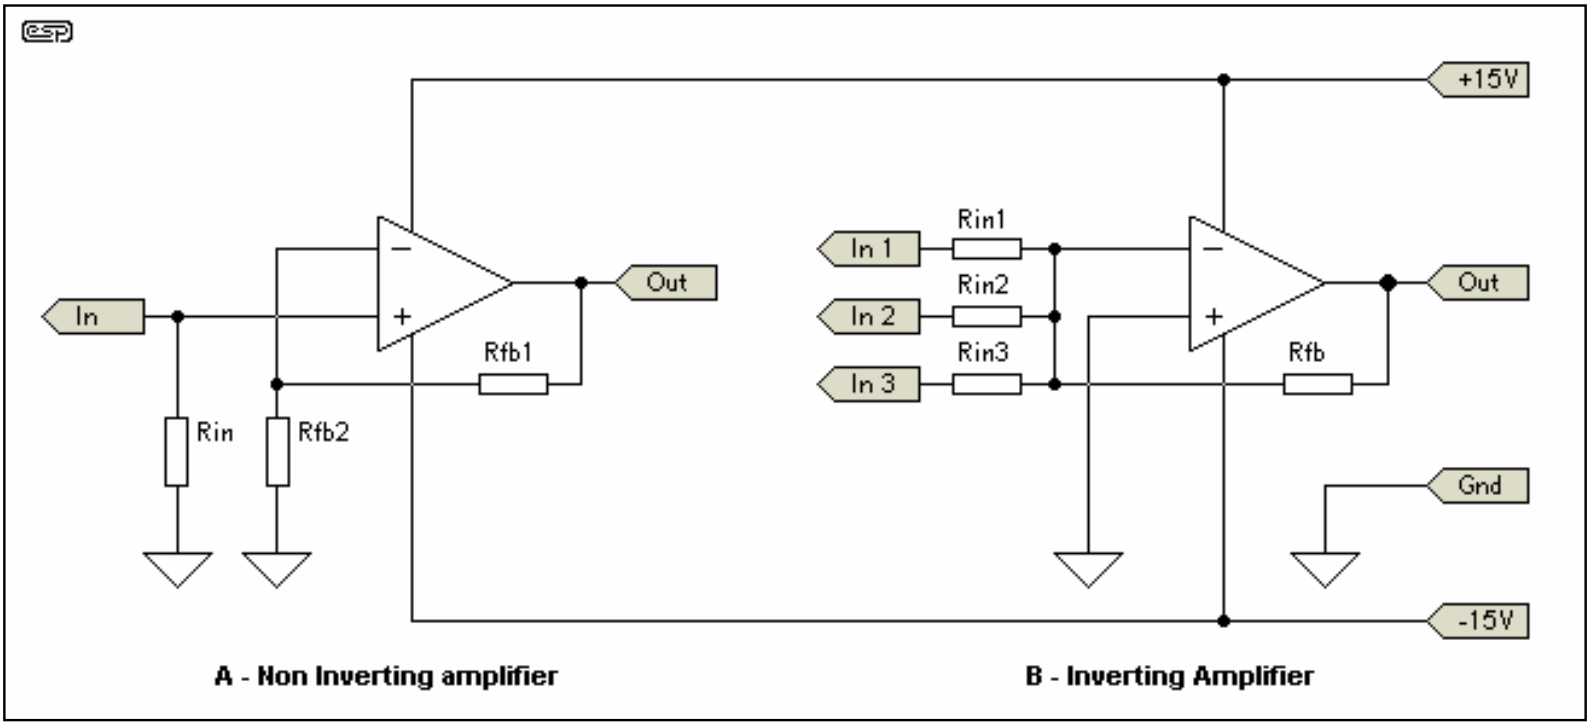

Figure 4.1 - Standard Opamp Configurations

Figure 4.1 shows the two most common opamp amplifier circuits. The first (4.1a) is non-inverting, and is the better connection for minimum noise. The voltage fed back through Rfb1 will cause a voltage to be developed across Rfb2. The output will correct itself until these two voltages are equal at any instant in time. It does not matter if the signal is a sinewave, square wave, or music, the opamp will keep up (provided you stay within its capabilities). Once the speed of the opamp is not significantly higher than the rate of change of the input (generally a factor of 10 is sufficient - i. e. the opamp needs to be 10 times faster than the highest frequency signal it is expected to amplify), the output will become distorted. At voltage gains of 10 or less, almost any opamp will be able to keep up with typical audio signals, but (and be warned) this is no guarantee that they will sound any good.

Input impedance is equal to Rin, and voltage gain (Av) is calculated from

$$Av = (Rfb1 + Rfb2) / Rfb2$$

The second circuit (4.1b) is an inverting amplifier, and is commonly used as a "summing" amplifier - the output is the negative sum of the three (or more) inputs. It is also called a "virtual earth" mixer, because the -ve input is a virtual earth (remember my "First law of opamps"). If the +ve input is earthed (grounded), then the opamp must try to keep the -ve input at the same voltage - namely 0V.

It does this by adjusting its output until the current flowing through Rfb is exactly the same (but of the opposite polarity) as the current flowing into the inputs from each Rin. They must all sum to 0V, as they are equal and opposite. This is done with amazing speed, and good opamps will continue to succeed in fulfilling the First Law up to over 100kHz or more (depending on gain). Lesser devices will start to have trouble, and the appearance of a measurable voltage at the -ve

input is an indication that the opamp can no longer keep up with the signal.

Input impedance is equal to RinX (where X is the number of the input), and voltage gain is calculated from

$$Av = Rfb / RinX$$

Multiple inputs can all have different gains (and input impedances). There are two catches to this circuit. The first is that if the source does not have an output impedance significantly lower than Rin, then the gain will be lower than expected. The other, not always realised, is that if the circuit is configured for a gain of 1 (actually it is technically correct to refer to it as -1), Rin1, Rin2 etc. will all be equal to Rfb. If the circuit has 10 inputs, then from the opamp's perspective it has a gain of 10, and its frequency response and noise will reflect this.

There are literally hundreds of different opamp circuit configurations. Feedback circuits with frequency dependent components (capacitors or inductors) make the opamp into a filter, or a phono equaliser, or almost anything else.

Power Opamps

Opamps even come in power versions, using a TO-220 (or other specialised) case, and are typically capable of around 25W into an 8 Ohm speaker load. These devices, while not exactly to audiophile standards, are still very capable, and have been used by many domestic appliance manufacturers in such things as high-end TV sets and standard hi-fi equipment. Some of the more advanced devices are capable of output power up to 80W.

They typically have distortion figures below 0.1%, and can be used anywhere a small, convenient and cheap power amp is required. The circuit looks almost identical to that of a small signal opamp, except that a Zobel stabilisation network is used on the output to prevent oscillation.

Part 5 - Some Basic Linear Circuit Building Blocks

There are some circuits in the world of electronics that are just too useful. While some have been around for many years, others only became practical with the advent of the transistor. The circuits described are a mixture, some are very old, and others much newer.

I shall not go into the history (this is an electronics tutorial, not a history lesson), but will show the various stages in their basic form for each type of circuit.

On the topic of current sources, sinks and mirrors, click here to see the full article describing how they are most commonly used in audio circuits (and why).

Current Sources And Sinks

The constant current source (or sink) is one of the most versatile and widely used of the circuits shown in this section. The ideal current source provides a current into a load that is independent of the

resistance (or impedance) of the load, from zero to infinity. As always, the ideal does not exist, but within the capabilities of the power supply voltage, it is quite simple to do, and surprisingly accurate.

There is no real difference between the two circuits - one sources current (or sinks electrons) or vice versa. Sometimes it might help to consider the circuit "upside down" to see that there is no real difference, only one of terminology.

As an example, if we wanted to supply a current that were fixed at 1A into any load impedance, then we might use a circuit similar to that in Figure 5.1 - a basic transistor current source. As shown, this will supply 1A into any resistance from zero Ohms up to a little under 50 Ohms. The power supply is the limiting factor - to be able to supply the same current into 1M Ohm would need a 1,000,000V power supply, which is an unrealistic expectation.

The current source or sink can be imagined as a device with infinite impedance - this must be the case if the current remains unchanged even as the load resistance is varied over a wide range. Naturally, the impedance of actual current sources is not infinite, but can easily reach values of many megohms, even in a simple circuit.

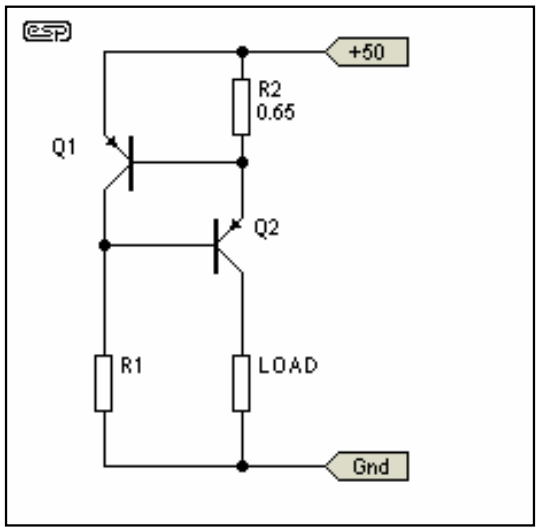

Figure 5.1 - A Basic Transistor Current Source / Sink

The operation of the circuit is simple. If the voltage across the emitter resistor of Q2 attempts to exceed 0.65V (the base turn-on voltage for a silicon transistor), then Q1 will turn on, and short out all base current to Q2 except for exactly that amount required to maintain the specified current of 1A. If the collector current of Q2 falls, then the voltage across the emitter resistor also falls. This turns off Q1 until the current is again stable at the preset value. (This is only one way to make a current source - there are many others.)

Thermal stability is not good. The emitter-base potential falls at 2mV / degree C, so as the temperature increases, the current will fall from the nominal 1A. At low temperatures, the opposite will occur. A precision voltage reference can be used, or an opamp can monitor the voltage across the resistor, resulting in a much more stable current. Fortunately, in most circuits, it is not that critical, so the circuit of Figure 5.1 is very common.

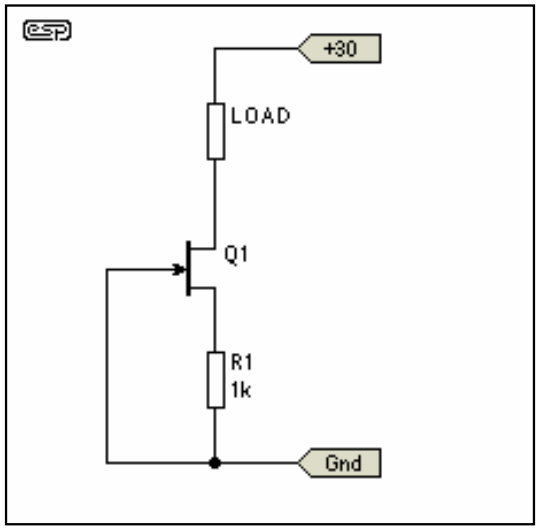

Figure 5.2 - A JFET Current Source / Sink

Junction FETs, being a depletion mode device, can be used as a current source very easily, as shown in Figure 5.2. Because JFETs are mainly low current devices, the useful range is from about 0.1mA up to 10mA or so. This is ideal for many of the circuits that need a current source. The actual current is dependent on the FET's characteristics, but is sufficiently stable for many non-critical applications. Based on the FET curve shown in Figure 3.2a, this current source will supply a current of about 0.4mA into a load from zero to 72k Ohms. The voltage is also lower, because of the lower voltage rating of most FETs.

Current Mirror

The current mirror is one of the "new" circuits, and works well with bipolar transistors. It is unusual to see this circuit implemented with valves or FETs, and I will not change this (i.e. I will show transistors only). Figure 5.3 shows a simple current mirror (this version is not very accurate, but is still extremely effective and commonly used).

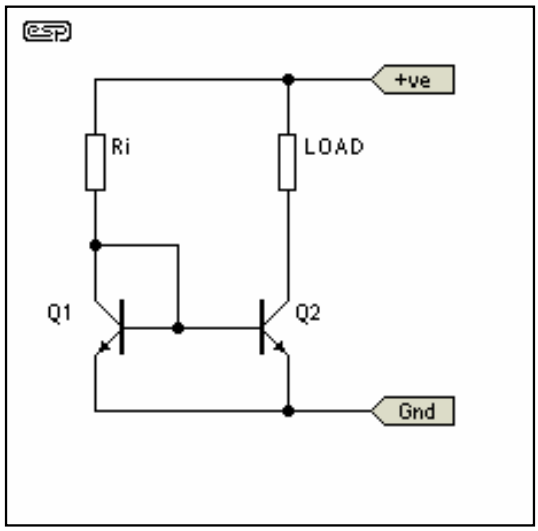

Figure 5.3 - A Simple Current Mirror

Any current injected into the collector/base circuit of Q1 (via Ri) will be "mirrored" by Q2, which will

draw the same current through its load resistor (within the capability of the transistor and power supply). Current mirrors are sometimes used as current sources (one less resistor), and are not as dependent on temperature, since both transistors will ideally be at the same temperature. It is not uncommon to use dual transistors (or thermal bonding) to ensure stability.

Long Tailed Pair

The long tailed (or differential) pair is an old circuit, and is used with valves, FETs and Bats. It was originally designed in the valve era, and provides a means for the comparison of two voltages. The long tailed pair (LTP) is used as the input stage of most opamps, and many (if not most) modern power amplifiers.

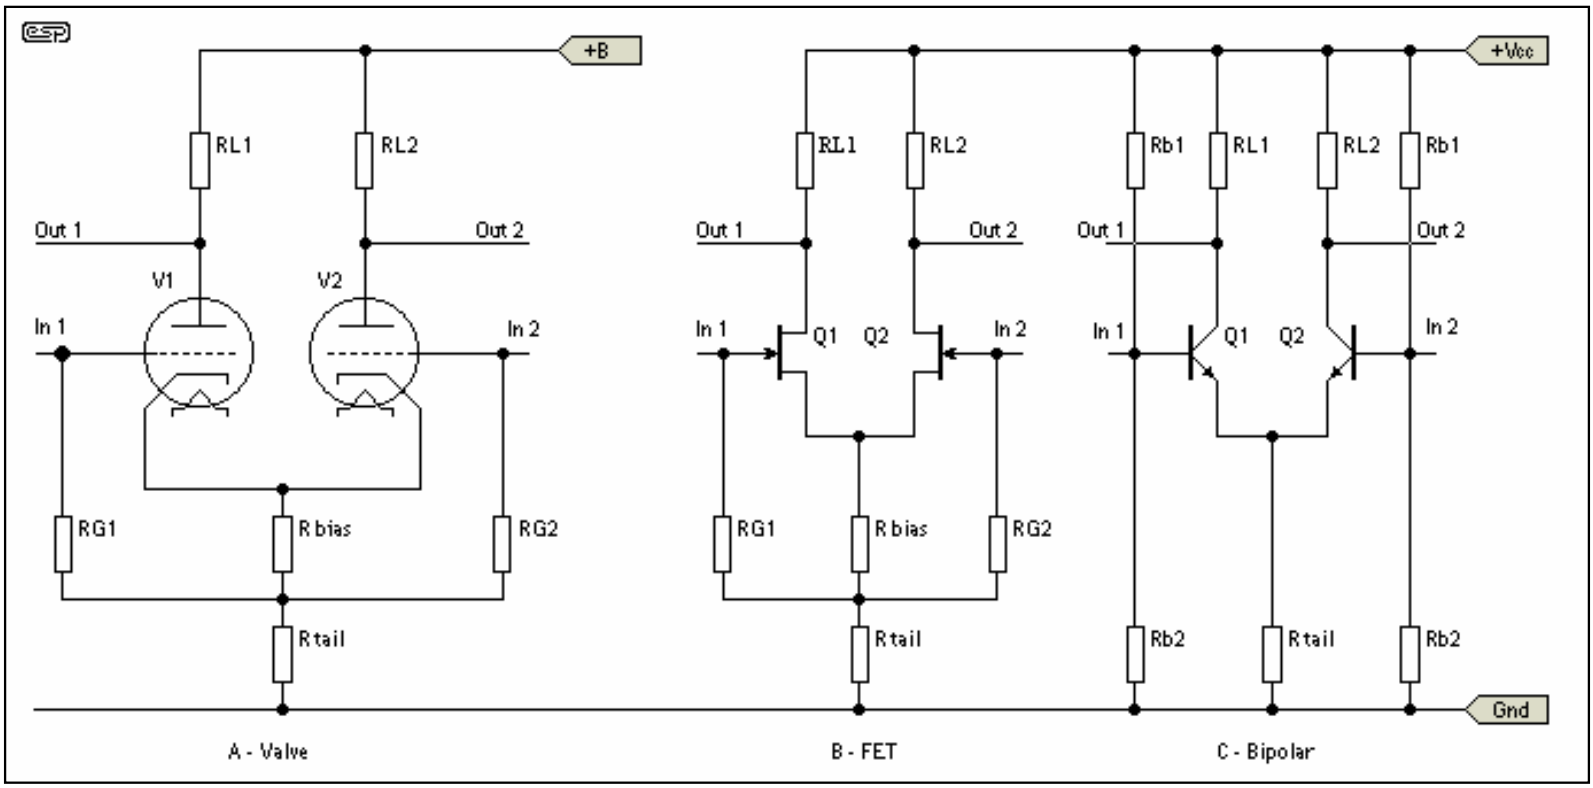

Figure 5.4 - The Long Tailed Pair - All Common Devices

As can be seen in Figure 5.4, the LTP can be made using valves (A), JFETs (B) or bipolar transistors (C). Valves and JFETs can be self biased as shown, but BJT circuits must have external bias resistors. A pair of MOSFETs could be used, but at the typical currents used (less than 5mA), the gain and linearity would be very poor. Although each circuit is shown using a resistor as the "tail", in FET and bipolar circuits this is most commonly a current source (or sink if you prefer).

The use of a current source stabilises the overall current, so the device input current is not affected by supply voltage changes, or variations in the input bias voltages.

In each case, the circuit has an inverting and a non-inverting input, and an inverted and non-inverted output. Application of the same voltage and polarity to both inputs at once results in (theoretically) zero output - this is called the common mode signal, and is commonly quoted for opamps as the common mode rejection ratio.

The valve and FET versions only require capacitive coupling, as they are self biasing as shown. The bipolar circuit cannot be self biased, and requires the biasing resistors Rb1 and Rb2 for each input.

The output of each version may be taken from either or both outputs, and may be capacitively or direct coupled. Direct coupling is very common with LTP circuits, especially in opamps and audio power amplifiers, where it is the rule, rather than the exception.

When used as the input stage of an amplifier, the LTP uses one input as the signal input, and the other is used for the application of feedback, in the same way as in an opamp.

Grounded Grid (Gate or Base) Circuits

Sometimes, it is desirable to have an extremely low input impedance, for example where the output impedance of the source is very low. One way to achieve this is to use the control element (grid, gate or base) as the reference, and apply the signal to the cathode, source or emitter (as appropriate). Figure 5.5 shows an example of grounded (or common) grid (A), gate (B) and emitter (C).

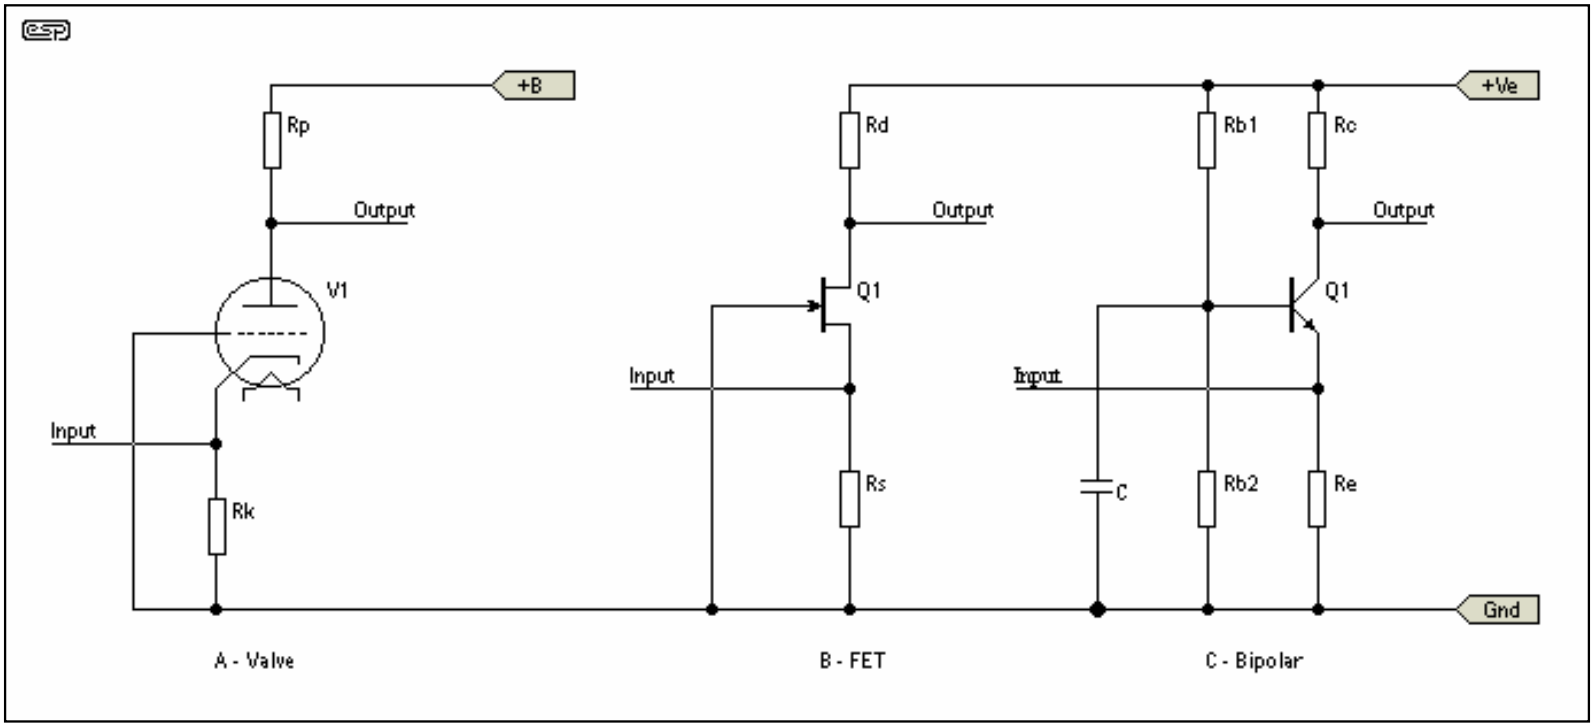

Figure 5.5 - Common Grid, Gate and Base Amplifiers

Apart from having an extremely low input impedance, this class of amplifier has an additional advantage. The normal capacitance from output to input is bypassed to earth, and no longer acts as a feedback path. Such circuits are therefore capable of a much better high frequency response than when used in the "conventional" way, and are common in radio frequency circuits. The bypass path is direct for a valve or FET, and is via a capacitance for the bipolar circuit.

All inputs and outputs must be capacitively coupled, unless the preceding circuit is to be direct coupled (unusual) or the output is direct coupled to a follower (quite common).

Because the input impedance is so low, there are few applications in audio, except where this circuit is used in conjunction with a "normal" amplifier stage. This forms a new circuit, called cascode.

Cascode

This circuit was developed in the valve era, primarily to obtain better response at high radio frequencies. Valves have capacitance between the plate and grid, and this acts as a feedback path at high frequencies, causing a drop in gain as the frequency is increased. This is the so-called "Miller" effect. Operating in cascode allows the circuit to have a high input impedance (via the normal grid input), and the grounded grid amplifier (the signal is applied to the cathode) means that there is no feedback from plate to grid, and the grid acts as a shield to prevent feedback to the cathode. The lower half of the stage contributes a relatively small amount of gain, and is not subject to the feedback effect since it is operating as a current amplifier (there is very little voltage swing on the plate, so there is little or no signal to feed back).

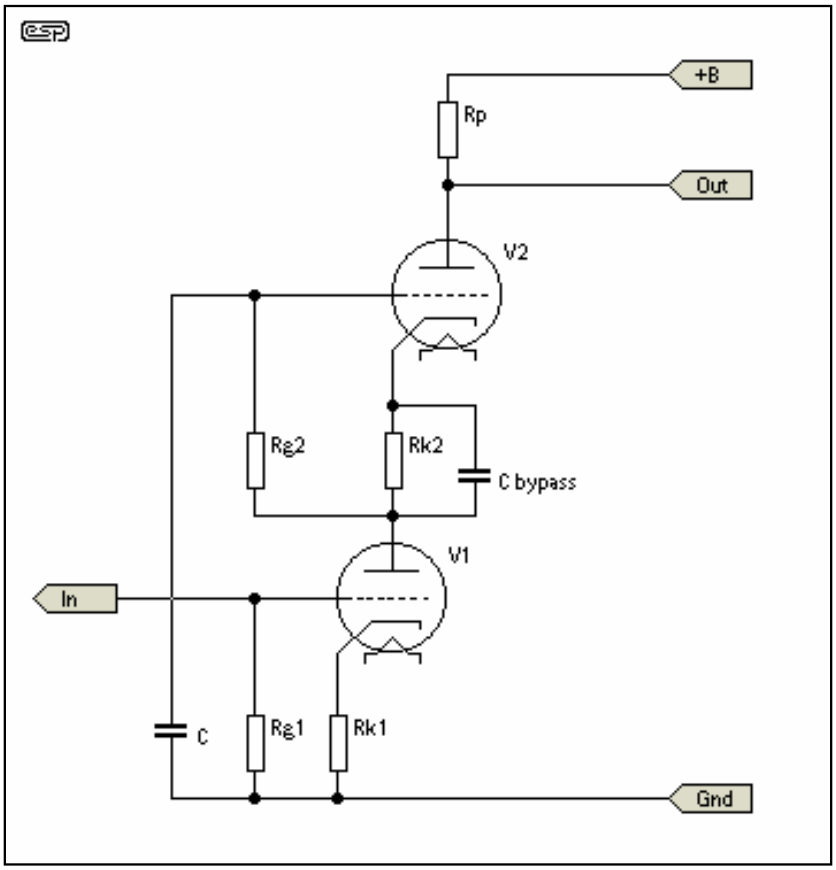

Figure 5.6 - Valve Cascode Amplifier

As can be seen, the grid of V2 is earthed via the capacitor for all signal frequencies, allowing V2 to operate as common grid. The capacitor (C bypass) is used to ensure that there is no gain lost due to cathode degeneration (local feedback). The cathode of V1 will also be bypassed in many cases, especially where low noise is a primary goal.

The same principles can be applied to FETs or Bats, and has similar advantages. The capacitance between Drain and gate (or collector and base) is isolated in the same way as with a valve circuit, with the signal being coupled to the source or emitter by the first device. Figure 5.7 shows a composite

JFET / BJT cascode circuit, which will have better linearity than a conventional amplifier, and a much better high frequency response.

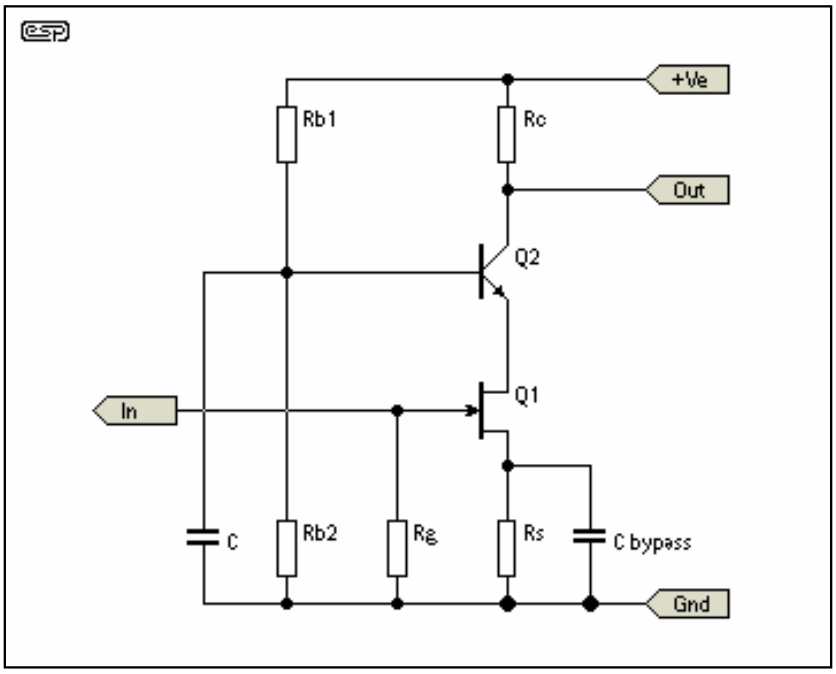

Figure 5.7 - Composite FET / BJT Cascode Amplifier

This type of circuit is not uncommon in high performance opamps, where very wide bandwidth and good linearity before feedback are required. Cascode circuits are also sometimes seen in solid state power amplifier circuits, where the designer is trying to obtain the maximum possible bandwidth from the amp.

The base of Q2 is grounded to all signal frequencies, so the stage operates as a common base circuit. Using a JFET as the input element means that the circuit has a high input impedance, while the BJT ensures maximum gain. To obtain even more gain, Rc might be replaced by a current source, in which case the gain from this single stage can exceed 1000 times, with wide bandwidth and excellent linearity.

Conclusion

Section 5 finalises this series - at least until such time as I find (or someone points out) a mistake or major omission that I will then have to fix, there will be no further updates.

The articles in this series describe the essential building blocks of nearly all circuits in common use today. There are others (of course) but they are most often combinations of the above - for example, a LTP stage can be built using two cascode circuits, a current source and a current mirror. The resulting circuit looks complex, but is simply a combination of common circuits such as those shown.

Other circuits are modification of the basic stages to exploit what might otherwise be

seen as a deficiency - for example circuits that deliberately exploit the temperature dependency of a BJT can be used as high gain thermal sensors, or to stabilise the quiescent current in a power amplifier.

There are also some bizarre combinations possible. A valve and BJT operating in cascode would be interesting, and would no doubt have some desirable characteristics (I haven't seen this particular combination, but there is no reason that it would not work). Likewise, a valve with a transistor current source instead of the load resistor would have far better linearity and more gain than a simple resistor loaded version.

In many cases, ICs are available to accomplish many of the functions described. Opamps are an obvious one, but there are also IC current sources, transistor arrays (ideal for current mirror applications because of the excellent thermal tracking), plus quite a few others.

I hope that I have shed some light on the subject, and that you get some benefit from my musings.

New! "Cold Soldering" - a review of the Coldheat Classic Iron, tested on a commercial electronic kit. What are the benefits and drawbacks? More details....

This written guide will help beginners and novices to obtain effective results when soldering **electronic components**. If you have little or no experience of using a soldering iron, then EPE *(Everyday Practical Electronics* magazine) recommends that you practice your soldering technique on some fresh surplus components and clean stripboard (protoboard), before experimenting with a proper constructional project. This will help you to avoid the risk of disappointment when you start to assemble your first prototypes. If you've never soldered before, then read on!

Everyday Practical Electronics magazine contains the widest variety of interesting projects and information for beginners, trainees, hobbyists and professionals in electronics. This *Basic Soldering Guide* was condensed from our fully-illustrated series *Build Your Own Projects*, written by Alan Winstanley and published in Everyday Practical Electronics magazine, from November 1996 to March 1997. Gas-Powered irons

The most fundamental skill needed to assemble any electronic project is that of ***soldering***. It takes some practice to make the perfect joint, but, like riding a bicycle, once learned is never forgotten! The idea is simple: to join electrical parts together to form an electrical connection, using a molten mixture of lead and tin (solder*) with a soldering iron. A large range of soldering irons is available - which one is suitable for you depends on your budget and how serious your interest in electronics is.

[*Note: the use of lead in solder is now increasingly prohibited in many countries. "Lead free" solder is now statutory instead.]

Electronics catalogues often include a selection of well-known brands of soldering iron. Excellent British-made ones include the universally popular Antex, Adcola and Litesold makes. Other popular brands include those made by Weller and Ungar. A very basic mains electric soldering iron can cost from under £5 (US$ 8), but expect a reasonable model to be approximately £10-£12 (US$ 16 - 20) - though it's possible to spend into three figures on a soldering iron "station" if you're really serious! Check some suppliers' catalogues for some typical types. Certain factors you need to bear in mind include:-

Voltage: most irons run from the mains at 240V. However, low voltage types (e.g. 12V or 24V) generally form part of a "soldering station" and are designed to be used with a special controller made by the same manufacturer.

Wattage: Typically, they may have a power rating of between 15-25 watts or so, which is fine for most work. A higher wattage does ***not*** mean that the iron runs hotter - it simply means that there is more power in reserve for coping with larger joints. This also depends partly on the design of the "bit" (the tip of the iron). Consider a higher wattage iron simply as being more "unstoppable" when it comes to heavier-duty work, because it won't cool down so quickly.

Temperature Control: the simplest and cheapest types don't have any form of temperature regulation. Simply plug them in and switch them on! Thermal regulation is "designed in" (by physics, not electronics!): they may be described as "thermally balanced" so that they have some degree of temperature "matching" but their output will otherwise not be controlled. Unregulated irons form an ideal general purpose iron for most users, and they generally cope well with printed circuit board soldering and general interwiring. Most of these "miniature" types of iron will be of little use when attempting to solder large joints (e.g. very large terminals or very thick wires) because the component being soldered will "sink" heat away from the tip of the iron, cooling it down too much. (This is where a higher wattage comes in useful.)

A proper temperature-controlled iron will be quite a lot more expensive - retailing at say £40 (US$ 60) or more - and will have some form of built-in thermostatic control, to ensure that the temperature of the bit (the tip of the iron) is maintained at a fixed level (within limits). This is desirable especially during more frequent use, since it helps to ensure that the temperature does not "overshoot" in between times, and also guarantees that the output will be relatively stable. Some irons have a bimetallic strip thermostat built into the handle which gives an audible "click" in use: other types use all-electronic controllers, and some may be adjustable using a screwdriver.

Yet more expensive still, ***soldering stations*** cost from £70 (US$ 115) upwards (the iron may be sold separately, so you can pick the type you prefer), and consist of a complete bench-top control unit into which a special *low-voltage* soldering iron is plugged. Some versions might have a built-in digital temperature readout, and will have a control knob to enable you to vary the setting. The temperature could be boosted for soldering larger joints, for example, or for using higher melting-point solders (e.g. silver solder). These are designed for the most discerning users, or for continuous production line/ professional use. The best stations have irons which are well balanced, with comfort-grip handles which remain cool all day. A thermocouple will be built into the tip or shaft, which monitors temperature.

Anti-static protection: if you're interested in soldering a lot of static-sensitive parts (e.g. CMOS chips or MOSFET transistors), more advanced and expensive soldering iron stations use static-dissipative materials in their construction to ensure that static does not build up on the iron itself. You may see these listed as "ESD safe" *(electrostatic discharge proof).* The cheapest irons won't necessarily be ESD-safe but never the less will still probably perform perfectly well in most hobby or educational applications, if you take the usual anti-static precautions when handling the components. The tip would need to be well earthed (grounded) in these circumstances.

Bits: it's useful to have a small selection of manufacturer's bits (soldering iron tips) available with different diameters or shapes, which can be changed depending on the type of work in hand. You'll probably find that you become accustomed to, and work best with, a particular shape of tip. Often, tips are *iron-coated* to preserve their life, or they may be bright-plated instead. Copper tips are seldom seen these days.

Spare parts: it's nice to know that spare parts may be available, so if the element blows, you don't need to replace the entire iron. This is especially so with expensive irons. Check through some of the larger mail-order catalogues.

You will occasionally see ***gas-powered*** soldering irons which use butane rather than the mains electrical supply to operate. They have a catalytic element which, once warmed up, continues to glow hot when gas passes over them. Service engineers use them for working on repairs where there may be no power available, or where a joint is tricky to reach with a normal iron, so they are really for occasional "on the spot" use for quick repairs, rather than for mainstream construction or assembly work. A ***solder gun*** is a pistol-shaped iron, typically running

at 100W or more, and is completely unsuitable for soldering modern electronic components: they're too hot, heavy and unwieldy for micro-electronics use. Plumbing, maybe..!

Soldering irons are best used along with a heat-resistant ***bench-type holder***, so that the hot iron can be safely parked in between use. Soldering stations already have this feature, otherwise a separate soldering iron stand is essential, preferably one with a holder for tip-cleaning sponges. Now let's look at how to use soldering irons properly, and how to put things right when a joint goes wrong.

Turning to the actual techniques of soldering, firstly it's best to *secure the work* somehow so that it doesn't move during soldering and affect your accuracy. In the case of a printed circuit board, various holding frames are fairly popular especially with densely populated boards: the idea is to insert all the parts on one side ("stuffing the board"), hold them in place with a special foam pad to prevent them falling out, turn the board over and then snip off the wires with cutters before making the joints. The frame saves an awful lot of turning the board over and over, especially with large boards. Other parts could be held firm in a modeller's small vice, for example.

Solder joints may need to possess some degree of mechanical strength in some cases, especially with wires soldered to, say, potentiometer or switch tags, and this means that the wire should be looped through the tag and secured before solder is applied. The down side is that it is more difficult to *de-solder* the joint (see later) and remove the wire afterwards, if required. Otherwise, in the case of an ordinary circuit board, components' wires are bent to fit through the board, inserted flush against the board's surface, splayed outwards a little so that the part grips the board, and then soldered.

In my view - opinions vary - it's generally better to snip the surplus wires leads off *first*, to make the joint more accessible and avoid applying a mechanical shock to the p.c.b. joint. However, in the case of semiconductors, I often tend to leave the snipping until *after* the joint has been made, since the excess wire will help to sink away some of the heat from the semiconductor junction. Integrated circuits can either be soldered directly into place if you are confident enough, or better, use a dual-in-line socket to prevent heat damage. The chip can then be swapped out if needed.

Parts which become hot in operation (e.g. some resistors), are raised above the board slightly to allow air to circulate. Some components, especially large electrolytic capacitors, may require a mounting clip to be screwed down to the board first, otherwise the part may eventually break off due to vibration.

The perfectly soldered joint will be nice and shiny looking, and will prove reliable in service. I would say that:

- **cleanliness**
- **temperature**
- **time**
- **adequate solder coverage**

are the key factors affecting the quality of the joint. A little effort spent now in soldering the perfect joint may save you - or somebody else - a considerable amount of time in troubleshooting a defective joint in the future. The basic principles are as follows.

Really Clean

Firstly, and without exception, all parts - including the iron tip itself - must be **clean** and **free from contamination**. Solder just will not "take" to dirty parts! Old components or copper board can be notoriously difficult to solder, because of the layer of oxidation which builds up on the surface of the leads. This repels the molten solder and this will soon be evident because the solder will "bead" into globules, going everywhere except where you need it. *Dirt is the enemy of a good quality soldered joint!*

Hence, it is an absolute necessity to ensure that parts are free from grease, oxidation and other contamination. In the case of old resistors or capacitors, for example, where the leads have started to oxidise, use a small hand-held file or perhaps scrape a knife blade or rub a fine emery cloth over them to reveal fresh metal underneath. Stripboard and copper printed circuit board will generally oxidise after a few months, especially if it has been fingerprinted, and the copper strips can be cleaned using an abrasive rubber block, like an aggressive eraser, to reveal fresh shiny copper underneath.

Also available is a fibre-glass filament brush, which is used propelling-pencil-like to remove any surface contamination. These tend to produce tiny particles which are highly irritating to skin, so avoid accidental contact with any debris. Afterwards, a wipe with a rag soaked in cleaning solvent will remove most grease marks and fingerprints. After preparing the surfaces, avoid touching the parts afterwards if at all possible.

Another side effect of having dirty surfaces is the tendency for people to want to apply *more heat* in an attempt to "force the solder to take". This will often do more harm than good because it may not be possible to burn off any contaminants anyway, and the component may be overheated. In the case of semiconductors, temperature is quite critical and they may be harmed by applying such excessive heat.

Before using the iron to make a joint, it should be "tinned" (coated with solder) by applying a few millimetres of solder, then wiped on a damp sponge preparing it for use: you should always do this immediately with a new bit, anyway. Personally, I always re-apply a very small amount of solder again, mainly to improve the thermal contact between the iron and the joint, so that the solder will flow more quickly and easily. It's sometimes better to tin larger parts as well before making the joint itself, but it isn't generally necessary with p.c.b. work. (All *EPE* printed circuit boards are "roller-tinned" to preserve their quality and to help with soldering.) A worthwhile product is Weller's *Tip Tinner & Cleaner*, a small 15 gram tinlet of paste onto which you dab a hot iron - the product cleans and tins the iron ready for use. An equivalent is Adcola *Tip-Save.*

Normal electronics grade solder is now "lead free" and typically contains Sn 97 Ag 2.5 Cu 0.5 (i.e. 97% tin, 2.5% silver and 0.5% copper). **It already contains cores of "flux"** which helps the molten solder to flow more easily over the joint. Flux removes oxides which arise during heating, and is seen as a brown fluid bubbling away on the joint. **The use of separate acid flux paste (e.g. as used by plumbers) should NEVER be necessary in normal electronics applications because electronics-grade solder already contains the correct grade of flux!** Other solders are available for specialist work, including aluminium and silver-solder. Different solder diameters are produced, too; 20-22 SWG (19-21 AWG) is 0.91-0.71mm diameter and is fine for most work. Choose 18 SWG (16 AWG) for larger joints requiring more solder.

Temperature

Another step to successful soldering is to ensure that the **temperature** of *all* the parts is raised to roughly the same level before applying solder. Imagine, for instance, trying to solder a resistor into place on a printed circuit board: it's far better to heat *both* the copper p.c.b. *and* the resistor lead at the same time before applying solder, so that the solder will flow much more readily over the joint. Heating one part but not the other is far less satisfactory joint, so strive to ensure that the iron is in contact with *all* the components first, before touching the solder to it. The melting point of most solder is in the region of 188°C (370°F) and the iron tip temperature is typically 330-350°C (626°-662°F). The latest lead-free solders typically require a higher temperature.

Now is the time

Next, the joint should be heated with the bit for just the right amount of **time** - during which a short length of solder is applied to the joint. Do **not** use the iron to carry molten solder over to the joint! Excessive time will damage the component and perhaps the circuit board copper foil too! Heat the joint with the tip of the iron, then continue heating whilst applying solder, then remove the iron and allow the joint to cool. This should take only a few seconds, with experience. The heating period depends on the temperature of your iron and size of the joint - and larger parts need more heat than smaller ones - but some parts (semiconductor diodes, transistors and i.c.s), are sensitive to heat and should not be heated for more than a few seconds. Novices sometimes buy a small clip-on heat-shunt, which resembles a pair of aluminium tweezers. In the case of, say, a transistor, the shunt is attached to one of the leads near to the transistor's body. Any excess heat then diverts up the heat shunt instead of into the transistor junction, thereby saving the device from over-heating. Beginners find them reassuring until they've gained more experience.

Solder Coverage

The final key to a successful solder joint is to apply an appropriate amount of solder. *Too much solder* is an unnecessary waste and may cause short circuits with adjacent joints. *Too little* and it may not support the component properly, or may not fully form a working joint. How much to apply, only really comes with practice. A few millimetres only, is enough for an "average" p.c.b. joint, (if there is such a thing).

Desoldering methods

A soldered joint which is improperly made will be electrically "noisy", unreliable and is likely to get worse in time. It may even not have made any electrical connection at all, or could work initially and then cause the equipment to fail at a later date! It can be hard to judge the

quality of a solder joint purely by appearances, because you cannot say how the joint actually formed on the *inside*, but by following the guidelines there is no reason why you should not obtain perfect results.

A joint which is poorly formed is often called a "dry joint". Usually it results from dirt or grease preventing the solder from melting onto the parts properly, and is often noticeable because of the tendency of the solder not to "spread" but to form beads or globules instead, perhaps partially. Alternatively, if it seems to take an inordinately long time for the solder to spread, this is another sign of possible dirt and that the joint may potentially be a dry one.

There will undoubtedly come a time when you need to *remove* the solder from a joint: possibly to replace a faulty component or fix a dry joint. The usual way is to use a ***desoldering pump*** or vacuum pump which works like a small spring-loaded bicycle pump, only in reverse! (More demanding users using CMOS devices might need a pump which is ESD safe.) A spring-loaded plunger is released at the push of a button and the molten solder is then drawn up into the pump. It may take one or two attempts to clean up a joint this way, but a small desoldering pump is an invaluable tool especially for p.c.b. work.

Sometimes, it's effective to actually *add more* solder and then desolder the whole lot with a pump, if the solder is particularly awkward to remove. Care is needed, though, to ensure that the boards and parts are not damaged by excessive heat; the pumps themselves have a P.T.F.E. nozzle which is heat proof but may need replacing occasionally.

An excellent alternative to a pump is to use *desoldering braid*, including the famous American "Soder-Wick" (sic) or Adcola "TISA-Wick" which are packaged in small dispenser reels. This product is a specially treated fine copper braid which draws molten solder up into the braid where it solidifies. The best way is to use the tip of the hot iron to press a short length of braid down onto the joint to be de-soldered. The iron will subsequently melt the solder, which will be drawn up into the braid. Take extreme care to ensure that you don't allow the solder to cool with the braid adhering to the work, or you run the risk of damaging p.c.b. copper tracks when you attempt to pull the braid off the joint. See my photo gallery for more details.

I recommend buying a small reel of de-soldering braid, especially for larger or difficult joints which would take several attempts with a pump. It is surprisingly effective, especially on difficult joints where a desoldering pump may prove a struggle.

Here's a summary of how to make the perfect solder joint.

1. All parts must be clean and free from dirt and grease.
2. Try to secure the work firmly.
3. "Tin" the iron tip with a small amount of solder. Do this immediately, with new tips being used for the first time.
4. Clean the tip of the hot soldering iron on a damp sponge.
5. Many people then add a tiny amount of fresh solder to the cleansed tip.
6. Heat all parts of the joint with the iron for under a second or so.
7. Continue heating, then apply sufficient solder only, to form an adequate joint.
8. Remove and return the iron safely to its stand.
9. It only takes two or three seconds at most, to solder the average p.c.b. joint.
10. Do not move parts until the solder has cooled.

Troubleshooting Guide

- Solder won't "take" - grease or dirt present - desolder and clean up the parts. Or, material may not be suitable for soldering with lead/tin solder (eg aluminium).
- Joint is crystalline or grainy-looking - has been moved before being allowed to cool, or joint was not heated adequately - too small an iron/ too large a joint.
- Solder joint forms a "spike" - probably overheated, burning away the flux.

First Aid

If you are unlucky enough to receive burns which require treatment, here's what to do :-

1. Immediately cool the affected area with cold running water for several minutes.
2. Remove any rings etc. before swelling starts.
3. Apply a sterile dressing to protect against infection.
4. Do not apply lotions, ointments etc., nor prick any blisters which form later.
5. Seek professional medical advice where necessary.

1.0 Introduction

National Semiconductor has a broad portfolio of monolithic power integrated circuits covering power levels from a few hundred milliwatts up to 60W of non-clipped continuous average power. These ICs cover most audio applications by themselves, however, for really high power applications, other methods need to be employed because IC packages have limited power dissipation capabilities.

There are many different ways of obtaining over 100W of output power. Most high-end power amplifier manufacturers utilize discrete circuits which allows them to market their amplifiers as “specially designed.” However, there is a price to be paid for discrete amplifier designs; they are complex, difficult to design, require many components, lack the comprehensive protection mechanisms of integrated circuits and are not as reliable.

Other methods of obtaining output power greater than 100W include the use of power ICs as drivers for discrete power transistors. There are a number of these types of circuits, but they too possess all of the same flaws as discrete circuits, including a lack of comprehensive output stage protection.

2.0 Objective

The objective is to provide simple high power solutions that are conservatively designed, highly reliable and have low part count. This document provides three specific, but not unique, application circuits that provide output power of 100W, 200W, and above. These circuits are the parallel, bridged, and bridged/parallel configurations.

These three circuits are simple to understand, simple to build and require very few external components compared to discrete power amplifier designs. Simplicity of design and few components make this solution much more reliable than discrete amplifiers. In addition, these circuits inherently possess the full protection of each individual IC that is very difficult and time consuming to design discretely. Finally, these circuits are well known and have been in industry for years.

3.0 Conclusion

The BR100 (100W Bridged Circuit), PA100 (100W parallel circuit), and the BPA200 (200W Bridged/Parallel Circuit) are high power solutions that can be used in many applications, but they are primarily targeted for home theater amplifier applications such as powered subwoofers, self-powered speakers, and surround sound amplifiers.

While bridged amplifier configurations are able to provide high power levels, they also consume four times more power than a conventional single-ended solution. However, it is feasible to conservatively design a 100W bridged amplifier solution, as will be shown here. The bridged solution is designed to drive an 8Ω nominal load for self-powered speaker or powered subwoofer applications.

The parallel amplifier is another configuration that can be used to obtain higher output power levels by combining two IC outputs and doubling output current drive capability. The parallel topology provides a great way of achieving higher power levels while keeping within IC power dissipation limits by driving low impedance loads, which is the case for many self-powered speaker and powered subwoofer designs. The main advantage of the parallel configuration is its ability to divide total power dissipation between ICs, since each amplifier is providing half of the load current. Another advantage of the parallel design is that unlike the bridge design, more than two ICs can be used. In fact, any number of ICs can be used in a parallel design and when configured the same will share the power dissipation equally. For example, using four ICs to drive a 1Ω load means that each IC dissipates 1/4 of the total power dissipation. In other words, the load to each IC looks like a 4Ω load (Number Of ICs in Parallel * Load Impedance = Load Impedance seen by each individual IC.) Odd numbers of ICs can also be used.

For lower impedance loads (<8Ω), the parallel circuit is a good solution for 100W power levels using just two devices. Power levels above 100W may be obtained by using more than two devices to increase output current capability and power dissipation limits along with lower impedance loads.

If the bridged and parallel configurations are combined, the outcome is a very high power amplifier solution that far exceeds the capabilities of one IC alone, while maintaining reasonable power dissipation levels within each IC. The bridged portion doubles the output voltage swing and quadruples the total power dissipation while the parallel portion halves the current between each IC set and divides the total power dissipation between each of the four ICs. The result is higher system output power with each IC not exceeding its individual power dissipation capabilities. Higher output power levels are attained, while the ICs run at a normal temperature, keeping long term reliability high. The schematic of the Bridged/Parallel Amplifier is shown in Figure 13.

The bridged/parallel circuit using four devices will produce the maximum output power (>200W) into loads with an impedance from 4Ω to 8Ω. For loads less than 4Ω, additional devices may need to be placed in parallel or the supply voltage reduced.

The data in the following sections will exemplify that the parallel, bridged, and bridged/parallel solutions using multiple power ICs can meet high fidelity specifications while providing output power from 100W up to 400W. The low noise and excellent linearity traits of the monolithic IC are transferred to the high power solution, making the circuit even more attractive. In addition, the protection mechanisms within the IC, which are not easily designed discretely, are inherently designed into the circuit.

While the data show what specs can be achieved by the configurations, as always, good design practices need to be followed to achieve the stated results. In addition to good electrical and layout design practices, the thermal design is equally critical with Overture ICs. The following section will expand on the thermal design aspects of Overture ICs. This concept of “design by power dissipation” is applicable to all types of high power solutions.

The PA100, BR100, and BPA200 schematics and test results exemplify what can be achieved with proper component selection, thermal design, and layout techniques.

4.0 Thermal Background

The voltage and current ratings of a power semiconductor are typically the first specs considered in designing high power amplifiers. The same is true for an integrated monolithic power amplifier. However, power dissipation ratings are equally important to the long term reliability of the power amplifier design. When using a monolithic IC in its intended application and within its specified capabilities, the thermal design is relatively straightforward. When an IC is used beyond is capabilities, as in high power circuits, power dissipation issues become more critical and not as straight-

4.0 Thermal Background (Continued)

forward. Therefore, the designer must understand the IC's power dissipation capabilities before using the IC in a booster configuration.

4.1 TYPICAL CHARACTERISTIC DATA

The power dissipation capabilities of a power IC are either specified in the datasheet or can be derived from its guaranteed output power specification. While the power dissipation rating for the LM3886T is 125W, this number can be misleading. Its power dissipation specification is derived from the IC's junction-to-case thermal resistance, θ_{JC} = 1˚C/W, the maximum junction temperature, T_J = 150˚C, and the ambient air, T_A = 25˚C. As stated in the datasheet, the device must be derated based on these parameters while operating at elevated temperatures. The heat sinking requirements for the application are based on these parameters so that the IC will not go into Thermal Shutdown (TSD). The real problem for Overture ICs, however, comes from the sensitivity of the output stage's unique SPiKe™ Protection which dynamically monitors the output transistor's temperature. While the thermal shutdown circuitry is enabled at T_J = 150˚C, SPiKe circuitry is enabled at T_J = 250˚C for instantaneous power spikes in the output stage transistor. As the overall temperature of the IC increases, SPiKe circuitry becomes even more sensitive causing it to turn on before the 125W limit is reached. TSD circuitry will continue to function globally for the IC in conjunction with the SPiKe circuitry. However, protection circuitry should not be activated under normal operating conditions. The question then becomes, what is the power dissipation limit for the IC such that SPiKe circuitry is not enabled? Knowing the power dissipation limit and keeping the case temperature of the IC as cool as possible will expand the output power capability without activating SPiKe Protection.

The other way to determine IC power dissipation capabilities is to analyze the output power specification in the datasheet. In the case of the LM3886T, there are two output power specification guarantees: 60W (min) into a 4Ω load using ±28V supplies and 50W(typ) into an 8Ω load from ±35V supplies. Using these two conditions and the theoretical maximum power dissipation equation shown below, results in the following maximum power dissipations:

4.2 SINGLE-ENDED AMPLIFIER Pdmax EQUATION:

$$Pdmax = V_{CCtot}^2/2\pi^2R_L$$

Non-Isolated LM3886T:

$$1.\ V_{CC} = \pm 28V,\ R_L = 4\Omega$$

$$Pdmax = V_{CCtot}^2/2\pi^2R_L = (\pm 28V)^2/2\pi^2(4\Omega) = 39.7W$$

$$2.\ V_{CC} = \pm 35V,\ R_L = 8\Omega$$

$$Pdmax = V_{CCtot}^2/2\pi^2R_L = (\pm 35V)^2/2\pi^2(8\Omega) = 31.0W$$

These results show that the IC can handle a maximum of ≈ 40W of continuous power dissipation without SPiKe Protection being turned on under continuous sinusoidal input with proper heat sinking. The same theory applies to other Overture ICs as well, like the LM3876T, which is capable of dissipating 31W with proper heat sinking. It should be noted that the results shown above are for the non-isolated power package, where the back of the package is tied to the silicon substrate, or –Vee. The isolated power package has overmolded plastic on the back keeping the package electrically isolated from the silicon substrate. This extra amount of plastic increases the package thermal resistance from 1˚C/W for the non-isolated version to ≈ 2˚C/W for the isolated version. The result of increased thermal resistance is higher die temperature under the same conditions even though the heat sink temperature will not change.

There are two major points to note:

1. The maximum power dissipation analysis was taken into account using regulated power supplies. The IC for the whole analysis is being tested at the worst case power dissipation point for a constant full-load power supply voltage. When using an unregulated power supply, the no-load voltage will be somewhat higher (15%–35%) causing the overall maximum power dissipation to be higher than expected.
2. In the real "audio" application, the average music power dissipation is much less than the maximum power dissipation created by a sinusoidal input. Therefore, the IC will run cooler than expected due to the lower power dissipation.

However, when you put these two points together, they mostly cancel out, but only for music stimulus. Product qualifications may go through worse case power dissipation scenarios which implies that sinusoids will be used with unregulated power supplies. Therefore, when doing the thermal portion of the design, the higher supply voltages will increase the IC power dissipation and must be taken into account.

4.3 BRIDGED-OUTPUT AMPLIFIER Pdmax EQUATION

To determine the Pdmax equation for a bridged amplifier solution, the single-ended Pdmax equation is used as a starting point. A bridged amplifier solution requires two amplifiers and each amplifier will see 1/2 the total impedance. Adding these factors of 2 and 1/2 into the single-ended Pdmax equation results in the total Pdmax equation for a bridged amplifier.

$$Pdmax_{BTL} = 2*[V_{CCtot}^2/2\pi^2(/½R_L)] = 4*(V_{CCtot}^2/2\pi^2R_L)$$

The bridged-output Pdmax equation represents the bridged amplifier solution. If a dual amplifier IC is used, then the total Pdmax would need to be dissipated in the single IC package. However, if two individual ICs are used, then the total power dissipation is divided between each IC.

Two Non-Isolated LM3886Ts:

$$V_{CC} = \pm 28V,\ R_L = 4\Omega$$

$$Pdmax = 4V_{CCtot}^2/2\pi^2R_L = 4(\pm 28V)^2/2\pi^2(4\Omega) = 158.8W$$

$$Pdmax = 158.8W$$

$$Pdmax/IC = 79.4W$$

Therefore, using a bridged configuration, V_{cc} would have to be equal to ±20V to keep the IC's power dissipation within

4.0 Thermal Background (Continued)

40W/IC when driving a 4Ω load! This equates to about 110W of output power in bridged-mode driving a 4Ω load. When driving an 8Ω load, and using the same bridged pdmax equation and a maximum of 40W/IC of power dissipation, the supply voltages would have to be ±28V. This equates to about 120W of output power.

4.4 PARALLEL AMPLIFIER Pdmax EQUATION

To determine the Pdmax equation for a parallel amplifier solution the single-ended Pdmax equation is used as a starting point. Since a parallel solution has the load connected the same as single-ended solution (one side to GND) just more devices driving the load, the equation does not change for total Pdmax.

$$Pdmax_{PA} = V_{CCtot}^2/2\pi^2R_L$$

The advantage of the parallel solution is total Pdmax is divided equally among each of the amplifiers in the parallel solution. By dividing up the total power dissipation among two or more ICs, lower impedance loads can be driven for much higher power solutions. National's Overture power amplifier series amplifiers will give the most output power and power dissipation will be kept within limits when each amplifier sees a load impedance of 4Ω – 8Ω.

Each amplifier in a parallel solution sees a load impedance equal to the total load impedance * the number of amplifiers used. So for a 4Ω solution using two amplifiers will result in each amplifier seeing an 8Ω load. Using National's LM3886 in a two device parallel solution driving a 4Ω load will typically provide 110W of output power. For a 2Ω solution using two LM3886 ICs will result in each IC seeing a 4Ω load and typically provide 120W of output power. Or four LM3886 ICs may be used so each IC sees an 8Ω load typically providing 200W of output power. Three ICs may also be used so that each IC sees a 6Ω load typically providing 150W of output power.

4.5 BRIDGED/PARALLEL AMPLIFIER Pdmax EQUATION

The bridged/parallel amplifier consist of two amplifiers in bridge mode then additional amplifiers in parallel to the amplifiers on each side of the bridge (see Figure 13 and 17). To find the equation for $Pdmax_{BPA}$ the $Pdmax_{BTL}$ equation is used as a starting point. As discussed above, adding devices in parallel does not change the Pdmax equation so the total Pdmax for a bridged/parallel solution is the same as for a bridged solution.

$$Pdmax_{BPA} = 4*(V_{CCtot}^2/2\pi^2R_L)$$

This total power dissipation is divided equally among all of the amplifiers in the circuit. To determine the Pdmax equation for each amplifier in a bridged/parallel circuit the $Pdmax_{BPA}$ equation is used as a starting point. The $Pdmax_{BPA}$ equation calculates the total peak power dissipation for the entire circuit. To find the power for each side of the bridge the $Pdmax_{BPA}$ equation must be multiplied by a factor of 1/2 giving:

$$Pdmax_{BPA(IC)} = 4*(V_{CCtot}^2/2\pi^2R_L) * (½) = 2*(V_{CCtot}^2/2\pi^2R_L)$$

Adding one additional amplifier in parallel to each side of the bridge as shown in Figures 13 and 17 divides the power between the two amplifiers in parallel on each side of the bridge. The equation must be multiplied by another factor of 1/2 giving:

$$Pdmax_{BPA(IC)} = 2*(V_{CCtot}^2/2\pi^2R_L) * (½) = V_{CCtot}^2/2\pi^2R_L$$

which is just the single-ended Pdmax equation. If more devices are added in parallel to each side of the bridge then instead of a factor of ½ a factor of 1/(Number of Amplifiers) would be used in the last step above.

An alternate way to arrive at the $Pdmax_{BPA(IC)}$ equation is to use the singled-ended Pdmax equation and determine the load impedance seen by each amplifier in the circuit. As discussed above, a bridge circuit means each side of the bridge will see 1/2 the load impedance and a parallel circuit results in each amplifier seeing a load impedance equal to the load * the number of amplifiers in parallel. Putting these two results together gives a general equation for $Pdmax_{BPA(IC)}$.

$$Pdmax_{BPA(IC)} = V_{CCtot}^2/2\pi^2[(\#\text{ of amps in parallel}/2)*R_L]$$

Where # of amps in parallel is the number of amplifiers in parallel on each side of the bridge and not the total number of amplifiers in parallel. As an example, if a 4Ω load is used and the number of amplifiers in parallel is three per side of the bridge (six amplifiers total) then the load seen by each amplifier is: 3/2 * 4Ω = 6Ω.

4.6 THERMAL CONCLUSION

Because of National's portfolio of products and the capabilities of the bridged/parallel circuit, the bridged solution is applicable for a power output window between 80W and 120W. Trying to exceed this power level without a rigorous thermal design will be difficult to achieve. More caution needs to be applied along with better thermal management for bridged circuit designs. The proposed bridged/parallel solution is a more robust design than the bridged circuit, allowing higher output power levels to be obtained by paralleling the two bridged sets of ICs. Table 1 below summarizes the maximum supply voltages for each type of configuration and load impedance while keeping Pdmax per LM3886 IC to less than 40W. See Figure 3, 6, and 13 for detailed information on each circuit.

**NA = No Advantage compared to single-ended or other configurations

In addition to better heat sinking, the application of a small fan can substantially increase the IC's continuous power dissipation capabilities. While the air flow of the fan used to take the data is not known, its air flow seemed to be consistent with a typical computer fan. The IC maximum power dissipation data for an individual LM3886 is summarized below in *Table 2*. The data shown below should only be used as a guideline of possible IC power dissipation capability. Your electrical design parameters and thermal management may be different, changing the achievable results. As always, lab testing is recommended to verify any solution.

4.7 THERMAL TESTING CONDITIONS

The data summarized in *Table 2* was obtained by using the bridged/parallel configuration and the following conditions: The system was warmed up for an hour using a power dissipation of 30W per device with a 4Ω load. Four different temperature points were measured after stabilizing, then the supply voltages were incremented while insuring that SPiKe Protection was not enabled during each test by monitoring each amplifier output. The supply voltages continued to be incremented until SPiKe protection or thermal shutdown was enabled, providing the IC's power dissipation limits under those operating conditions.

The input stimulus was a 20Hz sinewave with an amplitude corresponding to the worst case power dissipation for the given load and supply voltage. The ICs were evenly spread out along the heatsink with dimensions of: 3.25" high x 13.25" long x 1.3125" deep. The main body of the heatsink is 0.25" thick with (10) 1.0625" deep fins and the heatsink is black anodized. (See section 9.2 for detailed drawing.) Unfortunately, the fins ran horizontally, which hindered heat radiation without a fan, but helped with air flow and heat dissipation when a fan was used.

This same testing procedure can be used for any number of booster circuits, including variations of the bridged/parallel circuit. Another variation would be to add more ICs in parallel to further reduce power dissipation, allowing low impedance loads to be driven to obtain even higher output power levels.

5.1 AUDIO TESTING

The following graphs represent the performance level attainable from the bridged circuit found in Figure 3 with a well designed PCB and properly heat sinked. The testing focused on maximum output power capabilities and amplifier linearity. The low THD+N plots shown in Figures 1 & 2 exemplify the high degree of linearity of the bridged circuit which directly translates into a cleaner sounding more transparent amplifier. Other bridged circuit topologies that use the output of one amplifier as the input to the second inverting amplifier inherently possess higher THD and noise that will degrade the solution's sound quality.

5.1.1 Linearity Tests

The linearity of the amplifier is represented by the low THD+N values shown in *Figures 1, 2*. *Figure 1* represents the THD+N vs Frequency for 1W, 56W, and 100W power levels. The 20kHz THD+N is less than 0.02% for 1W and about 0.008% for 56W and above. For normal listening levels, the THD+N is about 0.004% for most of the audio band. *Figure 2* represents the THD+N vs Output Power Level for 20Hz, 1kHz, and 20kHz. The THD+N between 20Hz and 1kHz is less than 0.004% from 1W to the clipping point. The 20kHz THD+N is less than 0.02% from 1W to the clipping point. The continuous clipping point power is around 105W while the power at 10% THD+N is about 140W. These THD+N graphs were obtained using relative THD units, which indicates that the noise level for the amplifier is quite low. Typically, the noise level becomes a significant THD+N contributor at low power levels and shows up as a linearly decreasing function of increasing input signal amplitude. The low power level THD+N for this amplifier is more than acceptable for home entertainment applications.

Figure 3 represents the bridged amplifier schematic. The design is extremely simple, consisting of a non-inverting power op amp configuration and an inverting power op amp configuration. The input to the amplifier solution goes to each individual configuration. While closed-loop gain matching is not critical, it is recommended to have fairly close values. The main functional point to note about this solution is that for a positive going input signal, amplifier U1 will have a positive changing output signal while U2 will have a negative changing output signal. The final voltage across the load is two times the peak amplitude of each individual amplifier output. Since output power is based on the square of the output voltage, the output power is theoretically quadrupled. This document will not go further into the functionality of the circuit as it is widely known in industry.

5.2.2 Electrical Design Notes

The following electrical design notes will aid in making the bridged amplifier design go more smoothly while also helping to achieve the highest level of performance.

- The input impedance of the inverting amplifier is essentially resistor, R_i. The value of this resistance affects the gain setting of the amplifier as well as the low frequency rolloff in conjunction with C_i. There is a tradeoff between having a low frequency rolloff, a high input impedance and a small capacitor size and value. It is critical to have a flat band response down to 20Hz while it is equally important to have a high enough input impedance so that heavy loading does not occur from the preamp stage. Using large valued low-cost capacitors implies the use of leaky electrolytics which affect the output offset voltage. Electrolytic capacitors are also less linear than other premium caps and should not be used in the signal path when not necessary. This tradeoff issue is the toughest portion of the design. The amplifier gain setting is just as one would expect for an inverting op amp. Of course, the input impedance issue can be quickly resolved by using a voltage follower as an input buffer, but it was omitted from this design to minimize cost and simplify the design. The values provided in the bridged schematic are at a good tradeoff point. There is sufficient input impedance for practically all audio op amps, the closed-loop gain setting is 11 for each amplifier, (gain of 22 overall) while the capacitor value of 4.7µF sets the low frequency –3dB rolloff at about 7Hz.
- The non-inverting input resistance, R_b, is used to create a voltage drop at the non-inverting terminal to offset the voltage at the inverting input terminal due to the input bias current flowing from the output to the inverting input. Generally, the value of this resistor equals the value of the feedback resistor so that the output offset voltage will be minimized close to zero. However, if this value is too large, noise can easily be picked up which will be amplified and seriously affect the THD+N performance. If the resistor is eliminated and the terminal is grounded, the THD+N performance will be much better, but it will not necessarily be optimized. By connecting the non-inverting input directly to a ground reference, any noise on that ground will be directly injected into the amplifier, amplified and thus will also affect the THD+N performance. The best solution is to use a value of resistance that is not too large that it picks up stray noise and not too small as to be affected by ground noise fluctuations. The value used in the previous plots was a 3.32kΩ resistor. It should be noted that this is not necessarily the optimized value and can change with varying circuit layouts.
- Low leakage signal path capacitors should be used where possible to reduce output offset voltages. This is not too big of an issue since each gain stage has only unity gain at DC. This is another reason why 1% resistor tolerances are not necessarily required. To obtain the highest quality amplifier, polypropylene capacitors should be employed in the signal path and supply bypassing.

6.1 AUDIO TESTING

The following graphs are the same format as those presented in the BR100 analysis, namely THD+N verses Frequency at 1W, 56W and 100W and THD verses Output Power with plots at 20Hz, 1kHz, and 20kHz.

6.1.1 Linearity Test

The linearity of the amplifier is represented by the low THD+N values shown in Figures 4, 5. Figure 4 represents the THD+N vs Frequency for 1W, 56W and 100W power levels. The 20kHz THD+N is less than 0.05% for all power levels. Figure 5 represents the THD+N vs Output Power Level for 20Hz, 1kHz, and 20kHz. The THD+N between 20Hz and 1kHz is less than 0.01% for power levels above 1W up to the clipping point. The 20kHz THD+N is 0.04% from 0.1W to the clipping point. The 1% THD+N power point is around 110W while the 10% THD+N power point is near 150W. These THD+N graphs were obtained using relative THD+N units, which indicates that the noise level for the amplifier is very low. Typically, the noise level becomes a significant THD+N contributor at lower power levels and shows up as a linearly decreasing function of increasing input signal amplitude. The low power level THD+N for this amplifier configuration is more than acceptable for home entertainment applications.

Figure 6 represents the parallel amplifier schematic. The design is extremely simple, consisting of two power op amps configured identically and tied in parallel to the load each through a 0.1Ω/3W resistor. The closer matched the gain of each IC the more equal the current sharing between them as well as the temperature of each IC due to power dissipation being near equal. This document will not go further into the functionality of the circuit as it is well known in industry.

- The input resistance is equal to R_{IN}.The value of R_{IN} should be high enough to eliminate any loading placed on the previous stage (i.e. pre-amplifier). The DC blocking input capacitor value should be calculated on the value of Rin to be sure the correct size is used so low frequency signals will be coupled in without severe attenuation. $f_{IN} = 1/(2\pi R_{IN}C_{IN})$.
- 1% gain setting resistors (R_i and R_f) will give good results but it is recommended 0.1% tolerance resistors be used for setting the gain of each op amp for closer matched gain and equal output current and power dissipation.
- The output resistors, R_{OUT}, wattage rating is based on the load impedance and the output current or maximum output power. As the load impedance is increased or reduced the output current is reduced or increased, respectively. The wattage rating of R_{OUT} should increase as output current increases and decrease as output current decreases. A very conservative design will use peak output current to calculate the needed wattage rating of R_{OUT} ($P = I^2R$).
- As always, the better the supply bypassing, the better the noise rejection and hence higher performance.

7.1 AUDIO TESTING

The following graphs represent the performance level attainable from the bridge/parallel circuit found in Figure 13 with a well designed PCB and properly heat sinked. The testing focused on maximum output power capabilities, amplifier linearity and noise level.

7.1.1 Linearity Tests

The linearity of the amplifier is represented by the low THD+N values shown in *Figures 7, 8*. *Figure 7* represents the THD+N vs Frequency for 1W, 56W, and 200W power levels. *Figure 8* represents the THD+N vs Output Power Level for 20Hz, 1kHz, and 20kHz. The THD+N between 20Hz and 1 kHz is less than 0.004% from 1W to the clipping point. The 20kHz THD+N is less than 0.02% from 1W to the clipping point, The continuous clipping point power is around 210W while the power at 10% THD+N is 300W. These THD+N graphs were obtained using relative THD+N units, which indicates that the noise level for the amplifier is quite low. Typically, the noise level becomes a significant THD+N contributor at low power levels and shows up as a linearly decreasing function of increasing input signal amplitude. In *Figure 8*, the THD+N decreases from 0.004% to 0.001% from 1W to the clipping point for frequencies between 20Hz and 1kHz. The THD+N with a 20kHz input decreases from 0.02% to 0.009% from 1W to 50W and rises thereafter up to about 0.015%.

7.1.2 Output Power Tests

Although the amplifier was deigned based on thermal dissipation capabilities using continuous sinusoidal inputs, the output power levels attainable are significantly greater with pulsed waveforms that more accurately reflect music material. The continuous clipping point power and burst power levels are shown in *Table 3* below:

TABLE 3. BPA200 Maximum Output Power Levels

Load Impedance	Continuous Clipping Point Power	Burst Clipping Point Power
8Ω	225W	295W
4Ω	335W	450W

The burst power levels were obtained using a 20Hz sinewave with two cycles on and twenty cycles off. The output power capability of the BPA200 is further substantiated by the power bandwidth measurement. The amplifier is capable of producing 200W continuously into an 8Ω load up to f = 90.5kHz with little change in THD+N. The graph in *Figure 9* shows the power bandwidth measurement. Also notice that the low frequency power in the graph is not rolled

7.1.3 Noise Floor Tests

The following plots exemplify the low-noise aspects of the BPA200. *Figure 10* was obtained using an 8k FFT relative to 1dBV with a measurement bandwidth of 22kHz. *Figure 11* is the same measurement as *Figure 10*, but shown in a logarithmic scale.

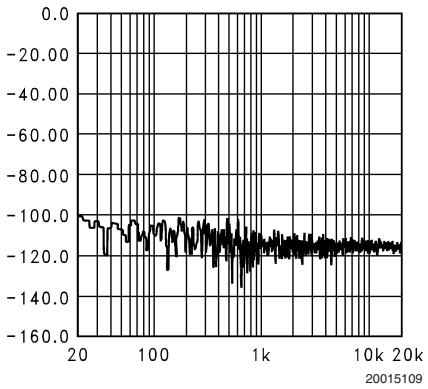

FIGURE 11. Log-Scale Noise Floor

An FFT analyzer is extremely handy in determining the noise culprit when debugging a new circuit and its layout, as well as evaluating the coupling effects of the 60Hz component and its harmonics. As shown in *Figure 12*, the noise level is quite low and the influence of the power supply is relatively small. The highest 60Hz components reach −105dBV, while the noise floor sits around −120dBV.

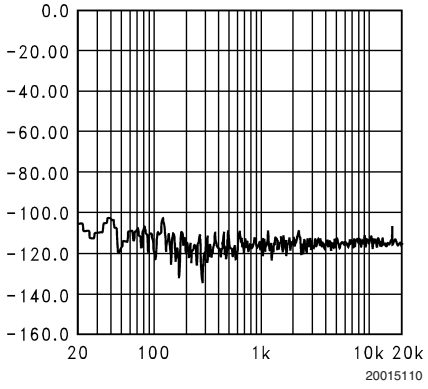

FIGURE 12. Log-Scale 60 Hz Noise Floor

Even with the limited number of graphs shown, the quality of this amplifier from a measurement perspective is quite good. However, with all audio equipment, nothing is really better than doing a listening test. It is recommended that listening test be done to confirm the audio quality of the different configurations presented.

7.0 BPA200–200W Bridged/Parallel Circuit (Continued)

7.1.4 Electrical Design Notes

The following electrical design notes will aid in obtaining a high performance amplifier solution.

- Input resistor values should be equal and have a 0.1% tolerance to minimize amplifier noise. These resistor pairs are R_{b1} & R_{i1}, R_{b2} & R_{i2}, R_{i3} & R_{c3}, and R_{i4} & R_{d3} as shown in Figure 13.
- 0.1% tolerance resistors for close gain matching should be used to minimize offset voltages when not using servo circuits.
- 1% tolerance high wattage ballast resistors are required when paralleling outputs to keep differently biased outputs from fighting each other. The wattage rating is dependent upon the amount of current expected to flow from each output and the resistance of the ballast resistor; $P = I^2R$. A good resistance value is 0.1Ω. Amplifier efficiency is lost if the resistor value is too large like 1Ω since 10A times 1Ω is 10V of output voltage drop.
- Low output offset voltage servo op amp is required to minimize solution output offset voltage.
- An input buffer is required because of the low input impedance from paralleling of the inputs. High valued gain setting resistors could be used at the risk of increasing noise susceptibility. The proposed solution with an input buffer (see Figures 13 & 17) provides the easiest way around gain resistor matching and providing a high input impedance.

7.2.2 Servo Circuits

While output ballast resistors in the basic bridge/parallel circuit work well to keep separately biased IC outputs from fighting each other, the addition of servo circuits will minimize output offset voltages that cause output voltage inequalities. Different output offset voltages cause a constant current to flow between outputs that increases IC power dissipation. By minimizing output offset voltages, all of the ICs will run cooler, expanding the IC's long term reliability and output power capability without activating sensitive protection circuits.

Typically, offset voltages are compensated for by using input and output coupling capacitors. Power amplifiers used in a single-supply configuration, utilize large value, large size electrolytic or polypropylene capacitors. This is because the load impedance is 4Ω or 8Ω and the RC combination creates a highpass filter that can rolloff audio frequencies. Since these output coupling capacitors have nonlinearities and are quite large, many designers choose to employ split power supplies. While split power supplies don't use these capacitors, a DC blocking capacitor is needed somewhere in the circuit to protect speakers. This capacitor is typically, C_{i1}, C_{i2}, C_{i3}, and C_{i4} as shown in *Figure 13*. With the application of a servo circuit, this capacitor can also be eliminated as shown in *Figures 14, 15*.

Servo circuits are essentially integrator op amp circuits that integrate offset voltage changes from the power op amp's output and feed back the integrated voltage to the opposite input of the power op amp. A servo circuit is required at each IC output of the bridge/parallel circuit to keep currents from flowing between IC outputs. Without each output compensated, one offset voltage will cause current to flow between ICs increasing power dissipation. If gain setting resistors are 0.1% and closely matched, the servo circuit may be left out, but DC blocking capacitors will be required.

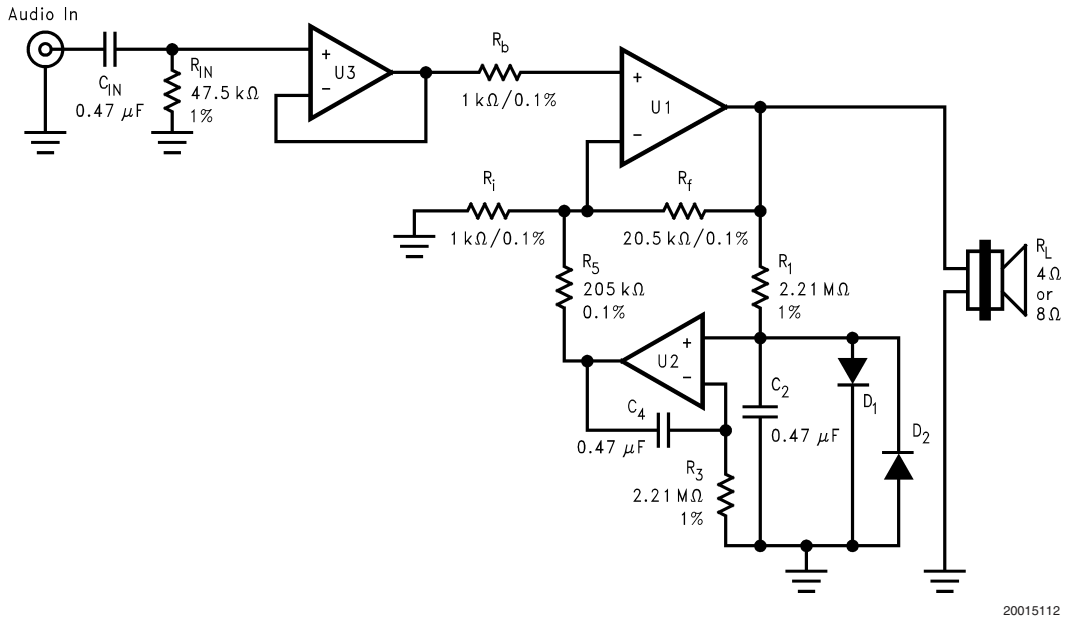

FIGURE 14. Non-Inverting Servo Amplifier Schematic

The inverting type servo amplifier applied to the inverting amplifier portion of the bridge/parallel circuit is shown in *Figure 15*. The non-inverting type servo circuit could be applied to the inverting input of U1 to achieve the same result, however, it uses an extra RC network that can be eliminated with the inverting type servo.

If a different power amplifier gain is desired, other component values can be used under the following conditions: In *Figure 14*, resistor R5 should be about 10 times the value of R_f, while R_i and R_b should be equal. In , *Figure 15*, resistor R3 should be about 10 times the value of R_f, while R_4 and R_i should be equal. For both the Non-Inverting and Inverting Servo solutions, the input clamping diodes should be low-leakage, with low-leakage film capacitors having a high-quality dielectric such as polypropylene or polystyrene (mylar), and metal-film resistors.

7.2.3 Power Supply Circuit

The power supply portion of the amplifier is made up of a typical unregulated bipolar power supply. The supply is comprised of an input AC line filter, surge protecting MOVs, a separate 385VA toroidal transformer for each channel, and 40,000µF of supply reservoir capacitance for each supply voltage rail.

LIFE SUPPORT POLICY

NATIONAL'S PRODUCTS ARE NOT AUTHORIZED FOR USE AS CRITICAL COMPONENTS IN LIFE SUPPORT DEVICES OR SYSTEMS WITHOUT THE EXPRESS WRITTEN APPROVAL OF THE PRESIDENT AND GENERAL COUNSEL OF NATIONAL SEMICONDUCTOR CORPORATION. As used herein:

1. Life support devices or systems are devices or systems which, (a) are intended for surgical implant into the body, or (b) support or sustain life, and whose failure to perform when properly used in accordance with instructions for use provided in the labeling, can be reasonably expected to result in a significant injury to the user.
2. A critical component is any component of a life support device or system whose failure to perform can be reasonably expected to cause the failure of the life support device or system, or to affect its safety or effectiveness.

BANNED SUBSTANCE COMPLIANCE

National Semiconductor certifies that the products and packing materials meet the provisions of the Customer Products Stewardship Specification (CSP-9-111C2) and the Banned Substances and Materials of Interest Specification (CSP-9-111S2) and contain no ''Banned Substances'' as defined in CSP-9-111S2.

IMPORTANT NOTICE

Texas Instruments Incorporated and its subsidiaries (TI) reserve the right to make corrections, modifications, enhancements, improvements, and other changes to its products and services at any time and to discontinue any product or service without notice. Customers should obtain the latest relevant information before placing orders and should verify that such information is current and complete. All products are sold subject to TI's terms and conditions of sale supplied at the time of order acknowledgment.

TI warrants performance of its hardware products to the specifications applicable at the time of sale in accordance with TI's standard warranty. Testing and other quality control techniques are used to the extent TI deems necessary to support this warranty. Except where mandated by government requirements, testing of all parameters of each product is not necessarily performed.

TI assumes no liability for applications assistance or customer product design. Customers are responsible for their products and applications using TI components. To minimize the risks associated with customer products and applications, customers should provide adequate design and operating safeguards.

TI does not warrant or represent that any license, either express or implied, is granted under any TI patent right, copyright, mask work right, or other TI intellectual property right relating to any combination, machine, or process in which TI products or services are used. Information published by TI regarding third party products or services does not constitute a license from TI to use such products or services or a warranty or endorsement thereof. Use of such information may require a license from a third party under the patents or other intellectual property of that third party, or a license from TI under the patents or other intellectual property of TI.

Reproduction of information in TI data books or data sheets is permissible only if reproduction is without alteration and is accompanied by all associated warranties, conditions, limitations, and notices. Reproduction of this information with alteration is an unfair and deceptive business practice. TI is not responsible or liable for such altered documentation.

Resale of TI products or services with statements different from or beyond the parameters stated by TI for that product or service voids all express and any implied warranties for the associated TI product or service and is an unfair and deceptive business practice. TI is not responsible or liable for any such statements.

Forward

Everyone interested in analog electronics should find some value in this book, and an effort has been made to make the material understandable to the relative novice while not too boring for the practicing engineer. Special effort has been taken to ensure that each chapter can stand alone for the reader with the proper background. Of course, this causes redundancy that some people might find boring, but it's worth the price to enable the satisfaction of a diversified audience.

Start at Chapter 1 if you are a novice, and read through until completion of Chapter 9. After Chapter 9 is completed, the reader can jump to any chapter and be confident that they are prepared for the material. More experienced people such as electronic technicians, digital engineers, and non-electronic engineers can start at Chapter 3 and read through Chapter 9. Senior electronic technicians, electronic engineers, and fledgling analog engineers can start anywhere they feel comfortable and read through Chapter 9. Experienced analog engineers should jump to the subject that interests them. Analog gurus should send their additions, corrections, and complaints to me, and if they see something that looks familiar, they should feel complimented that others appreciate their contributions.

Chapter 1 is a history and story chapter. It is not required reading for anyone, but it defines the op amp's place in the world of analog electronics. Chapter 2 reviews some basic physics and develops the fundamental circuit equations that are used throughout the book. Similar equations have been developed in other books, but the presentation here emphasizes material required for speedy op amp design. The ideal op amp equations are developed in Chapter 3, and this chapter enables the reader to rapidly compute op amp transfer equations including ac response. The emphasis on single power supply systems forces the designer to bias circuits when the inputs are referenced to ground, and Chapter 4 gives a detailed procedure that quickly yields a working solution every time.

Op amps can't exist without feedback, and feedback has inherent stability problems, so feedback and stability are covered in Chapter 5. Chapters 6 and 7 develop the voltage feedback op amp equations, and they teach the concept of relative stability and compensation of potentially unstable op amps. Chapter 8 develops the current feedback op amp equations and discusses current feedback stability. Chapter 9 compares current feedback and voltage feedback op amps. The meat of this book is Chapters 12, 13, and 14 where the reader is shown how design the converter to transducer/actuator interface with the aid of op amps.

The remaining chapters give support material for Chapters 12, 13, and 14. Chapter 18 was a late addition. Portable applications are expanding rapidly and they emphasize the need for low-voltage/low-power design techniques. Chapter 18 defines some parameters in a new way so they lend themselves to low voltage design, and it takes the reader through several low voltage designs.

Thanks to editor James Karki for his contribution. We never gave him enough time to do detailed editing, so if you find errors or typos, direct them to my attention. Thanks to Ted Thomas, a marketing manager with courage enough to support a book, and big thanks for Alun Roberts who paid for this effort. Thomas Kugelstadt, applications manager, thanks for your support and help.

Also many thanks to the contributing authors, James Karki, Richard Palmer, Thomas Kugelstadt, Perry Miller, Bruce Carter, and Richard Cesari who gave generously of their time.

Regards,

Ron Mancini
Chief Editor

Chapter 1

The Op Amp's Place In The World

Ron Mancini

In 1934 Harry Black[1] commuted from his home in New York City to work at Bell Labs in New Jersey by way of a railroad/ferry. The ferry ride relaxed Harry enabling him to do some conceptual thinking. Harry had a tough problem to solve; when phone lines were extended long distances, they needed amplifiers, and undependable amplifiers limited phone service. First, initial tolerances on the gain were poor, but that problem was quickly solved with an adjustment. Second, even when an amplifier was adjusted correctly at the factory, the gain drifted so much during field operation that the volume was too low or the incoming speech was distorted.

Many attempts had been made to make a stable amplifier, but temperature changes and power supply voltage extremes experienced on phone lines caused uncontrollable gain drift. Passive components had much better drift characteristics than active components had, thus if an amplifier's gain could be made dependent on passive components, the problem would be solved. During one of his ferry trips, Harry's fertile brain conceived a novel solution for the amplifier problem, and he documented the solution while riding on the ferry.

The solution was to first build an amplifier that had more gain than the application required. Then some of the amplifier output signal was fed back to the input in a manner that makes the circuit gain (circuit is the amplifier and feedback components) dependent on the feedback circuit rather than the amplifier gain. Now the circuit gain is dependent on the passive feedback components rather than the active amplifier. This is called negative feedback, and it is the underlying operating principle for all modern day op amps. Harry had documented the first intentional feedback circuit during a ferry ride. I am sure unintentional feedback circuits had been built prior to that time, but the designers ignored the effect!

I can hear the squeals of anguish coming from the managers and amplifier designers. I imagine that they said something like this, "it is hard enough to achieve 30-kHz gain–bandwidth (GBW), and now this fool wants me to design an amplifier with 3-MHz GBW. But, he is still going to get a circuit gain GBW of 30 kHz". Well, time has proven Harry right, but there is a minor problem that Harry didn't discuss in detail, and that is the oscillation

problem. It seems that circuits designed with large open loop gains sometimes oscillate when the loop is closed. A lot of people investigated the instability effect, and it was pretty well understood in the 1940s, but solving stability problems involved long, tedious, and intricate calculations. Years passed without anybody making the problem solution simpler or more understandable.

In 1945 H. W. Bode presented a system for analyzing the stability of feedback systems by using graphical methods. Until this time, feedback analysis was done by multiplication and division, so calculation of transfer functions was a time consuming and laborious task. Remember, engineers did not have calculators or computers until the ’70s. Bode presented a log technique that transformed the intensely mathematical process of calculating a feedback system’s stability into graphical analysis that was simple and perceptive. Feedback system design was still complicated, but it no longer was an art dominated by a few electrical engineers kept in a small dark room. Any electrical engineer could use Bode’s methods to find the stability of a feedback circuit, so the application of feedback to machines began to grow. There really wasn’t much call for electronic feedback design until computers and transducers become of age.

The first real-time computer was the analog computer! This computer used preprogrammed equations and input data to calculate control actions. The programming was hard wired with a series of circuits that performed math operations on the data, and the hard wiring limitation eventually caused the declining popularity of the analog computer. The heart of the analog computer was a device called an operational amplifier because it could be configured to perform many mathematical operations such as multiplication, addition, subtraction, division, integration, and differentiation on the input signals. The name was shortened to the familiar *op amp*, as we have come to know and love them. The op amp used an amplifier with a large open loop gain, and when the loop was closed, the amplifier performed the mathematical operations dictated by the external passive components. This amplifier was very large because it was built with vacuum tubes and it required a high-voltage power supply, but it was the heart of the analog computer, thus its large size and huge power requirements were accepted as the price of doing business. Many early op amps were designed for analog computers, and it was soon found out that op amps had other uses and were very handy to have around the physics lab.

At this time general-purpose analog computers were found in universities and large company laboratories because they were critical to the research work done there. There was a parallel requirement for transducer signal conditioning in lab experiments, and op amps found their way into signal conditioning applications. As the signal conditioning applications expanded, the demand for op amps grew beyond the analog computer requirements, and even when the analog computers lost favor to digital computers, the op amp survived because of its importance in universal analog applications. Eventually digital computers replaced the analog computers (a sad day for real-time measurements), but the demand for op amps increased as measurement applications increased.

The first signal conditioning op amps were constructed with vacuum tubes prior to the introduction of transistors, so they were large and bulky. During the ’50s, miniature vacuum tubes that worked from lower voltage power supplies enabled the manufacture of op amps that shrunk to the size of a brick used in house construction, so the op amp modules were nicknamed *bricks*. Vacuum tube size and component size decreased until an op amp was shrunk to the size of a single octal vacuum tube. Transistors were commercially developed in the ’60s, and they further reduced op amp size to several cubic inches, but the nickname brick still held on. Now the nickname brick is attached to any electronic module that uses potting compound or non-integrated circuit (IC) packaging methods. Most of these early op amps were made for specific applications, so they were not necessarily general purpose. The early op amps served a specific purpose, but each manufacturer had different specifications and packages; hence, there was little second sourcing among the early op amps.

ICs were developed during the late 1950s and early 1960s, but it wasn’t till the middle 1960s that Fairchild released the μA709. This was the first commercially successful IC op amp, and Robert J. Widler designed it. The μA709 had its share of problems, but any competent analog engineer could use it, and it served in many different analog applications. The major drawback of the μA709 was stability; it required external compensation and a competent analog engineer to apply it. Also, the μA709 was quite sensitive because it had a habit of self destructing under any adverse condition. The self-destruction habit was so prevalent that one major military equipment manufacturer published a paper titled something like, *The 12 Pearl Harbor Conditions of the μA709*. The μA741 followed the μA709, and it is an internally compensated op amp that does not require external compensation if operated under data sheet conditions. Also, it is much more forgiving than the μA709. There has been a never-ending series of new op amps released each year since then, and their performance and reliability has improved to the point where present day op amps can be used for analog applications by anybody.

The IC op amp is here to stay; the latest generation op amps cover the frequency spectrum from 5-kHz GBW to beyond 1-GHz GBW. The supply voltage ranges from guaranteed operation at 0.9 V to absolute maximum voltage ratings of 1000 V. The input current and input offset voltage has fallen so low that customers have problems verifying the specifications during incoming inspection. The op amp has truly become the universal analog IC because it performs all analog tasks. It can function as a line driver, comparator (one bit A/D), amplifier, level shifter, oscillator, filter, signal conditioner, actuator driver, current source, voltage source, and many other applications. The designer’s problem is how to rapidly select the correct circuit/op amp combination and then, how to calculate the passive component values that yield the desired transfer function in the circuit.

This book deals with op amp circuits — not with the innards of op amps. It treats the calculations from the circuit level, and it doesn’t get bogged down in a myriad of detailed calculations. Rather, the reader can start at the level appropriate for them, and quickly move on to the advanced topics. If you are looking for material about the innards of op amps

you are looking in the wrong place. The op amp is treated as a completed component in this book.

The op amp will continue to be a vital component of analog design because it is such a fundamental component. Each generation of electronics equipment integrates more functions on silicon and takes more of the analog circuitry inside the IC. Don't fear, as digital applications increase, analog applications also increase because the predominant supply of data and interface applications are in the real world, and the real world is an analog world. Thus, each new generation of electronics equipment creates requirements for new analog circuits; hence, new generations of op amps are required to fulfill these requirements. Analog design, and op amp design, is a fundamental skill that will be required far into the future.

Review of Circuit Theory

Ron Mancini

2.1 Introduction

Although this book minimizes math, some algebra is germane to the understanding of analog electronics. Math and physics are presented here in the manner in which they are used later, so no practice exercises are given. For example, after the voltage divider rule is explained, it is used several times in the development of other concepts, and this usage constitutes practice.

Circuits are a mix of passive and active components. The components are arranged in a manner that enables them to perform some desired function. The resulting arrangement of components is called a circuit or sometimes a circuit configuration. The art portion of analog design is developing the circuit configuration. There are many published circuit configurations for almost any circuit task, thus all circuit designers need not be artists.

When the design has progressed to the point that a circuit exists, equations must be written to predict and analyze circuit performance. Textbooks are filled with rigorous methods for equation writing, and this review of circuit theory does not supplant those textbooks. But, a few equations are used so often that they should be memorized, and these equations are considered here.

There are almost as many ways to analyze a circuit as there are electronic engineers, and if the equations are written correctly, all methods yield the same answer. There are some simple ways to analyze the circuit without completing unnecessary calculations, and these methods are illustrated here.

2.2 Laws of Physics

Ohm's law is stated as V=IR, and it is fundamental to all electronics. Ohm's law can be applied to a single component, to any group of components, or to a complete circuit. When the current flowing through any portion of a circuit is known, the voltage dropped across that portion of the circuit is obtained by multiplying the current times the resistance (Equation 2–1).

$$V = IR \tag{2–1}$$

In Figure 2–1, Ohm's law is applied to the total circuit. The current, (I) flows through the total resistance (R), and the voltage (V) is dropped across R.

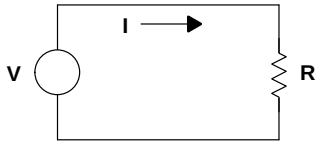

Figure 2–1. Ohm's Law Applied to the Total Circuit

In Figure 2–2, Ohm's law is applied to a single component. The current (I_R) flows through the resistor (R) and the voltage (V_R) is dropped across R. Notice, the same formula is used to calculate the voltage drop across R even though it is only a part of the circuit.

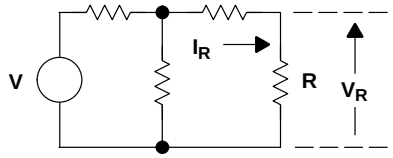

Figure 2–2. Ohm's Law Applied to a Component

Kirchoff's voltage law states that the sum of the voltage drops in a series circuit equals the sum of the voltage sources. Otherwise, the source (or sources) voltage must be dropped across the passive components. When taking sums keep in mind that the sum is an algebraic quantity. Kirchoff's voltage law is illustrated in Figure 2–3 and Equations 2–2 and 2–3.

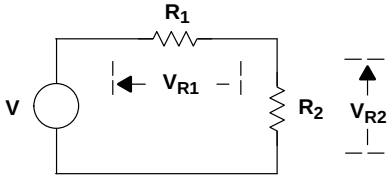

Figure 2–3. Kirchoff's Voltage Law

$$\sum V_{SOURCES} = \sum V_{DROPS} \tag{2–2}$$

$$V = V_{R1} + V_{R2} \tag{2–3}$$

Kirchoff's current law states: the sum of the currents entering a junction equals the sum of the currents leaving a junction. It makes no difference if a current flows from a current

source, through a component, or through a wire, because all currents are treated identically. Kirchoff's current law is illustrated in Figure 2–4 and Equations 2–4 and 2–5.

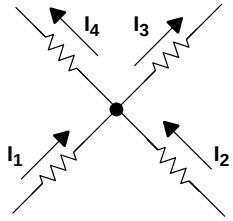

Figure 2–4. Kirchoff's Current Law

$$\sum I_{IN} = \sum I_{OUT} \tag{2–4}$$

$$I_1 + I_2 = I_3 + I_4 \tag{2–5}$$

2.3 Voltage Divider Rule

When the output of a circuit is not loaded, the voltage divider rule can be used to calculate the circuit's output voltage. Assume that the same current flows through all circuit elements (Figure 2–5). Equation 2–6 is written using Ohm's law as $V = I (R_1 + R_2)$. Equation 2–7 is written as Ohm's law across the output resistor.

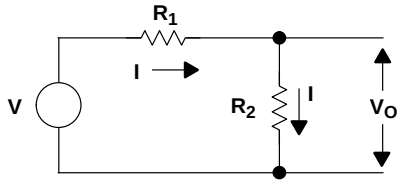

Figure 2–5. Voltage Divider Rule

$$I = \frac{V}{R_1 + R_2} \tag{2–6}$$

$$V_{OUT} = IR_2 \tag{2–7}$$

Substituting Equation 2–6 into Equation 2–7, and using algebraic manipulation yields Equation 2–8.

$$V_{OUT} = V \frac{R_2}{R_1 + R_2} \tag{2–8}$$

A simple way to remember the voltage divider rule is that the output resistor is divided by the total circuit resistance. This fraction is multiplied by the input voltage to obtain the out-

put voltage. Remember that the voltage divider rule always assumes that the output resistor is not loaded; the equation is not valid when the output resistor is loaded by a parallel component. Fortunately, most circuits following a voltage divider are input circuits, and input circuits are usually high resistance circuits. When a fixed load is in parallel with the output resistor, the equivalent parallel value comprised of the output resistor and loading resistor can be used in the voltage divider calculations with no error. Many people ignore the load resistor if it is ten times greater than the output resistor value, but this calculation can lead to a 10% error.

2.4 Current Divider Rule

When the output of a circuit is not loaded, the current divider rule can be used to calculate the current flow in the output branch circuit (R_2). The currents I_1 and I_2 in Figure 2–6 are assumed to be flowing in the branch circuits. Equation 2–9 is written with the aid of Kirchoff's current law. The circuit voltage is written in Equation 2–10 with the aid of Ohm's law. Combining Equations 2–9 and 2–10 yields Equation 2–11.

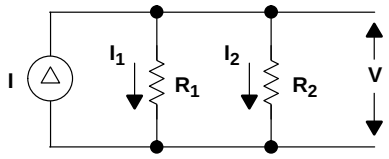

Figure 2–6. Current Divider Rule

$$I = I_1 + I_2 \tag{2–9}$$

$$V = I_1R_1 = I_2R_2 \tag{2–10}$$

$$I = I_1 + I_2 = I_2\frac{R_2}{R_1} + I_2 = I_2\left(\frac{R_1 + R_2}{R_1}\right) \tag{2–11}$$

Rearranging the terms in Equation 2–11 yields Equation 2–12.

$$I_2 = I\left(\frac{R_1}{R_1 + R_2}\right) \tag{2–12}$$

The total circuit current divides into two parts, and the resistance (R_1) divided by the total resistance determines how much current flows through R_2. An easy method of remembering the current divider rule is to remember the voltage divider rule. Then modify the voltage divider rule such that the opposite resistor is divided by the total resistance, and the fraction is multiplied by the input current to get the branch current.

2.5 Thevenin's Theorem

There are times when it is advantageous to isolate a part of the circuit to simplify the analysis of the isolated part of the circuit. Rather than write loop or node equations for the complete circuit, and solving them simultaneously, Thevenin's theorem enables us to isolate the part of the circuit we are interested in. We then replace the remaining circuit with a simple series equivalent circuit, thus Thevenin's theorem simplifies the analysis.

There are two theorems that do similar functions. The Thevenin theorem just described is the first, and the second is called Norton's theorem. Thevenin's theorem is used when the input source is a voltage source, and Norton's theorem is used when the input source is a current source. Norton's theorem is rarely used, so its explanation is left for the reader to dig out of a textbook if it is ever required.

The rules for Thevenin's theorem start with the component or part of the circuit being replaced. Referring to Figure 2–7, look back into the terminals (left from C and R_3 toward point XX in the figure) of the circuit being replaced. Calculate the no load voltage (V_{TH}) as seen from these terminals (use the voltage divider rule).

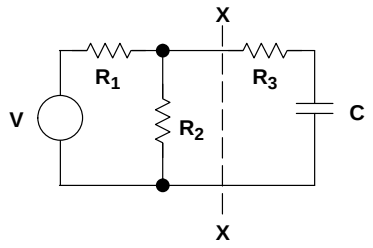

Figure 2–7. Original Circuit

Look into the terminals of the circuit being replaced, short independent voltage sources, and calculate the impedance between these terminals. The final step is to substitute the Thevenin equivalent circuit for the part you wanted to replace as shown in Figure 2–8.

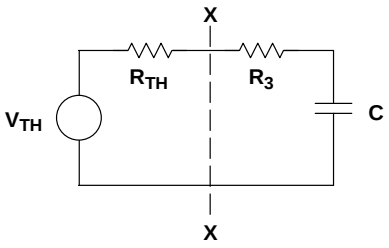

Figure 2–8. Thevenin's Equivalent Circuit for Figure 2–7

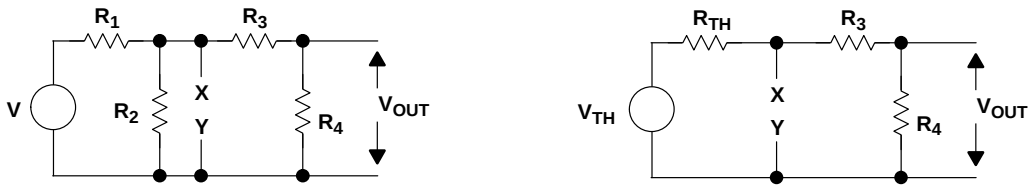
The Thevenin equivalent circuit is a simple series circuit, thus further calculations are simplified. The simplification of circuit calculations is often sufficient reason to use Thevenin's

theorem because it eliminates the need for solving several simultaneous equations. The detailed information about what happens in the circuit that was replaced is not available when using Thevenin's theorem, but that is no consequence because you had no interest in it.

As an example of Thevenin's theorem, let's calculate the output voltage (V_{OUT}) shown in Figure 2–9A. The first step is to stand on the terminals X–Y with your back to the output circuit, and calculate the open circuit voltage seen (V_{TH}). This is a perfect opportunity to use the voltage divider rule to obtain Equation 2–13.



(a) The Original Circuit **(b) The Thevenin Equivalent Circuit**

Figure 2–9. Example of Thevenin's Equivalent Circuit

$$V_{TH} = V \frac{R_2}{R_1 + R_2} \tag{2–13}$$

Still standing on the terminals X-Y, step two is to calculate the impedance seen looking into these terminals (short the voltage sources). The Thevenin impedance is the parallel impedance of R_1 and R_2 as calculated in Equation 2–14. Now get off the terminals X-Y before you damage them with your big feet. Step three replaces the circuit to the left of X-Y with the Thevenin equivalent circuit V_{TH} and R_{TH}.

$$R_{TH} = \frac{R_1 R_2}{R_1 + R_2} = R_1 \parallel R_2 \tag{2–14}$$

Note:

Two parallel vertical bars (||) are used to indicate parallel components as shown in Equation 2–14.

The final step is to calculate the output voltage. Notice the voltage divider rule is used again. Equation 2–15 describes the output voltage, and it comes out naturally in the form of a series of voltage dividers, which makes sense. That's another advantage of the voltage divider rule; the answers normally come out in a recognizable form rather than a jumble of coefficients and parameters.

$$V_{OUT} = V_{TH}\frac{R_4}{R_{TH} + R_3 + R_4} = V\left(\frac{R_2}{R_1 + R_2}\right)\frac{R_4}{\frac{R_1R_2}{R_1+R_2} + R_3 + R_4} \tag{2–15}$$

The circuit analysis is done the hard way in Figure 2–10, so you can see the advantage of using Thevenin's Theorem. Two loop currents, I_1 and I_2, are assigned to the circuit. Then the loop Equations 2–16 and 2–17 are written.

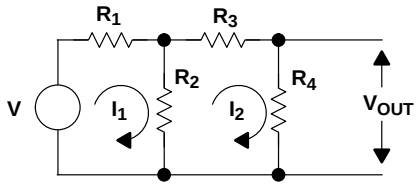


Figure 2–10. Analysis Done the Hard Way

$$V = I_1(R_1 + R_2) - I_2R_2 \tag{2–16}$$

$$I_2(R_2 + R_3 + R_4) = I_1R_2 \tag{2–17}$$

Equation 2–17 is rewritten as Equation 2–18 and substituted into Equation 2–16 to obtain Equation 2–19.

$$I_1 = I_2\frac{R_2 + R_3 + R_4}{R_2} \tag{2–18}$$

$$V = I_2\left(\frac{R_2 + R_3 + R_4}{R_2}\right)(R_1 + R_2) - I_2R_2 \tag{2–19}$$

The terms are rearranged in Equation 2–20. Ohm's law is used to write Equation 2–21, and the final substitutions are made in Equation 2–22.

$$I_2 = \frac{V}{\frac{R_2+R_3+R_4}{R_2}(R_1 + R_2) - R_2} \tag{2–20}$$

$$V_{OUT} = I_2R_4 \tag{2–21}$$

$$V_{OUT} = V\frac{R_4}{\frac{(R_2+R_3+R_4)(R_1+R_2)}{R_2} - R_2} \tag{2–22}$$

This is a lot of extra work for no gain. Also, the answer is not in a usable form because the voltage dividers are not recognizable, thus more algebra is required to get the answer into usable form.

2.6 Superposition

Superposition is a theorem that can be applied to any linear circuit. Essentially, when there are independent sources, the voltages and currents resulting from each source can be calculated separately, and the results are added algebraically. This simplifies the calculations because it eliminates the need to write a series of loop or node equations. An example is shown in Figure 2–11.

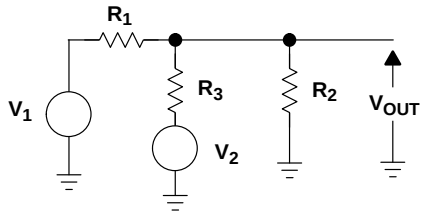

Figure 2–11. Superposition Example

When V_1 is grounded, V_2 forms a voltage divider with R_3 and the parallel combination of R_2 and R_1. The output voltage for this circuit (V_{OUT2}) is calculated with the aid of the voltage divider equation (2–23). The circuit is shown in Figure 2–12. The voltage divider rule yields the answer quickly.

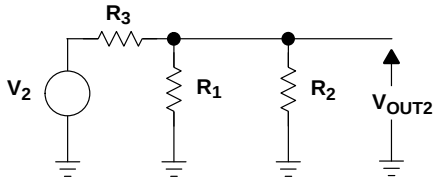

Figure 2–12. When V_1 is Grounded

$$V_{OUT2} = V_2 \frac{R_1 \parallel R_2}{R_3 + R_1 \parallel R_2} \tag{2–23}$$

Likewise, when V_2 is grounded (Figure 2–13), V_1 forms a voltage divider with R_1 and the parallel combination of R_3 and R_2, and the voltage divider theorem is applied again to calculate V_{OUT} (Equation 2–24).

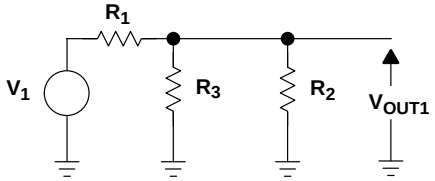

Figure 2–13. When V_2 is Grounded

$$V_{OUT1} = V_1 \frac{R_2 \parallel R_3}{R_1 + R_2 \parallel R_3} \tag{2–24}$$

After the calculations for each source are made the components are added to obtain the final solution (Equation 2–25).

$$V_{OUT} = V_1 \frac{R_2 \parallel R_3}{R_1 + R_2 \parallel R_3} + V_2 \frac{R_1 \parallel R_2}{R_3 + R_1 \parallel R_2} \tag{2–25}$$

The reader should analyze this circuit with loop or node equations to gain an appreciation for superposition. Again, the superposition results come out as a simple arrangement that is easy to understand. One looks at the final equation and it is obvious that if the sources are equal and opposite polarity, and when $R_1 = R_3$, then the output voltage is zero. Conclusions such as this are hard to make after the results of a loop or node analysis unless considerable effort is made to manipulate the final equation into symmetrical form.

2.7 Calculation of a Saturated Transistor Circuit

The circuit specifications are: when $V_{IN} = 12$ V, $V_{OUT} < 0.4$ V at $I_{SINK} < 10$ mA, and $V_{IN} < 0.05$ V, $V_{OUT} > 10$ V at $I_{OUT} = 1$ mA. The circuit diagram is shown in Figure 2–14.

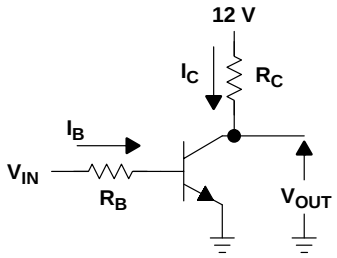

Figure 2–14. Saturated Transistor Circuit

The collector resistor must be sized (Equation 2–26) when the transistor is off, because it has to be small enough to allow the output current to flow through it without dropping more than two volts to meet the specification for a 10-V output.

$$R_C \leq \frac{V_{+12} - V_{OUT}}{I_{OUT}} = \frac{12 - 10}{1} = 2\ \text{k} \tag{2–26}$$

When the transistor is off, 1 mA can be drawn out of the collector resistor without pulling the collector or output voltage to less than ten volts (Equation 2–27). When the transistor is on, the base resistor must be sized (Equation 2–28) to enable the input signal to drive enough base current into the transistor to saturate it. The transistor beta is 50.

$$I_C = \beta I_B = \frac{V_{+12} - V_{CE}}{R_C} + I_L \approx \frac{V_{+12}}{R_C} + I_L \quad (2\text{–}27)$$

$$R_B \leq \frac{V_{IN} - V_{BE}}{I_B} \quad (2\text{–}28)$$

Substituting Equation 2–27 into Equation 2–28 yields Equation 2–29.

$$R_B \leq \frac{(V_{IN} - V_{BE})\beta}{I_C} = \frac{(12 - 0.6)50\ V}{\left[\frac{12}{2} + (10)\right] mA} = 35.6\ k \quad (2\text{–}29)$$

When the transistor goes on it sinks the load current, and it still goes into saturation. These calculations neglect some minor details, but they are in the 98% accuracy range.

2.8 Transistor Amplifier

The amplifier is an analog circuit (Figure 2–15), and the calculations, plus the points that must be considered during the design, are more complicated than for a saturated circuit. This extra complication leads people to say that analog design is harder than digital design (the saturated transistor is digital i.e.; on or off). Analog design is harder than digital design because the designer must account for all states in analog, whereas in digital only two states must be accounted for. The specifications for the amplifier are an ac voltage gain of four and a peak-to-peak signal swing of 4 volts.

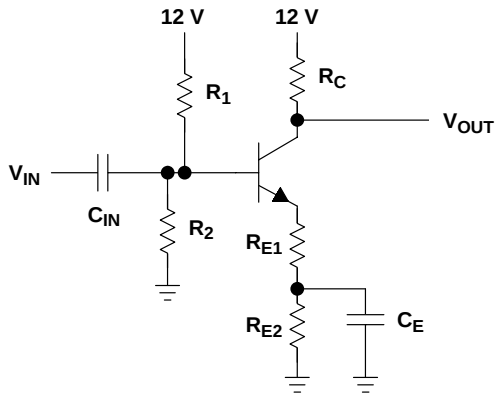

Figure 2–15. Transistor Amplifier

I_C is selected as 10 mA because the transistor has a current gain (β) of 100 at that point. The collector voltage is arbitrarily set at 8 V; when the collector voltage swings positive

2 V (from 8 V to 10 V) there is still enough voltage dropped across R_C to keep the transistor on. Set the collector-emitter voltage at 4 V; when the collector voltage swings negative 2 V (from 8 V to 6 V) the transistor still has 2 V across it, so it stays linear. This sets the emitter voltage (V_E) at 4 V.

$$R_C \leq \frac{V_{+12} - V_C}{I_C} = \frac{12\text{ V} - 8\text{ V}}{10\text{ mA}} = 400\ \Omega \tag{2–30}$$

$$R_E = R_{E1} + R_{E2} = \frac{V_E}{I_E} = \frac{V_E}{I_B + I_C} \cong \frac{V_E}{I_C} = \frac{4\text{ V}}{10\text{ mA}} = 400\ \Omega \tag{2–31}$$

Use Thevenin's equivalent circuit to calculate R_1 and R_2 as shown in Figure 2–16.

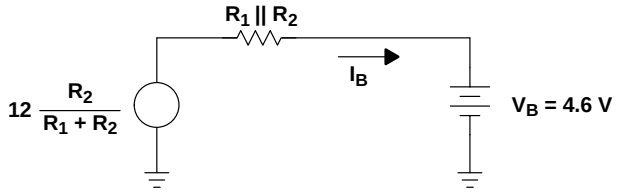

Figure 2–16. Thevenin Equivalent of the Base Circuit

$$I_B = \frac{I_C}{\beta} = \frac{10\text{ mA}}{100} = 0.1\text{ mA} \tag{2–32}$$

$$V_{TH} = \frac{12R_2}{R_1 + R_2} \tag{2–33}$$

$$R_{TH} = \frac{R_1 R_2}{R_1 + R_2} \tag{2–34}$$

We want the base voltage to be 4.6 V because the emitter voltage is then 4 V. Assume a voltage drop of 0.4 V across R_{TH}, so Equation 2–35 can be written. The drop across R_{TH} may not be exactly 0.4 V because of beta variations, but a few hundred mV does not matter is this design. Now, calculate the ratio of R_1 and R_2 using the voltage divider rule (the load current has been accounted for).

$$R_{TH} = \frac{0.4}{0.1}\text{k} = 4\text{ k} \tag{2–35}$$

$$V_{TH} = I_B R_{Th} + V_B = 0.4 + 4.6 = 5 = 12\frac{R_2}{R_1 + R_2} \tag{2–36}$$

$$R_2 = \frac{7}{5} R_1 \tag{2–37}$$

R_1 is almost equal to R_2, thus selecting R_1 as twice the Thevenin resistance yields approximately 4 K as shown in Equation 2–35. Hence, R_1 = 11.2 k and R_2 = 8 k. The ac gain is

approximately R_C/R_{E1} because C_E shorts out R_{E2} at high frequencies, so we can write Equation 2–38.

$$R_{E1} = \frac{R_C}{G} = \frac{400}{4} = 100\ \Omega \tag{2–38}$$

$$R_{E2} = R_E - R_{E1} = 400 - 100 = 300\ \Omega \tag{2–39}$$

The capacitor selection depends on the frequency response required for the amplifier, but 10 μF for C_{IN} and 1000 μF for C_E suffice for a starting point.

Chapter 3

Development of the Ideal Op Amp Equations

Ron Mancini

3.1 Ideal Op Amp Assumptions

The name *Ideal Op Amp* is applied to this and similar analysis because the salient parameters of the op amp are assumed to be perfect. There is no such thing as an ideal op amp, but present day op amps come so close to ideal that *Ideal Op Amp* analysis approaches actual analysis. Op amps depart from the ideal in two ways. First, dc parameters such as input offset voltage are large enough to cause departure from the ideal. The ideal assumes that input offset voltage is zero. Second, ac parameters such as gain are a function of frequency, so they go from large values at dc to small values at high frequencies.

This assumption simplifies the analysis, thus it clears the path for insight. It is so much easier to see the forest when the brush and huge trees are cleared away. Although the ideal op amp analysis makes use of perfect parameters, the analysis is often valid because some op amps approach perfection. In addition, when working at low frequencies, several kHz, the ideal op amp analysis produces accurate answers. Voltage feedback op amps are covered in this chapter, and current feedback op amps are covered in Chapter 8.

Several assumptions have to be made before the ideal op amp analysis can proceed. First, assume that the current flow into the input leads of the op amp is zero. This assumption is almost true in FET op amps where input currents can be less than a pA, but this is not always true in bipolar high-speed op amps where tens of μA input currents are found.

Second, the op amp gain is assumed to be infinite, hence it drives the output voltage to any value to satisfy the input conditions. This assumes that the op amp output voltage can achieve any value. In reality, saturation occurs when the output voltage comes close to a power supply rail, but reality does not negate the assumption, it only bounds it.

Also, implicit in the infinite gain assumption is the need for zero input signal. The gain drives the output voltage until the voltage between the input leads (the error voltage) is zero. This leads to the third assumption that the voltage between the input leads is zero. The implication of zero voltage between the input leads means that if one input is tied to

a hard voltage source such as ground, then the other input is at the same potential. The current flow into the input leads is zero, so the input impedance of the op amp is infinite.

Fourth, the output impedance of the ideal op amp is zero. The ideal op amp can drive any load without an output impedance dropping voltage across it. The output impedance of most op amps is a fraction of an ohm for low current flows, so this assumption is valid in most cases. Fifth, the frequency response of the ideal op amp is flat; this means that the gain does not vary as frequency increases. By constraining the use of the op amp to the low frequencies, we make the frequency response assumption true.

Table 3–1 lists the basic ideal op amp assumptions and FIgure 3–1shows the ideal op amp.

Table 3–1. Basic Ideal Op Amp Assumptions

Input current	I_{IN}	0
Input offset voltage	V_{OS}	0
Input impedance	Z_{IN}	∞
Output impedance	Z_{OUT}	0
Gain	a	∞

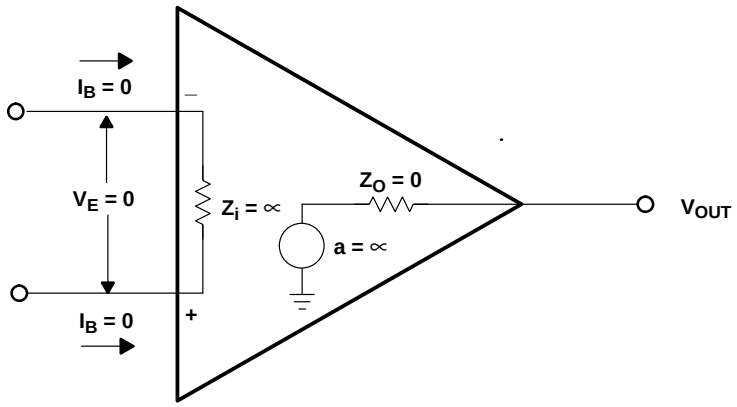

Figure 3–1. The Ideal Op Amp

3.2 The Noninverting Op Amp

The noninverting op amp has the input signal connected to its noninverting input (Figure 3–2), thus its input source sees an infinite impedance. There is no input offset voltage because $V_{OS} = V_E = 0$, hence the negative input must be at the same voltage as the positive input. The op amp output drives current into R_F until the negative input is at the voltage, V_{IN}. This action causes V_{IN} to appear across R_G.

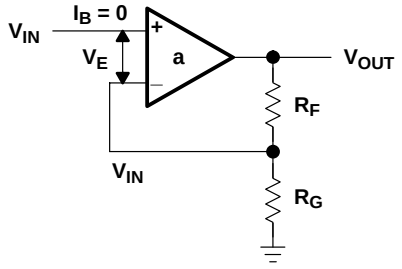

Figure 3–2. The Noninverting Op Amp

The voltage divider rule is used to calculate V_{IN}; V_{OUT} is the input to the voltage divider, and V_{IN} is the output of the voltage divider. Since no current can flow into either op amp lead, use of the voltage divider rule is allowed. Equation 3–1 is written with the aid of the voltage divider rule, and algebraic manipulation yields Equation 3–2 in the form of a gain parameter.

$$V_{IN} = V_{OUT} \frac{R_G}{R_G + R_F} \tag{3–1}$$

$$\frac{V_{OUT}}{V_{IN}} = \frac{R_G + R_F}{R_G} = 1 + \frac{R_F}{R_G} \tag{3–2}$$

When R_G becomes very large with respect to R_F, $(R_F/R_G) \Rightarrow 0$ and Equation 3–2 reduces to Equation 3–3.

$$V_{OUT} = 1 \tag{3–3}$$

Under these conditions $V_{OUT} = 1$ and the circuit becomes a unity gain buffer. R_G is usually deleted to achieve the same results, and when R_G is deleted, R_F can also be deleted (RF must be shorted when it is deleted). When R_F and R_G are deleted, the op amp output is connected to its inverting input with a wire. Some op amps are self-destructive when R_F is left out of the circuit, so R_F is used in many buffer designs. When R_F is included in a buffer circuit, its function is to protect the inverting input from an over voltage to limit the current through the input ESD (electro-static discharge) structure (typically < 1 mA), and it can have almost any value (20 k is often used). R_F can never be left out of the circuit

in a current feedback amplifier design because R_F determines stability in current feedback amplifiers.

Notice that the gain is only a function of the feedback and gain resistors; therefore the feedback has accomplished its function of making the gain independent of the op amp parameters. The gain is adjusted by varying the ratio of the resistors. The actual resistor values are determined by the impedance levels that the designer wants to establish. If R_F = 10 k and R_G = 10 k the gain is two as shown in Equation 2, and if R_F = 100 k and R_G = 100 k the gain is still two. The impedance levels of 10 k or 100 k determine the current drain, the effect of stray capacitance, and a few other points. The impedance level does not set the gain; the ratio of R_F/R_G does.

3.3 The Inverting Op Amp

The noninverting input of the inverting op amp circuit is grounded. One assumption made is that the input error voltage is zero, so the feedback keeps inverting the input of the op amp at a virtual ground (not actual ground but acting like ground). The current flow in the input leads is assumed to be zero, hence the current flowing through R_G equals the current flowing through R_F. Using Kirchoff's law, we write Equation 3–4; and the minus sign is inserted because this is the inverting input. Algebraic manipulation gives Equation 3–5.

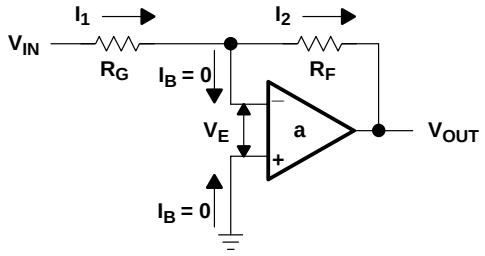

Figure 3–3. The Inverting Op Amp

$$I_1 = \frac{V_{IN}}{R_G} = -I_2 = -\frac{V_{OUT}}{R_F} \tag{3–4}$$

$$\frac{V_{OUT}}{V_{IN}} = -\frac{R_F}{R_G} \tag{3–5}$$

Notice that the gain is only a function of the feedback and gain resistors, so the feedback has accomplished its function of making the gain independent of the op amp parameters. The actual resistor values are determined by the impedance levels that the designer wants to establish. If R_F = 10 k and R_G = 10 k the gain is minus one as shown in Equation

3–5, and if R_F = 100 k and R_G = 100 k the gain is still minus one. The impedance levels of 10 k or 100 k determine the current drain, the effect of stray capacitance, and a few other points. The impedance level does not set the gain; the ratio of R_F/R_G does.

One final note; the output signal is the input signal amplified and inverted. The circuit input impedance is set by R_G because the inverting input is held at a virtual ground.

3.4 The Adder

An adder circuit can be made by connecting more inputs to the inverting op amp (Figure 3–4). The opposite end of the resistor connected to the inverting input is held at virtual ground by the feedback; therefore, adding new inputs does not affect the response of the existing inputs.

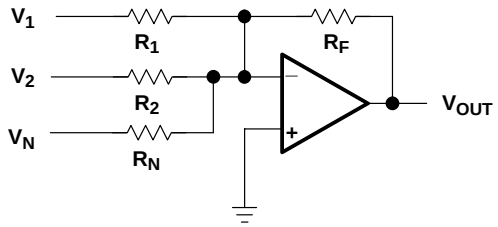

Figure 3–4. The Adder Circuit

Superposition is used to calculate the output voltages resulting from each input, and the output voltages are added algebraically to obtain the total output voltage. Equation 3–6 is the output equation when V_1 and V_2 are grounded. Equations 3–7 and 3–8 are the other superposition equations, and the final result is given in Equation 3–9.

$$V_{OUTN} = -\frac{R_F}{R_N} V_N \tag{3–6}$$

$$V_{OUT1} = -\frac{R_F}{R_1} V_1 \tag{3–7}$$

$$V_{OUT2} = -\frac{R_F}{R_2} V_2 \tag{3–8}$$

$$V_{OUT} = -\left(\frac{R_F}{R_1} V_1 + \frac{R_F}{R_2} V_2 + \frac{R_F}{R_N} V_N\right) \tag{3–9}$$

3.5 The Differential Amplifier

The differential amplifier circuit amplifies the difference between signals applied to the inputs (Figure 3–5). Superposition is used to calculate the output voltage resulting from each input voltage, and then the two output voltages are added to arrive at the final output voltage.

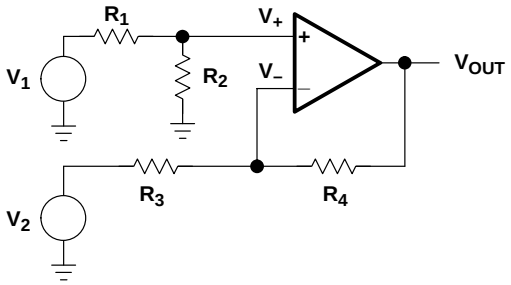

Figure 3–5. The Differential Amplifier

The op amp input voltage resulting from the input source, V_1, is calculated in Equations 3–10 and 3–11. The voltage divider rule is used to calculate the voltage, V_+, and the noninverting gain equation (Equation 3–2) is used to calculate the noninverting output voltage, V_{OUT1}.

$$V_+ = V_1 \frac{R_2}{R_1 + R_2} \tag{3–10}$$

$$V_{OUT1} = V_+(G_+) = V_1 \frac{R_2}{R_1 + R_2}\left(\frac{R_3 + R_4}{R_3}\right) \tag{3–11}$$

The inverting gain equation (Equation 3–5) is used to calculate the stage gain for V_{OUT2} in Equation 3–12. These inverting and noninverting gains are added in Equation 3–13.

$$V_{OUT2} = V_2\left(-\frac{R_4}{R_3}\right) \tag{3–12}$$

$$V_{OUT} = V_1 \frac{R_2}{R_1 + R_2}\left(\frac{R_3 + R_4}{R_3}\right) - V_2 \frac{R_4}{R_3} \tag{3–13}$$

When $R_2 = R_4$ and $R_1 = R_3$, Equation 3–13 reduces to Equation 3–14.

$$V_{OUT} = (V_1 - V_2)\frac{R_4}{R_3} \tag{3–14}$$

It is now obvious that the differential signal, $(V_1–V_2)$, is multiplied by the stage gain, so the name differential amplifier suits the circuit. Because it only amplifies the differential

portion of the input signal, it rejects the common-mode portion of the input signal. A common-mode signal is illustrated in Figure 3–6. Because the differential amplifier strips off or rejects the common-mode signal, this circuit configuration is often employed to strip dc or injected common-mode noise off a signal.

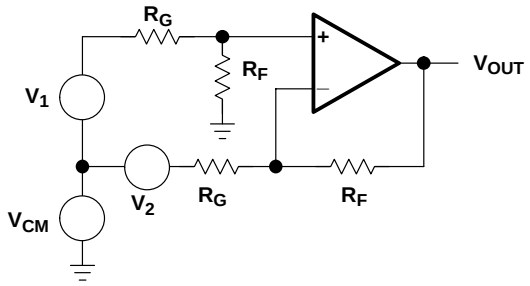

Figure 3–6. Differential Amplifier With Common-Mode Input Signal

The disadvantage of this circuit is that the two input impedances cannot be matched when it functions as a differential amplifier, thus there are two and three op amp versions of this circuit specially designed for high performance applications requiring matched input impedances.

3.6 Complex Feedback Networks

When complex networks are put into the feedback loop, the circuits get harder to analyze because the simple gain equations cannot be used. The usual technique is to write and solve node or loop equations. There is only one input voltage, so superposition is not of any use, but Thevenin's theorem can be used as is shown in the example problem given below.

Sometimes it is desirable to have a low resistance path to ground in the feedback loop. Standard inverting op amps can not do this when the driving circuit sets the input resistor value, and the gain specification sets the feedback resistor value. Inserting a *T* network in the feedback loop (FIgure 3–7) yields a degree of freedom that enables both specifications to be met with a low dc resistance path in the feedback loop.

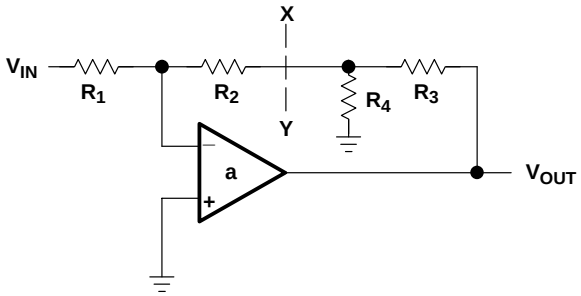

Figure 3–7. T Network in Feedback Loop

Break the circuit at point X–Y, stand on the terminals looking into R_4, and calculate the Thevenin equivalent voltage as shown in Equation 3–15. The Thevenin equivalent impedance is calculated in Equation 3–16.

$$V_{TH} = V_{OUT} \frac{R_4}{R_3 + R_4} \tag{3–15}$$

$$R_{TH} = R_3 \parallel R_4 \tag{3–16}$$

Replace the output circuit with the Thevenin equivalent circuit as shown in Figure 5–8, and calculate the gain with the aid of the inverting gain equation as shown in Equation 3–17.

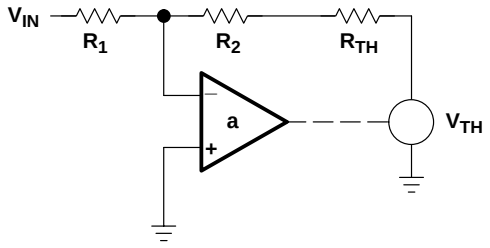

Figure 3–8. Thevenin's Theorem Applied to T Network

Substituting the Thevenin equivalents into Equation 3–17 yields Equation 3–18.

$$-\frac{V_{TH}}{V_{IN}} = \frac{R_2 + R_{TH}}{R_1} \tag{3–17}$$

$$-\frac{V_{OUT}}{V_{IN}} = \frac{R_2 + R_{TH}}{R_1}\left(\frac{R_3 + R_4}{R_4}\right) = \frac{R_2 + \left(R_3 \parallel R_4\right)}{R_1}\left(\frac{R_3 + R_4}{R_4}\right) \tag{3–18}$$

Algebraic manipulation yields Equation 3–19.

$$-\frac{V_{OUT}}{V_{IN}} = \frac{R_2 + R_3 + \frac{R_2 R_3}{R_4}}{R_1} \tag{3–19}$$

Specifications for the circuit you are required to build are an inverting amplifier with an input resistance of 10 k (R_G = 10 k), a gain of 100, and a feedback resistance of 20 K or less. The inverting op amp circuit can not meet these specifications because R_F must equal 1000 k. Inserting a *T* network with $R_2 = R_4$ = 10 k and R_3 = 485 k approximately meets the specifications.

3.7 Video Amplifiers

Video signals contain high frequencies, and they use coaxial cable to transmit and receive signals. The cable connecting these circuits has a characteristic impedance of 75 Ω. To prevent reflections, which cause distortion and ghosting, the input and output circuit impedances must match the 75 Ω cable.

Matching the input impedance is simple for a noninverting amplifier because its input impedance is very high; just make R_{IN} = 75 Ω. R_F and R_G can be selected as high values, in the hundreds of Ohms range, so that they have minimal affect on the impedance of the input or output circuit. A matching resistor, R_M, is placed in series with the op amp output to raise its output impedance to 75 Ω; a terminating resistor, R_T, is placed at the input of the next stage to match the cable (Figure 3–9).

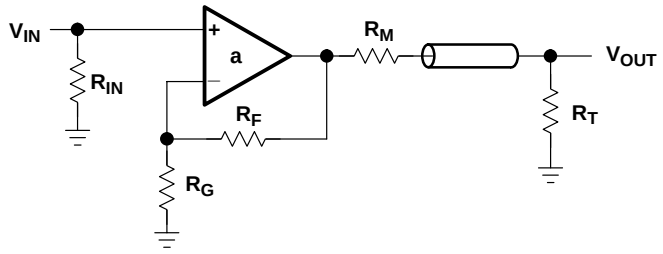

Figure 3–9. Video Amplifier

The matching and terminating resistors are equal in value, and they form a voltage divider of 1/2 because R_T is not loaded. Very often R_F is selected equal to R_G so that the op amp gain equals two. Then the system gain, which is the op amp gain multiplied by the divider gain, is equal to one ($2 \times 1/2 = 1$).

3.8 Capacitors

Capacitors are a key component in a circuit designer's tool kit, thus a short discussion on evaluating their affect on circuit performance is in order. Capacitors have an impedance of $X_C = 1/2\pi fC$. Note that when the frequency is zero the capacitive impedance (also known as reactance) is infinite, and that when the frequency is infinite the capacitive impedance is zero. These end-points are derived from the final value theorem, and they are used to get a rough idea of the effect of a capacitor. When a capacitor is used with a resistor, they form what is called a break-point. Without going into complicated math, just accept that the break frequency occurs at $f = 1/(2\pi RC)$ and the gain is –3 dB at the break frequency.

The low pass filter circuit shown in Figure 3–10 has a capacitor in parallel with the feedback resistor. The gain for the low pass filter is given in Equation 3–20.

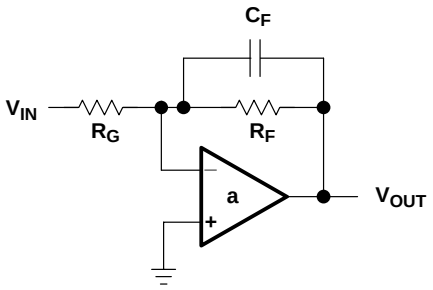

Figure 3–10. Low-Pass Filter

$$\frac{V_{OUT}}{V_{IN}} = -\frac{X_C \parallel R_F}{R_G} \tag{3–20}$$

At very low frequencies $X_C \Rightarrow \infty$, so R_F dominates the parallel combination in Equation 20, and the capacitor has no effect. The gain at low frequencies is $-R_F/R_G$. At very high frequencies $X_C \Rightarrow 0$, so the feedback resistor is shorted out, thus reducing the circuit gain to zero. At the frequency where $X_C = R_F$ the gain is reduced by $\sqrt{2}$ because complex impedances in parallel equal half the vector sum of both impedances.

Connecting the capacitor in parallel with R_G where it has the opposite effect makes a high pass filter (Figure 3–11). Equation 3–21 gives the equation for the high pass filter.

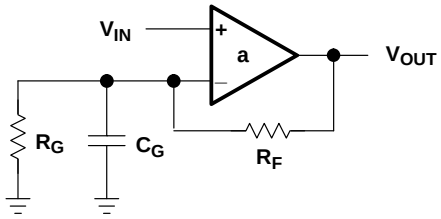

Figure 3–11. High-Pass Filter

$$\frac{V_{OUT}}{V_{IN}} = 1 + \frac{R_F}{X_C \parallel R_G} \tag{3–21}$$

At very low frequencies $X_C \Rightarrow \infty$, so R_G dominates the parallel combination in Equation 3–21, and the capacitor has no effect. The gain at low frequencies is $1+R_F/R_G$. At very high frequencies $X_C \Rightarrow 0$, so the gain setting resistor is shorted out thus increasing the circuit gain to maximum.

This simple technique is used to predict the form of a circuit transfer function rapidly. Better analysis techniques are presented in later chapters for those applications requiring more precision.

3.9 Summary

When the proper assumptions are made, the analysis of op amp circuits is straightforward. These assumptions, which include zero input current, zero input offset voltage, and infinite gain, are realistic assumptions because the new op amps make them true in most applications.

When the signal is comprised of low frequencies, the gain assumption is valid because op amps have very high gain at low frequencies. When CMOS op amps are used, the input current is in the femto amp range; close enough to zero for most applications. Laser trimmed input circuits reduce the input offset voltage to a few micro volts; close enough to zero for most applications. The ideal op amp is becoming real; especially for undemanding applications.

Chapter 4

Single-Supply Op Amp Design Techniques

Ron Mancini

4.1 Single Supply versus Dual Supply

The previous chapter assumed that all op amps were powered from dual or split supplies, and this is not the case in today's world of portable, battery-powered equipment. When op amps are powered from dual supplies (see Figure 4–1), the supplies are normally equal in magnitude, opposing in polarity, and the center tap of the supplies is connected to ground. Any input sources connected to ground are automatically referenced to the center of the supply voltage, so the output voltage is automatically referenced to ground.

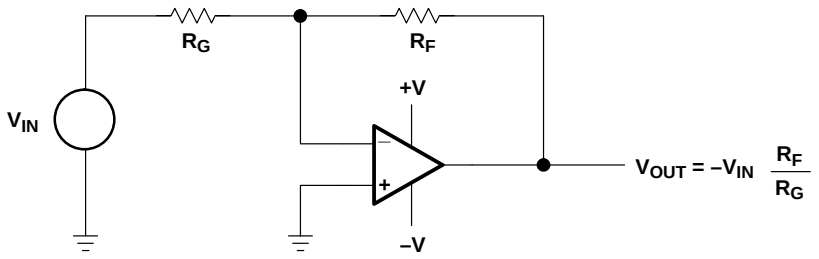

Figure 4–1. Split-Supply Op Amp Circuit

Single-supply systems do not have the convenient ground reference that dual-supply systems have, thus biasing must be employed to ensure that the output voltage swings between the correct voltages. Input sources connected to ground are actually connected to a supply rail in single-supply systems. This is analogous to connecting a dual-supply input to the minus power rail. This requirement for biasing the op amp inputs to achieve the desired output voltage swing complicates single-supply designs.

When the signal source is not referenced to ground (see Figure 4–2), the voltage difference between ground and the reference voltage is amplified along with the signal. Unless the reference voltage was inserted as a bias voltage, and such is not the case when the input signal is connected to ground, the reference voltage must be stripped from the signal so that the op amp can provide maximum dynamic range.

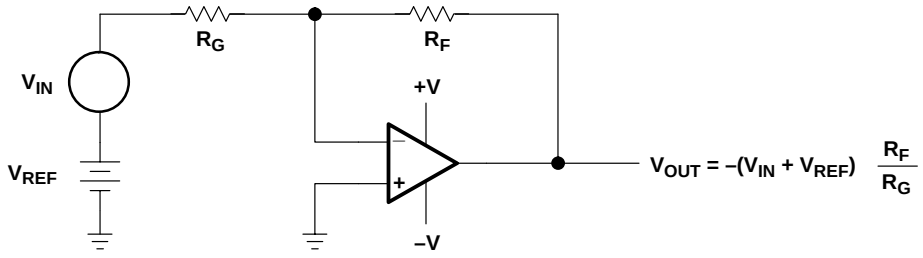

Figure 4–2. Split-Supply Op Amp Circuit With Reference Voltage Input

An input bias voltage is used to eliminate the reference voltage when it must not appear in the output voltage (see Figure 4–3). The voltage, V_{REF}, is in both input circuits, hence it is named a common-mode voltage. Voltage feedback op amps reject common-mode voltages because their input circuit is constructed with a differential amplifier (chosen because it has natural common-mode voltage rejection capabilities).

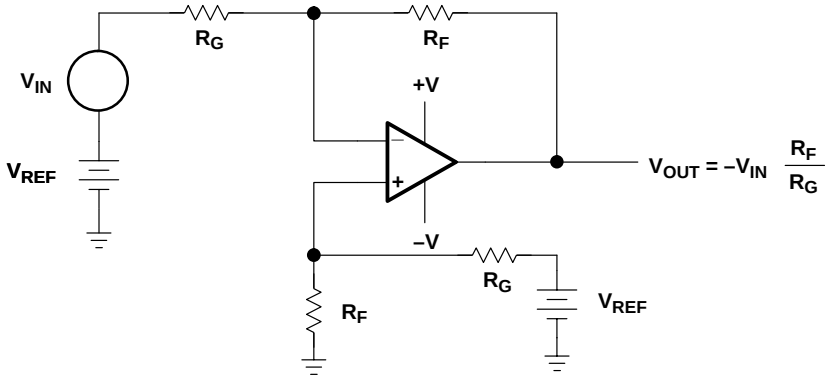

Figure 4–3. Split-Supply Op Amp Circuit With Common-Mode Voltage

When signal sources are referenced to ground, single-supply op amp circuits exhibit a large input common-mode voltage. Figure 4–4 shows a single-supply op amp circuit that has its input voltage referenced to ground. The input voltage is not referenced to the midpoint of the supplies like it would be in a split-supply application, rather it is referenced to the lower power supply rail. This circuit does not operate when the input voltage is positive because the output voltage would have to go to a negative voltage, hard to do with a positive supply. It operates marginally with small negative input voltages because most op amps do not function well when the inputs are connected to the supply rails.

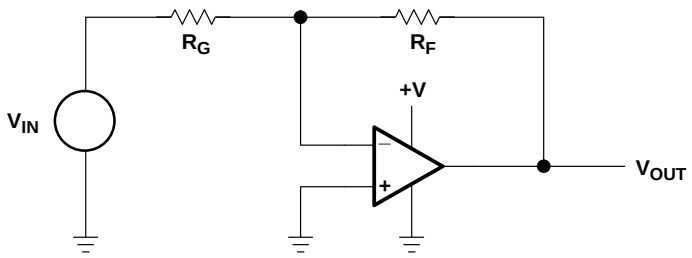

Figure 4–4. Single-Supply Op Amp Circuit

The constant requirement to account for inputs connected to ground or different reference voltages makes it difficult to design single-supply op amp circuits. Unless otherwise specified, all op amp circuits discussed in this chapter are single-supply circuits. The single-supply may be wired with the negative or positive lead connected to ground, but as long as the supply polarity is correct, the wiring does not affect circuit operation.

Use of a single-supply limits the polarity of the output voltage. When the supply voltage V_{CC} = 10 V, the output voltage is limited to the range $0 \leq V_{out} \leq 10$. This limitation precludes negative output voltages when the circuit has a positive supply voltage, but it does not preclude negative input voltages when the circuit has a positive supply voltage. As long as the voltage on the op amp input leads does not become negative, the circuit can handle negative input voltages.

Beware of working with negative (positive) input voltages when the op amp is powered from a positive (negative) supply because op amp inputs are highly susceptible to reverse voltage breakdown. Also, insure that all possible start-up conditions do not reverse bias the op amp inputs when the input and supply voltage are opposite polarity.

4.2 Circuit Analysis

The complexities of single-supply op amp design are illustrated with the following example. Notice that the biasing requirement complicates the analysis by presenting several conditions that are not realizable. It is best to wade through this material to gain an understanding of the problem, especially since a cookbook solution is given later in this chapter. The previous chapter assumed that the op amps were ideal, and this chapter starts to deal with op amp deficiencies. The input and output voltage swing of many op amps are limited as shown in Figure 4–7, but if one designs with the selected rail-to-rail op amps, the input/output swing problems are minimized. The inverting circuit shown in Figure 4–5 is analyzed first.

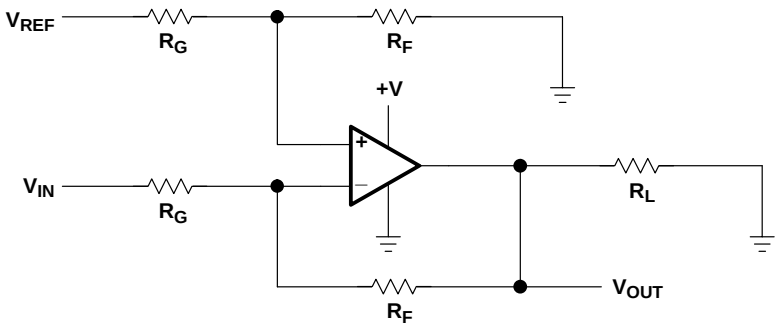

Figure 4–5. Inverting Op Amp

Equation 4–1 is written with the aid of superposition, and simplified algebraically, to acquire Equation 4–2.

$$V_{OUT} = V_{REF}\left(\frac{R_F}{R_G + R_F}\right)\left(\frac{R_F + R_G}{R_G}\right) - V_{IN}\frac{R_F}{R_G} \tag{4–1}$$

$$V_{OUT} = \left(V_{REF} - V_{IN}\right)\frac{R_F}{R_G} \tag{4–2}$$

As long as the load resistor, R_L, is a large value, it does not enter into the circuit calculations, but it can introduce some second order effects such as limiting the output voltage swings. Equation 4–3 is obtained by setting V_{REF} equal to V_{IN}, and there is no output voltage from the circuit regardless of the input voltage. The author unintentionally designed a few of these circuits before he created an orderly method of op amp circuit design. Actually, a real circuit has a small output voltage equal to the lower transistor saturation voltage, which is about 150 mV for a TLC07X.

$$V_{OUT} = \left(V_{REF} - V_{IN}\right)\frac{R_F}{R_G} = \left(V_{IN} - V_{IN}\right)\frac{R_F}{R_G} = 0 \tag{4–3}$$

When $V_{REF} = 0$, $V_{OUT} = -V_{IN}(R_F/R_G)$, there are two possible solutions to Equation 4–2. First, when V_{IN} is any positive voltage, V_{OUT} should be negative voltage. The circuit can not achieve a negative voltage with a positive supply, so the output saturates at the lower power supply rail. Second, when V_{IN} is any negative voltage, the output spans the normal range according to Equation 4–5.

$$V_{IN} \geq 0, \qquad V_{OUT} = 0 \tag{4–4}$$

$$V_{IN} \leq 0, \qquad V_{OUT} = \left|V_{IN}\right| \frac{R_F}{R_G} \tag{4–5}$$

When V_{REF} equals the supply voltage, V_{CC}, we obtain Equation 4–6. In Equation 4–6, when V_{IN} is negative, V_{OUT} should exceed V_{CC}; that is impossible, so the output saturates. When V_{IN} is positive, the circuit acts as an inverting amplifier.

$$V_{OUT} = \left(V_{CC} - V_{IN}\right)\frac{R_F}{R_G} \quad (4–6)$$

The transfer curve for the circuit shown in Figure 4–6 (V_{CC} = 5 V, $R_G = R_F$ = 100 kΩ, R_L = 10 kΩ) is shown in Figure 4–7.

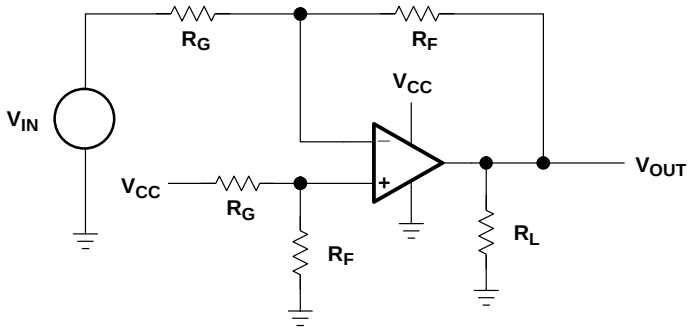

Figure 4–6. Inverting Op Amp With V_{CC} Bias

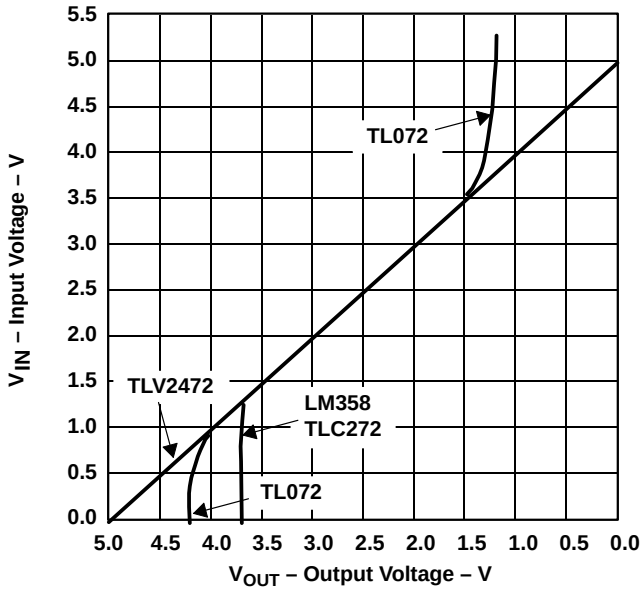

Figure 4–7. Transfer Curve for Inverting Op Amp With V_{CC} Bias

Four op amps were tested in the circuit configuration shown in Figure 4–6. Three of the old generation op amps, LM358, TL07X, and TLC272 had output voltage spans of 2.3 V to 3.75 V. This performance does not justify the ideal op amp assumption that was made in the previous chapter unless the output voltage swing is severely limited. Limited output or input voltage swing is one of the worst deficiencies a single-supply op amp can have because the limited voltage swing limits the circuit's dynamic range. Also, limited voltage swing frequently results in distortion of large signals. The fourth op amp tested was the newer TLV247X, which was designed for rail-to-rail operation in single-supply circuits. The TLV247X plotted a perfect curve (results limited by the instrumentation), and it amazed the author with a textbook performance that justifies the use of ideal assumptions. Some of the older op amps must limit their transfer equation as shown in Equation 4–7.

$$V_{OUT} = \left(V_{CC} - V_{IN}\right)\frac{R_F}{R_G} \quad \text{for} \quad V_{OH} \geq V_{OUT} \geq V_{OL} \tag{4–7}$$

The noninverting op amp circuit is shown in Figure 4–8. Equation 4–8 is written with the aid of superposition, and simplified algebraically, to acquire Equation 4–9.

$$V_{OUT} = V_{IN}\left(\frac{R_F}{R_G + R_F}\right)\left(\frac{R_F + R_G}{R_G}\right) - V_{REF}\,\frac{R_F}{R_G} \tag{4–8}$$

$$V_{OUT} = \left(V_{IN} - V_{REF}\right)\frac{R_F}{R_G} \tag{4–9}$$

When $V_{REF} = 0$, $V_{OUT} = V_{IN}\,\frac{R_F}{R_G}$, there are two possible circuit solutions. First, when V_{IN} is a negative voltage, V_{OUT} must be a negative voltage. The circuit can not achieve a negative output voltage with a positive supply, so the output saturates at the lower power supply rail. Second, when V_{IN} is a positive voltage, the output spans the normal range as shown by Equation 4–11.

$$V_{IN} \leq 0, \qquad V_{OUT} = 0 \tag{4–10}$$

$$V_{IN} \geq 0, \qquad V_{OUT} = V_{IN} \tag{4–11}$$

The noninverting op amp circuit is shown in Figure 4–8 with $V_{CC} = 5$ V, $R_G = R_F = 100$ kΩ, and $R_L = 10$ kΩ. The transfer curve for this circuit is shown in Figure 4–9; a TLV247X serves as the op amp.

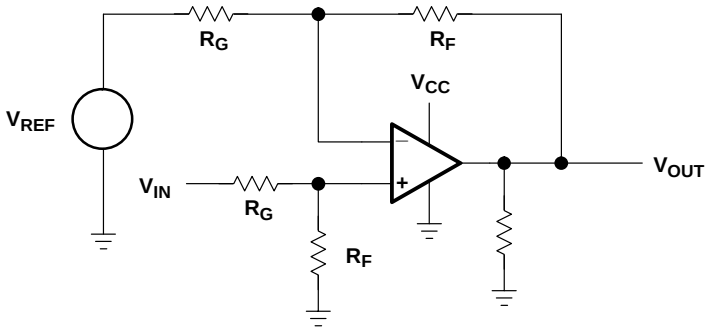

Figure 4–8. Noninverting Op Amp

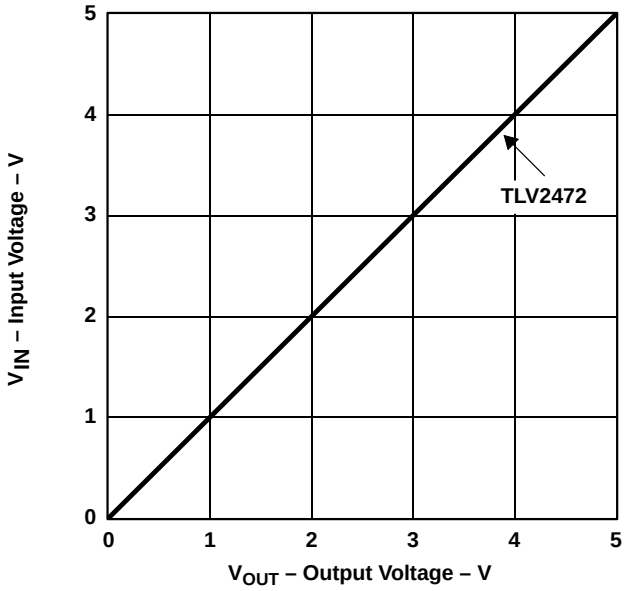

Figure 4–9. Transfer Curve for Noninverting Op Amp

There are many possible variations of inverting and noninverting circuits. At this point many designers analyze these variations hoping to stumble upon the one that solves the circuit problem. Rather than analyze each circuit, it is better to learn how to employ simultaneous equations to render specified data into equation form. When the form of the desired equation is known, a circuit that fits the equation is chosen to solve the problem. The resulting equation must be a straight line, thus there are only four possible solutions.

4.3 Simultaneous Equations

Taking an orderly path to developing a circuit that works the first time starts here; follow these steps until the equation of the op amp is determined. Use the specifications given for the circuit coupled with simultaneous equations to determine what form the op amp equation must have. Go to the section that illustrates that equation form (called a case), solve the equation to determine the resistor values, and you have a working solution.

A linear op amp transfer function is limited to the equation of a straight line (Equation 4–12).

$$y = \pm\ mx \pm b \tag{4–12}$$

The equation of a straight line has four possible solutions depending upon the sign of m, the slope, and b, the intercept; thus simultaneous equations yield solutions in four forms. Four circuits must be developed; one for each form of the equation of a straight line. The four equations, cases, or forms of a straight line are given in Equations 4–13 through 4–16, where electronic terminology has been substituted for math terminology.

$$V_{OUT} = +\ mV_{IN} + b \tag{4–13}$$

$$V_{OUT} = +\ mV_{IN} - b \tag{4–14}$$

$$V_{OUT} = -\ mV_{IN} + b \tag{4–15}$$

$$V_{OUT} = -\ mV_{IN} - b \tag{4–16}$$

Given a set of two data points for V_{OUT} and V_{IN}, simultaneous equations are solved to determine m and b for the equation that satisfies the given data. The sign of m and b determines the type of circuit required to implement the solution. The given data is derived from the specifications; i. e., a sensor output signal ranging from 0.1 V to 0.2 V must be interfaced into an analog-to-digital converter that has an input voltage range of 1 V to 4 V. These data points (V_{OUT} = 1 V @ V_{IN} = 0.1 V, V_{OUT} = 4 V @ V_{IN} = 0.2 V) are inserted into Equation 4–13, as shown in Equations 4–17 and 4–18, to obtain m and b for the specifications.

$$1 = m(0.1) + b \tag{4–17}$$

$$4 = m(0.2) + b \tag{4–18}$$

Multiply Equation 4–17 by 2 and subtract it from Equation 4–18.

$$2 = m(0.2) + 2b \tag{4–19}$$

$$b = -2 \tag{4–20}$$

After algebraic manipulation of Equation 4–17, substitute Equation 4–20 into Equation 4–17 to obtain Equation 4–21.

$$m = \frac{2 + 1}{0.1} = 30 \tag{4–21}$$

Now m and b are substituted back into Equation 4–13 yielding Equation 4–22.

$$V_{OUT} = 30V_{IN} - 2 \tag{4–22}$$

Notice, although Equation 4–13 was the starting point, the form of Equation 4–22 is identical to the format of Equation 4–14. The specifications or given data determine the sign of m and b, and starting with Equation 4–13, the final equation form is discovered after m and b are calculated. The next step required to complete the problem solution is to develop a circuit that has an m = 30 and b = –2. Circuits were developed for Equations 4–13 through 4–16, and they are given under the headings Case 1 through Case 4 respectively. There are different circuits that will yield the same equations, but these circuits were selected because they do not require negative references.

4.3.1 Case 1: $V_{OUT} = +mV_{IN}+b$

The circuit configuration that yields a solution for Case 1 is shown in Figure 4–10. The figure includes two 0.01-µF capacitors. These capacitors are called decoupling capacitors, and they are included to reduce noise and provide increased noise immunity. Sometimes two 0.01-µF capacitors serve this purpose, sometimes more extensive filtering is needed, and sometimes one capacitor serves this purpose. Special attention must be paid to the regulation and noise content of V_{CC} when V_{CC} is used as a reference because some portion of the noise content of V_{CC} will be multiplied by the circuit gain.

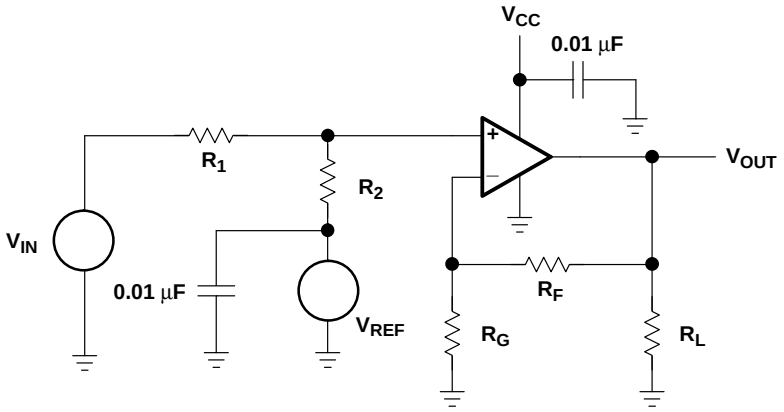

Figure 4–10. Schematic for Case1: $V_{OUT} = +mV_{IN} + b$

The circuit equation is written using the voltage divider rule and superposition.

$$V_{OUT} = V_{IN}\left(\frac{R_2}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) + V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \quad (4–23)$$

The equation of a straight line (case 1) is repeated in Equation 4–24 below so comparisons can be made between it and Equation 4–23.

$$V_{OUT} = mV_{IN} + b \quad (4–24)$$

Equating coefficients yields Equations 4–25 and 4–26.

$$m = \left(\frac{R_2}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \quad (4–25)$$

$$b = V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \quad (4–26)$$

Example; the circuit specifications are V_{OUT} = 1 V at V_{IN} = 0.01 V, V_{OUT} = 4.5 V at V_{IN} = 1 V, R_L = 10 k, five percent resistor tolerances, and V_{CC} = 5 V. No reference voltage is available, thus V_{CC} is used for the reference input, and V_{REF} = 5 V. A reference voltage source is left out of the design as a space and cost savings measure, and it sacrifices noise performance, accuracy, and stability performance. Cost is an important specification, but the V_{CC} supply must be specified well enough to do the job. Each step in the subsequent design procedure is included in this analysis to ease learning and increase boredom. Many steps are skipped when subsequent cases are analyzed.

The data is substituted into simultaneous equations.

$$1 = m(0.01) + b \quad (4–27)$$

$$4.5 = m(1.0) + b \quad (4–28)$$

Equation 4–27 is multiplied by 100 (Equation 4–29) and Equation 4–28 is subtracted from Equation 4–29 to obtain Equation 4–30.

$$100 = m(1.0) + 100b \quad (4–29)$$

$$b = \frac{95.5}{99} = 0.9646 \quad (4–30)$$

The slope of the transfer function, m, is obtained by substituting b into Equation 4–27.

$$m = \frac{1–b}{0.01} = \frac{1–0.9646}{0.01} = 3.535 \quad (4–31)$$

Now that b and m are calculated, the resistor values can be calculated. Equations 4–25 and 4–26 are solved for the quantity $(R_F + R_G)/R_G$, and then they are set equal in Equation 4–32 thus yielding Equation 4–33.

$$\frac{R_F + R_G}{R_G} = m\left(\frac{R_1 + R_2}{R_2}\right) = \frac{b}{V_{CC}}\left(\frac{R_1 + R_2}{R_1}\right) \quad (4–32)$$

$$R_2 = \frac{3.535}{\frac{0.9646}{5}} R_1 = 18.316 R_1 \quad (4–33)$$

Five percent tolerance resistors are specified for this design, so we choose R_1 = 10 kΩ, and that sets the value of R_2 = 183.16 kΩ. The closest 5% resistor value to 183.16 kΩ is 180 kΩ; therefore, select R_1 = 10 kΩ and R_2 = 180 kΩ. Being forced to yield to reality by choosing standard resistor values means that there is an error in the circuit transfer function because m and b are not exactly the same as calculated. The real world constantly forces compromises into circuit design, but the good circuit designer accepts the challenge and throws money or brains at the challenge. Resistor values closer to the calculated values could be selected by using 1% or 0.5% resistors, but that selection increases cost and violates the design specification. The cost increase is hard to justify except in precision circuits. Using ten-cent resistors with a ten-cent op amp usually is false economy.

The left half of Equation 4–32 is used to calculate R_F and R_G.

$$\frac{R_F + R_G}{R_G} = m\left(\frac{R_1 + R_2}{R_2}\right) = 3.535\left(\frac{180 + 10}{180}\right) = 3.73 \quad (4–34)$$

$$R_F = 2.73 R_G \quad (4–35)$$

The resulting circuit equation is given below.

$$V_{OUT} = 3.5 V_{IN} + 0.97 \quad (4–36)$$

The gain setting resistor, R_G, is selected as 10 kΩ, and 27 kΩ, the closest 5% standard value is selected for the feedback resistor, R_F. Again, there is a slight error involved with standard resistor values. This circuit must have an output voltage swing from 1 V to 4.5 V. The older op amps can not be used in this circuit because they lack dynamic range, so the TLV247X family of op amps is selected. The data shown in Figure 4–7 confirms the op amp selection because there is little error. The circuit with the selected component values is shown in Figure 4–11. The circuit was built with the specified components, and the transfer curve is shown in Figure 4–12.

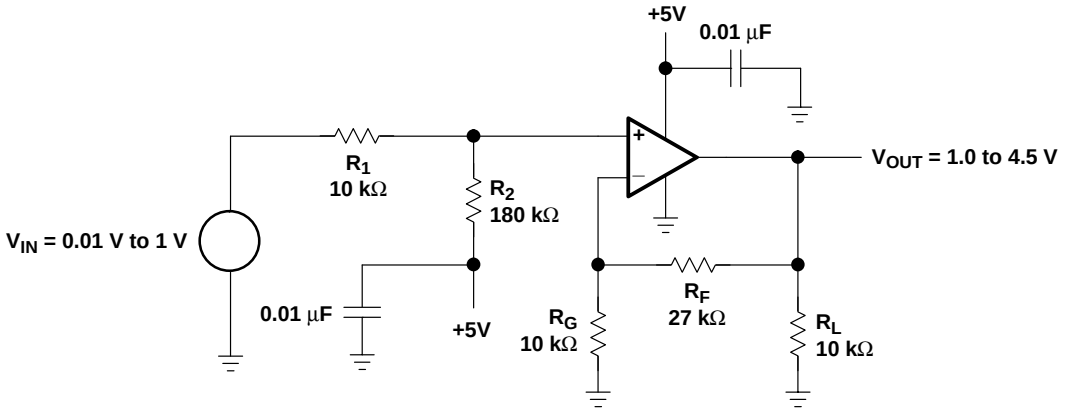

Figure 4–11. Case 1 Example Circuit

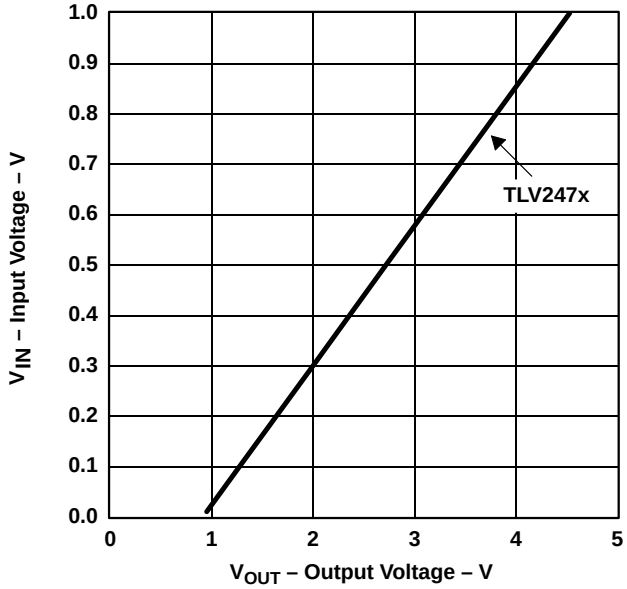

Figure 4–12. Case 1 Example Circuit Measured Transfer Curve

The transfer curve shown is a straight line, and that means that the circuit is linear. The V_{OUT} intercept is about 0.98 V rather than 1 V as specified, and this is excellent performance considering that the components were selected randomly from bins of resistors. Different sets of components would have slightly different slopes because of the resistor tolerances. The TLV247X has input bias currents and input offset voltages, but the effect of these errors is hard to measure on the scale of the output voltage. The output voltage

measured 4.53 V when the input voltage was 1 V. Considering the low and high input voltage errors, it is safe to conclude that the resistor tolerances have skewed the gain slightly, but this is still excellent performance for 5% components. Often lab data similar to that shown here is more accurate than the 5% resistor tolerance, but do not fall into the trap of expecting this performance, because you will be disappointed if you do.

The resistors were selected in the k-Ω range arbitrarily. The gain and offset specifications determine the resistor ratios, but supply current, frequency response, and op amp drive capability determine their absolute values. The resistor value selection in this design is high because modern op amps do not have input current offset problems, and they yield reasonable frequency response. If higher frequency response is demanded, the resistor values must decrease, and resistor value decreases reduce input current errors, while supply current increases. When the resistor values get low enough, it becomes hard for another circuit, or possibly the op amp, to drive the resistors.

4.3.2 Case 2: $V_{OUT} = +mV_{IN} - b$

The circuit shown in Figure 4–13 yields a solution for Case 2. The circuit equation is obtained by taking the Thevenin equivalent circuit looking into the junction of R_1 and R_2. After the R_1, R_2 circuit is replaced with the Thevenin equivalent circuit, the gain is calculated with the ideal gain equation (Equation 4–37).

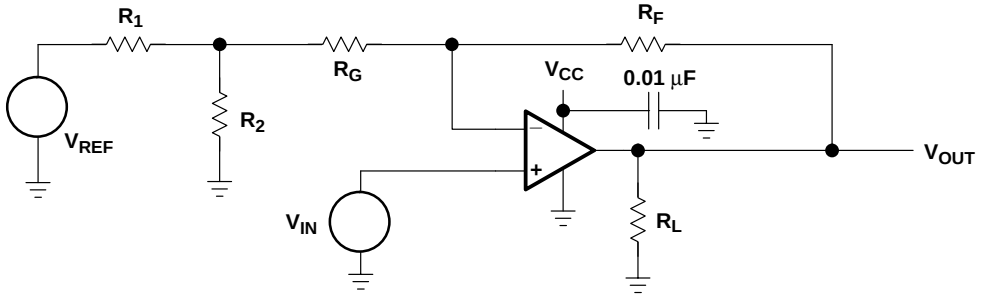

Figure 4–13. Schematic for Case 2: $V_{OUT} = +mV_{IN} - b$

$$V_{OUT} = V_{IN}\left(\frac{R_F + R_G + R_1 \parallel R_2}{R_G + R_1 \parallel R_2}\right) - V_{REF}\left(\frac{R_2}{R_1 + R_2}\right)\left(\frac{R_F}{R_G + R_1 \parallel R_2}\right) \qquad (4\text{–}37)$$

Comparing terms in Equations 4–37 and 4–14 enables the extraction of m and b.

$$m = \frac{R_F + R_G + R_1 \parallel R_2}{R_G + R_1 \parallel R_2} \tag{4–38}$$

$$|b| = V_{REF}\left(\frac{R_2}{R_1 + R_2}\right)\left(\frac{R_F}{R_G + R_1 \parallel R_2}\right) \tag{4–39}$$

The specifications for an example design are: V_{OUT} = 1.5 V @ V_{IN} = 0.2 V, V_{OUT} = 4.5 V @ V_{IN} = 0.5 V, V_{REF} = V_{CC} = 5 V, R_L = 10 kΩ, and 5% resistor tolerances. The simultaneous equations, (Equations 4–40 and 4–41), are written below.

$$1.5 = 0.2m + b \tag{4–40}$$

$$4.5 = 0.5m + b \tag{4–41}$$

From these equations we find that b = -0.5 and m = 10. Making the assumption that $R_1||R_2 << R_G$ simplifies the calculations of the resistor values.

$$m = 10 = \frac{R_F + R_G}{R_G} \tag{4–42}$$

$$R_F = 9R_G \tag{4–43}$$

Let R_G = 20 kΩ, and then R_F = 180 kΩ.

$$b = V_{CC}\left(\frac{R_F}{R_G}\right)\left(\frac{R_2}{R_1 + R_2}\right) = 5\left(\frac{180}{20}\right)\left(\frac{R_2}{R_1 + R_2}\right) \tag{4–44}$$

$$R_1 = \frac{1–0.01111}{0.01111}R_2 = 89R_2 \tag{4–45}$$

Select R_2 = 0.82 kΩ and R_1 equals 72.98 kΩ. Since 72.98 kΩ is not a standard 5% resistor value, R_1 is selected as 75 kΩ. The difference between the selected and calculated value of R_1 has about a 3% effect on b, and this error shows up in the transfer function as an intercept rather than a slope error. The parallel resistance of R_1 and R_2 is approximately 0.82 kΩ and this is much less than R_G, which is 20 kΩ, thus the earlier assumption that $R_G >> R1||R2$ is justified. R_2 could have been selected as a smaller value, but the smaller values yielded poor standard 5% values for R_1. The final circuit is shown in Figure 4–14 and the measured transfer curve for this circuit is shown in Figure 4–15.

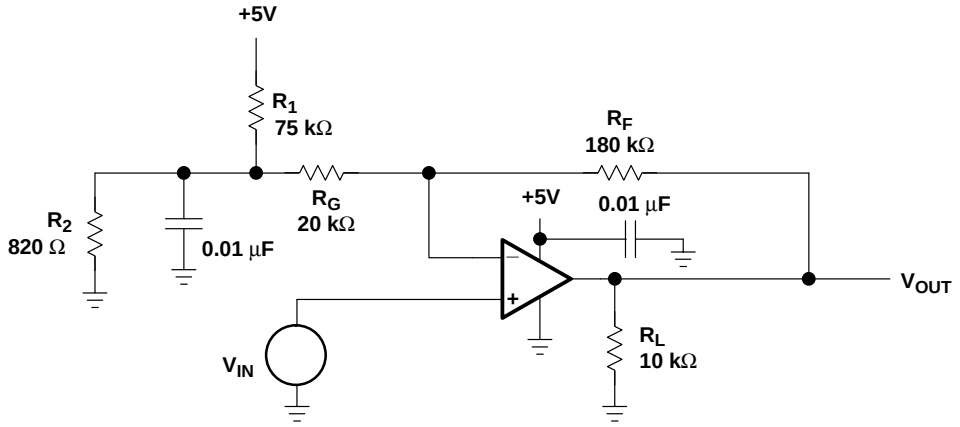

Figure 4–14. Case 2 Example Circuit

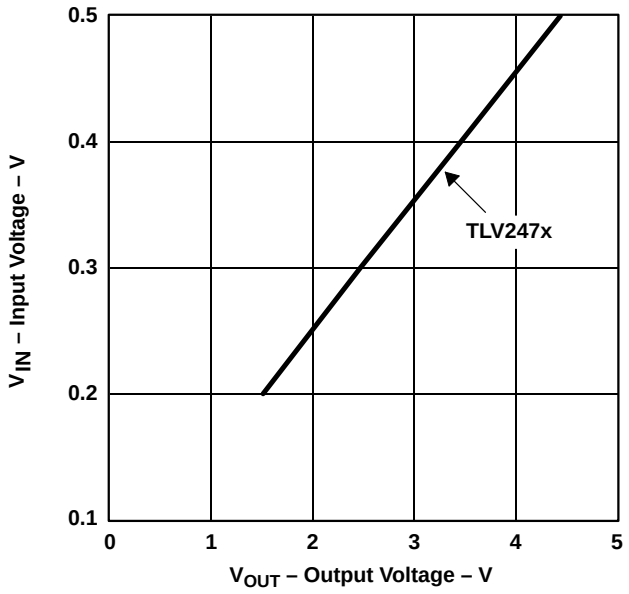

Figure 4–15. Case 2 Example Circuit Measured Transfer Curve

The TLV247X was used to build the test circuit because of its wide dynamic range. The transfer curve plots very close to the theoretical curve; the direct result of using a high performance op amp.

4.3.3 Case 3: $V_{OUT} = -mV_{IN} + b$

The circuit shown in Figure 4–16 yields the transfer function desired for Case 3.

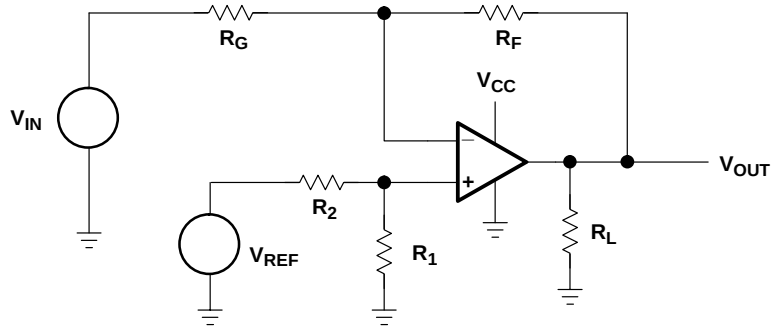

Figure 4–16. Schematic for Case 3: $V_{OUT} = -mV_{IN} + b$

The circuit equation is obtained with superposition.

$$V_{OUT} = -V_{IN}\left(\frac{R_F}{R_G}\right) + V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \quad (4–46)$$

Comparing terms between Equations 4–45 and 4–15 enables the extraction of m and b.

$$|m| = \frac{R_F}{R_G} \quad (4–47)$$

$$b = V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \quad (4–48)$$

The design specifications for an example circuit are: V_{OUT} = 1 V @ V_{IN} = -0.1 V, V_{OUT} = 6 V @ V_{IN} = -1 V, $V_{REF} = V_{CC}$ = 10 V, R_L = 100 Ω, and 5% resistor tolerances. The supply voltage available for this circuit is 10 V, and this exceeds the maximum allowable supply voltage for the TLV247X. Also, this circuit must drive a back-terminated cable that looks like two 50-Ω resistors connected in series, thus the op amp must be able to drive 6/100 = 60 mA. The stringent op amp selection criteria limits the choice to relatively new op amps if ideal op amp equations are going to be used. The TLC07X has excellent single-supply input performance coupled with high output current drive capability, so it is selected for this circuit. The simultaneous equations (Equations 4–49 and 4–50), are written below.

$$1 = (-0.1)m + b \quad (4–49)$$

$$6 = (-1)m + b \quad (4–50)$$

From these equations we find that b = 0.444 and m = –5.6.

$$|m| = 5.56 = \frac{R_F}{R_G} \tag{4–51}$$

$$R_F = 5.56R_G \tag{4–52}$$

Let R_G = 10 kΩ, and then R_F = 56.6 kΩ, which is not a standard 5% value, hence R_F is selected as 56 kΩ.

$$b = V_{CC}\left(\frac{R_F + R_G}{R_G}\right)\left(\frac{R_1}{R_1 + R_2}\right) = 10\left(\frac{56 + 10}{10}\right)\left(\frac{R_1}{R_1 + R_2}\right) \tag{4–53}$$

$$R_2 = \frac{66–0.4444}{0.4444}R_1 = 147.64R_1 \tag{4–54}$$

The final equation for the example is given below

$$V_{OUT} = -5.56V_{IN} + 0.444 \tag{4–55}$$

Select R_1 = 2 kΩ and R_2 = 295.28 kΩ. Since 295.28 kΩ is not a standard 5% resistor value, R_1 is selected as 300 kΩ. The difference between the selected and calculated value of R_1 has a nearly insignificant effect on b. The final circuit is shown in Figure 4–17, and the measured transfer curve for this circuit is shown in Figure 4–18.

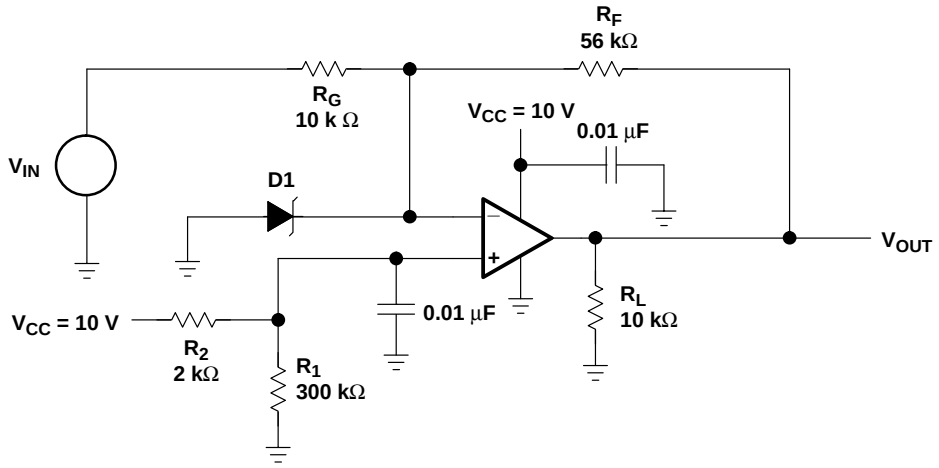

Figure 4–17. Case 3 Example Circuit

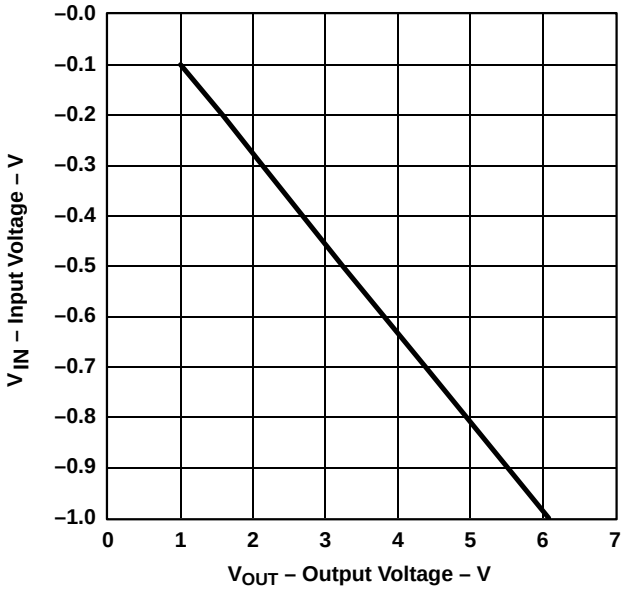

Figure 4–18. Case 3 Example Circuit Measured Transfer Curve

As long as the circuit works normally, there are no problems handling the negative voltage input to the circuit, because the inverting lead of the TLC07X is at a positive voltage. The positive op amp input lead is at a voltage of approximately 65 mV, and normal op amp operation keeps the inverting op amp input lead at the same voltage because of the assumption that the error voltage is zero. When V_{CC} is powered down while there is a negative voltage on the input circuit, most of the negative voltage appears on the inverting op amp input lead.

The most prudent solution is to connect the diode, D_1, with its cathode on the inverting op amp input lead and its anode at ground. If a negative voltage gets on the inverting op amp input lead, it is clamped to ground by the diode. Select the diode type as germanium or Schottky so the voltage drop across the diode is about 200 mV; this small voltage does not harm most op amp inputs. As a further precaution, R_G can be split into two resistors with the diode inserted at the junction of the two resistors. This places a current limiting resistor between the diode and the inverting op amp input lead.

4.3.4 Case 4: $V_{OUT} = -mV_{IN} - b$

The circuit shown in Figure 4–19 yields a solution for Case 4. The circuit equation is obtained by using superposition to calculate the response to each input. The individual responses to V_{IN} and V_{REF} are added to obtain Equation 4–56.

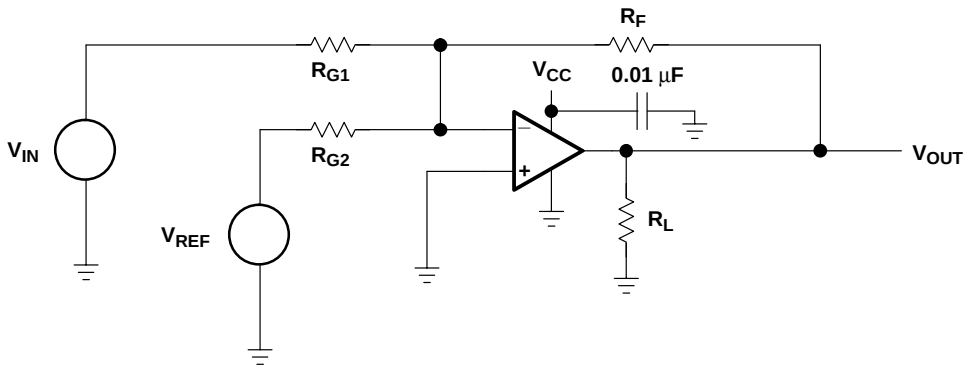

Figure 4–19. Schematic for Case 4: $V_{OUT} = -mV_{IN} - b$

$$V_{OUT} = -V_{IN}\frac{R_F}{R_{G1}} - V_{REF}\frac{R_F}{R_{G2}} \tag{4–56}$$

Comparing terms in Equations 4–56 and 4–16 enables the extraction of m and b.

$$|m| = \frac{R_F}{R_{G1}} \tag{4–57}$$

$$|b| = V_{REF}\frac{R_F}{R_{G2}} \tag{4–58}$$

The design specifications for an example circuit are: V_{OUT} = 1 V @ V_{IN} = –0.1 V, V_{OUT} = 5 V @ V_{IN} =– 0.3 V, $V_{REF} = V_{CC}$ = 5 V, R_L = 10 kΩ, and 5% resistor tolerances. The simultaneous Equations 4–59 and 4–60, are written below.

$$1 = (-0.1)m + b \tag{4–59}$$

$$5 = (-0.3)m + b \tag{4–60}$$

From these equations we find that b = –1 and m = –20. Setting the magnitude of m equal to Equation 4–57 yields Equation 4–61.

$$|m| = 20 = \frac{R_F}{R_{G1}} \tag{4–61}$$

$$R_F = 20R_{G1} \tag{4–62}$$

Let R_{G1} = 1 kΩ, and then R_F = 20 kΩ.

$$|b| = V_{CC}\left(\frac{R_F}{R_{G1}}\right) = 5\left(\frac{R_F}{R_{G2}}\right) = 1 \quad (4–63)$$

$$R_{G2} = \frac{R_F}{0.2} = \frac{20}{0.2} = 100\ k\Omega \quad (4–64)$$

The final equation for this example is given in Equation 4–63.

$$V_{OUT} = -20V_{IN} - 1 \quad (4–65)$$

The final circuit is shown in Figure 4–20 and the measured transfer curve for this circuit is shown in Figure 4–21.

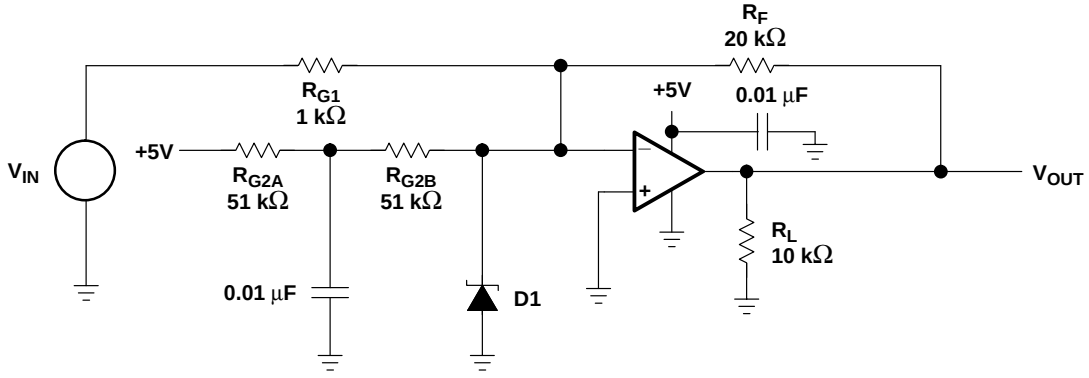

Figure 4–20. Case 4 Example Circuit

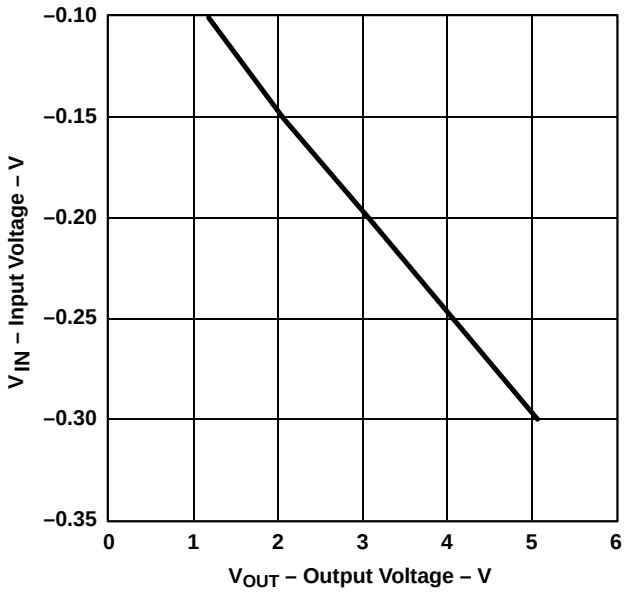

Figure 4–21. Case 4 Example Circuit Measured Transfer Curve

The TLV247X was used to build the test circuit because of its wide dynamic range. The transfer curve plots very close to the theoretical curve, and this results from using a high performance op amp.

As long as the circuit works normally there are no problems handling the negative voltage input to the circuit because the inverting lead of the TLV247X is at a positive voltage. The positive op amp input lead is grounded, and normal op amp operation keeps the inverting op amp input lead at ground because of the assumption that the error voltage is zero. When V_{CC} is powered down while there is a negative voltage on the inverting op amp input lead.

The most prudent solution is to connect the diode, D_1, with its cathode on the inverting op amp input lead and its anode at ground. If a negative voltage gets on the inverting op amp input lead it is clamped to ground by the diode. Select the diode type as germanium or Schottky so the voltage drop across the diode is about 200 mV; this small voltage does not harm most op amp inputs. R_{G2} is split into two resistors ($R_{G2A} = R_{G2B} = 51\ k\Omega$) with a capacitor inserted at the junction of the two resistors. This places a power supply filter in series with V_{CC}.

4.4 Summary

Single-supply op amp design is more complicated than split-supply op amp design, but with a logical design approach excellent results are achieved. Single-supply design used to be considered technically limiting because older op amps had limited capability. The new op amps, such as the TLC247X, TLC07X, and TLC08X have excellent single-supply parameters; thus when used in the correct applications these op amps yield rail-to-rail performance equal to their split-supply counterparts.

Single-supply op amp design usually involves some form of biasing, and this requires more thought, so single-supply op amp design needs discipline and a procedure. The recommended design procedure for single-supply op amp design is:

- Substitute the specification data into simultaneous equations to obtain m and b (the slope and intercept of a straight line).
- Let m and b determine the form of the circuit.
- Choose the circuit configuration that fits the form.
- Using the circuit equations for the circuit configuration selected, calculate the resistor values.
- Build the circuit, take data, and verify performance.
- Test the circuit for nonstandard operating conditions (circuit power off while interface power is on, over/under range inputs, etc.).
- Add protection components as required.
- Retest.

When this procedure is followed, good results follow. As single-supply circuit designers expand their horizon, new challenges require new solutions. Remember, the only equation a linear op amp can produce is the equation of a straight line. That equation only has four forms. The new challenges may consist of multiple inputs, common-mode voltage rejection, or something different, but this method can be expanded to meet these challenges.

Chapter 5

Feedback and Stability Theory

Ron Mancini

5.1 Why Study Feedback Theory?

The gain of all op amps decreases as frequency increases, and the decreasing gain results in decreasing accuracy as the ideal op amp assumption ($a \Rightarrow \infty$) breaks down. In most real op amps the open loop gain starts to decrease before 10 Hz, so an understanding of feedback is required to predict the closed loop performance of the op amp. The real world application of op amps is feedback controlled, and depends on op amp open loop gain at a given frequency. A designer must know theory to be able to predict the circuit response regardless of frequency or open loop gain.

Analysis tools have something in common with medicine because they both can be distasteful but necessary. Medicine often tastes bad or has undesirable side effects, and analysis tools involve lots of hard learning work before they can be applied to yield results. Medicine assists the body in fighting an illness; analysis tools assist the brain in learning/designing feedback circuits.

The analysis tools given here are a synopsis of salient points; thus they are detailed enough to get you where you are going without any extras. The references, along with thousands of their counterparts, must be consulted when making an in-depth study of the field. Aspirin, home remedies, and good health practice handle the majority of health problems, and these analysis tools solve the majority of circuit problems.

Ideal op amp circuits can be designed without knowledge of feedback analysis tools, but these circuits are limited to low frequencies. Also, an understanding of feedback analysis tools is required to understand AC effects like ringing and oscillations.

5.2 Block Diagram Math and Manipulations

Electronic systems and circuits are often represented by block diagrams, and block diagrams have a unique algebra and set of transformations[1]. Block diagrams are used because they are a shorthand pictorial representation of the cause-and-effect relationship between the input and output in a real system. They are a convenient method for characterizing the functional relationships between components. It is not necessary to understand the functional details of a block to manipulate a block diagram.

The input impedance of each block is assumed to be infinite to preclude loading. Also, the output impedance of each block is assumed to be zero to enable high fan-out. The systems designer sets the actual impedance levels, but the fan-out assumption is valid because the block designers adhere to the system designer's specifications. All blocks multiply the input times the block quantity (see Figure 5–1) unless otherwise specified within the block. The quantity within the block can be a constant as shown in Figure 5–1(c), or it can be a complex math function involving Laplace transforms. The blocks can perform time-based operations such as differentiation and integration.

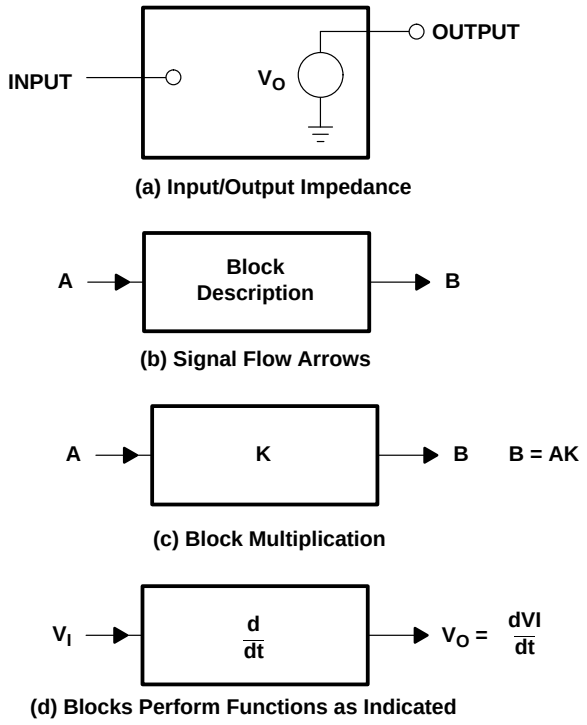

Figure 5–1. Definition of Blocks

Adding and subtracting are done in special blocks called summing points. Figure 5–2 gives several examples of summing points. Summing points can have unlimited inputs, can add or subtract, and can have mixed signs yielding addition and subtraction within a single summing point. Figure 5–3 defines the terms in a typical control system, and Figure 5–4 defines the terms in a typical electronic feedback system. Multiloop feedback systems (Figure 5–5) are intimidating, but they can be reduced to a single loop feedback system, as shown in the figure, by writing equations and solving for V_{OUT}/V_{IN}. An easier method for reducing multiloop feedback systems to single loop feedback systems is to follow the rules and use the transforms given in Figure 5–6.

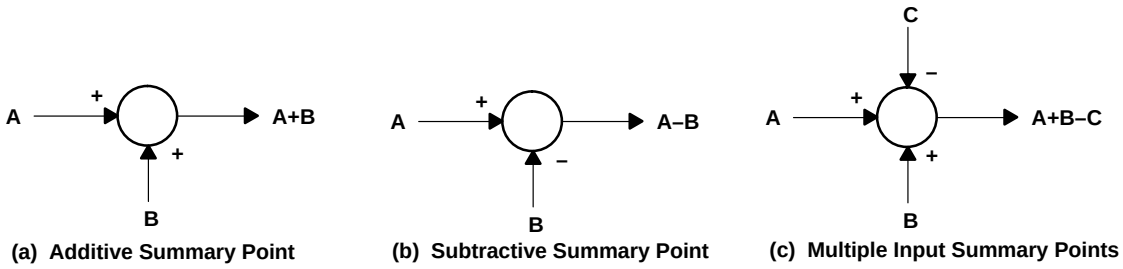

Figure 5–2. Summary Points

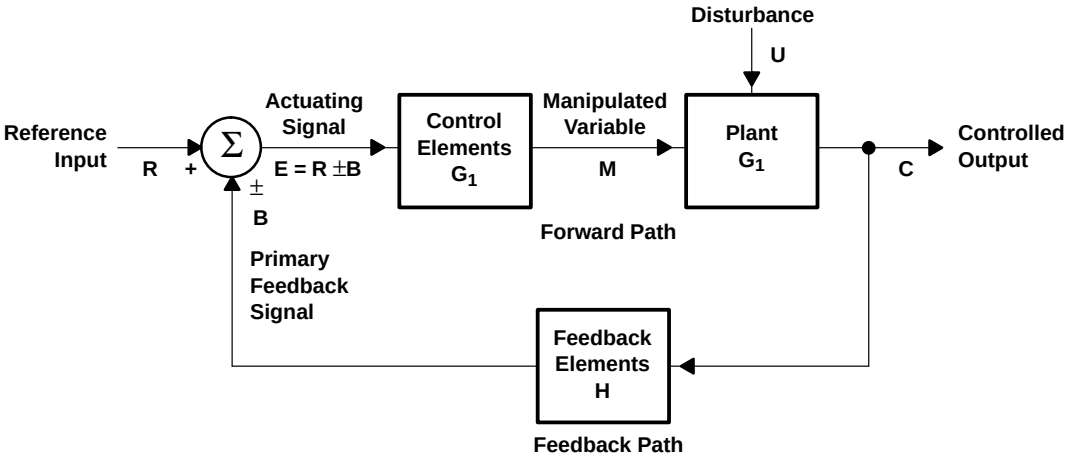

Figure 5–3. Definition of Control System Terms

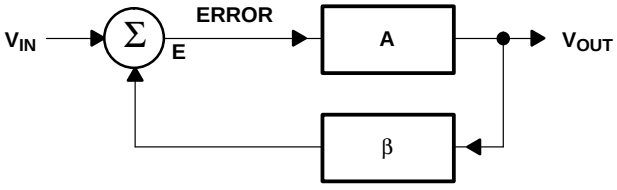

Figure 5–4. Definition of an Electronic Feedback Circuit

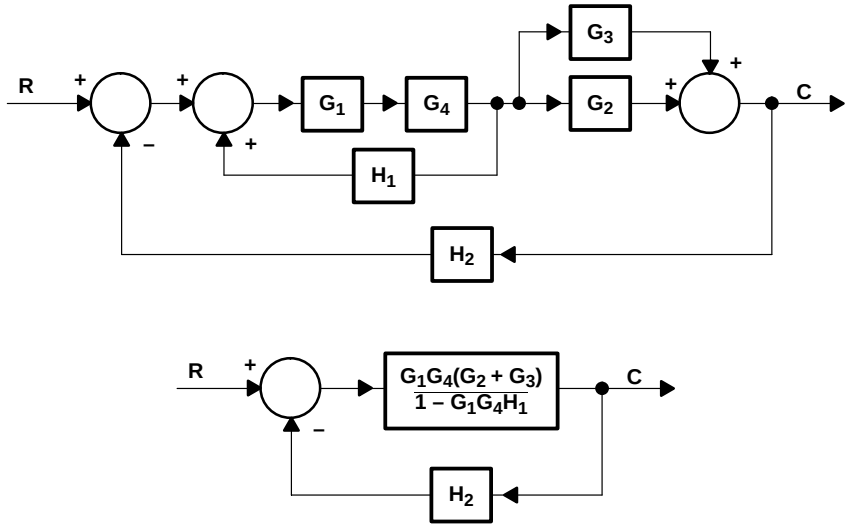

Figure 5–5. Multiloop Feedback System

Block diagram reduction rules:

- Combine cascade blocks.
- Combine parallel blocks.
- Eliminate interior feedback loops.
- Shift summing points to the left.
- Shift takeoff points to the right.
- Repeat until canonical form is obtained.

Figure 5–6 gives the block diagram transforms. The idea is to reduce the diagram to its canonical form because the canonical feedback loop is the simplest form of a feedback loop, and its analysis is well documented. All feedback systems can be reduced to the canonical form, so all feedback systems can be analyzed with the same math. A canonical loop exists for each input to a feedback system; although the stability dynamics are independent of the input, the output results are input dependent. The response of each input of a multiple input feedback system can be analyzed separately and added through superposition.

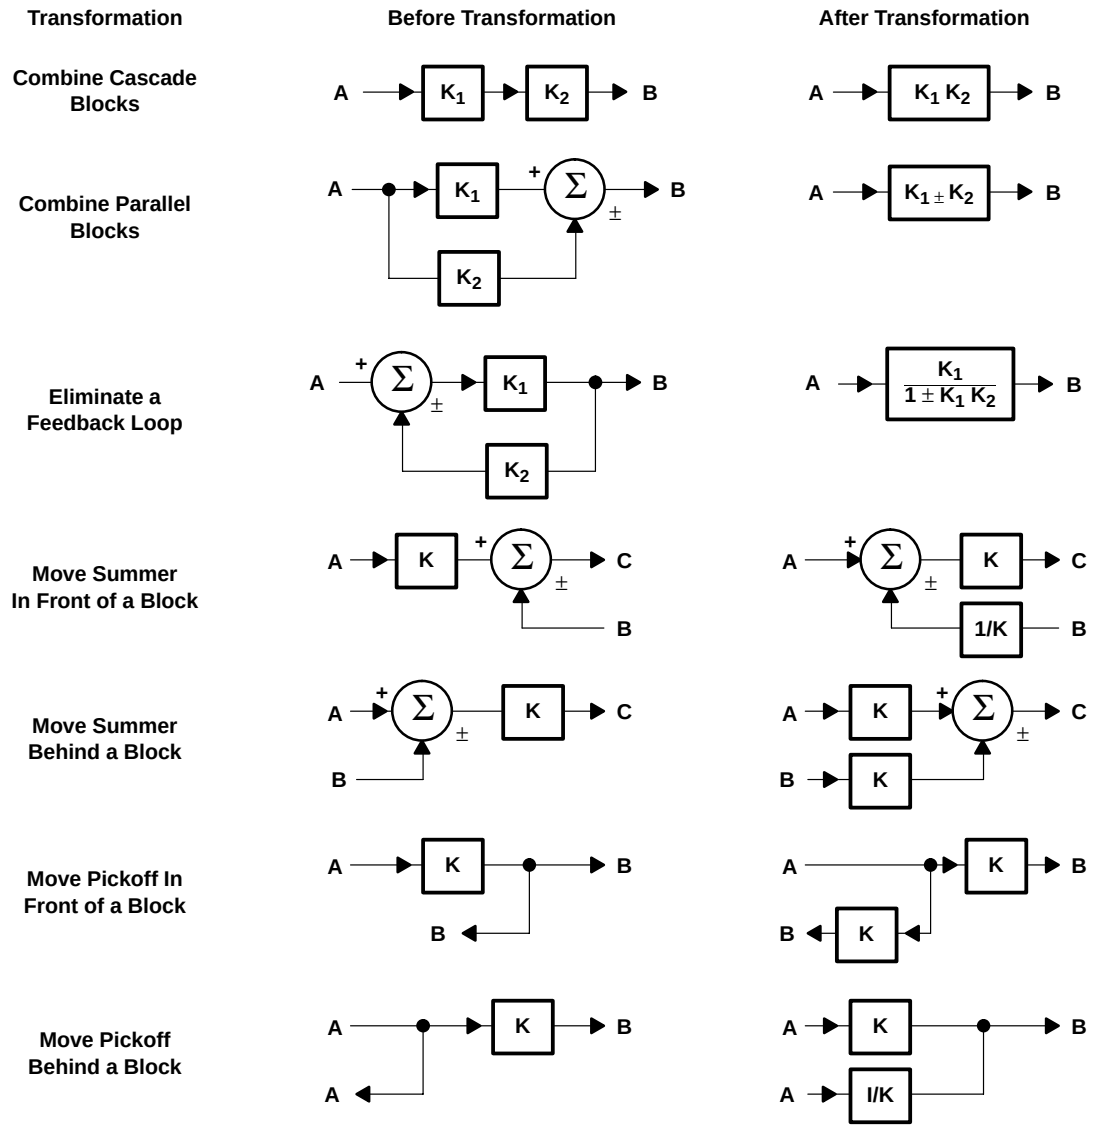

Figure 5–6. Block Diagram Transforms

5.3 Feedback Equation and Stability

Figure 5–7 shows the canonical form of a feedback loop with control system and electronic system terms. The terms make no difference except that they have meaning to the system engineers, but the math does have meaning, and it is identical for both types of terms. The electronic terms and negative feedback sign are used in this analysis, because subsequent chapters deal with electronic applications. The output equation is written in Equation 5–1.

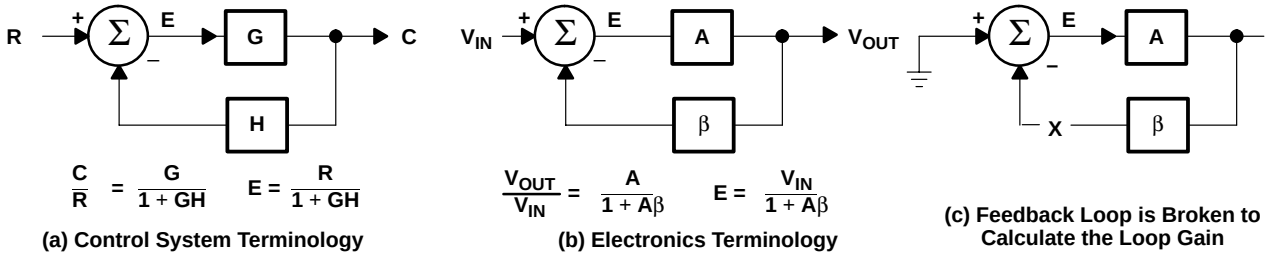

Figure 5–7. Comparison of Control and Electronic Canonical Feedback Systems

$$V_{OUT} = EA \tag{5–1}$$

The error equation is written in Equation 5–2.

$$E = V_{IN} - \beta V_{OUT} \tag{5–2}$$

Combining Equations 5–1 and 5–2 yields Equation 5–3.

$$\frac{V_{OUT}}{A} = V_{IN} - \beta V_{OUT} \tag{5–3}$$

Collecting terms yields Equation 5–4.

$$V_{OUT}\left(\frac{1}{A} + \beta\right) = V_{IN} \tag{5–4}$$

Rearranging terms yields the classic form of the feedback Equation 5–5.

$$\frac{V_{OUT}}{V_{IN}} = \frac{A}{1 + A\beta} \tag{5–5}$$

When the quantity $A\beta$ in Equation 5–5 becomes very large with respect to one, the one can be neglected, and Equation 5–5 reduces to Equation 5–6, which is the ideal feedback equation. Under the conditions that $A\beta >> 1$, the system gain is determined by the feedback factor β. Stable passive circuit components are used to implement the feedback factor, thus in the ideal situation, the closed loop gain is predictable and stable because β is predictable and stable.

$$\frac{V_{OUT}}{V_{IN}} = \frac{1}{\beta} \tag{5–6}$$

The quantity Aβ is so important that it has been given a special name: loop gain. In Figure 5–7, when the voltage inputs are grounded (current inputs are opened) and the loop is broken, the calculated gain is the loop gain, Aβ. Now, keep in mind that we are using complex numbers, which have magnitude and direction. When the loop gain approaches minus one, or to express it mathematically $1\angle -180°$, Equation 5–5 approaches $1/0 \Rightarrow \propto$. The circuit output heads for infinity as fast as it can using the equation of a straight line. If the output were not energy limited, the circuit would explode the world, but happily, it is energy limited, so somewhere it comes up against the limit.

Active devices in electronic circuits exhibit nonlinear phenomena when their output approaches a power supply rail, and the nonlinearity reduces the gain to the point where the loop gain no longer equals $1\angle -180°$. Now the circuit can do two things: first it can become stable at the power supply limit, or second, it can reverse direction (because stored charge keeps the output voltage changing) and head for the negative power supply rail.

The first state where the circuit becomes stable at a power supply limit is named lockup; the circuit will remain in the locked up state until power is removed and reapplied. The second state where the circuit bounces between power supply limits is named oscillatory. Remember, the loop gain, Aβ, is the sole factor determining stability of the circuit or system. Inputs are grounded or disconnected, so they have no bearing on stability.

Equations 5–1 and 5–2 are combined and rearranged to yield Equation 5–7, which is the system or circuit error equation.

$$E = \frac{V_{IN}}{1 + A\beta} \tag{5–7}$$

First, notice that the error is proportional to the input signal. This is the expected result because a bigger input signal results in a bigger output signal, and bigger output signals require more drive voltage. As the loop gain increases, the error decreases, thus large loop gains are attractive for minimizing errors.

5.4 Bode Analysis of Feedback Circuits

H. W. Bode developed a quick, accurate, and easy method of analyzing feedback amplifiers, and he published a book about his techniques in 1945.[2] Operational amplifiers had not been developed when Bode published his book, but they fall under the general classification of feedback amplifiers, so they are easily analyzed with Bode techniques. The mathematical manipulations required to analyze a feedback circuit are complicated because they involve multiplication and division. Bode developed the Bode plot, which simplifies the analysis through the use of graphical techniques.

The Bode equations are log equations that take the form 20LOG(F(t)) = 20LOG(|F(t)|) + phase angle. Terms that are normally multiplied and divided can now be added and subtracted because they are log equations. The addition and subtraction is done graphically, thus easing the calculations and giving the designer a pictorial representation of circuit performance. Equation 5–8 is written for the low pass filter shown in Figure 5–8.

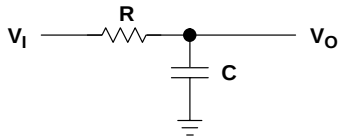

Figure 5–8. Low-Pass Filter

$$\frac{V_{OUT}}{V_{IN}} = \frac{\frac{1}{C\,s}}{R + \frac{1}{C\,s}} = \frac{1}{1 + RCs} = \frac{1}{1 + \tau s} \qquad (5\text{–}8)$$

Where: $s = j\omega$, $j = \sqrt{(-1)}$, and $RC = \tau$

The magnitude of this transfer function is $|V_{OUT}/V_{IN}| = 1/\sqrt{1^2 + (\tau\omega)^2}$. This magnitude, $|V_{OUT}/V_{IN}| \cong 1$ when $\omega = 0.1/\tau$, it equals 0.707 when $\omega = 1/\tau$, and it is approximately = 0.1 when $\omega = 10/\tau$. These points are plotted in Figure 5–9 using straight line approximations. The negative slope is –20 dB/decade or –6 dB/octave. The magnitude curve is plotted as a horizontal line until it intersects the breakpoint where $\omega = 1/\tau$. The negative slope begins at the breakpoint because the magnitude starts decreasing at that point. The gain is equal to 1 or 0 dB at very low frequencies, equal to 0.707 or –3 dB at the break frequency, and it keeps falling with a –20 dB/decade slope for higher frequencies.

The phase shift for the low pass filter or any other transfer function is calculated with the aid of Equation 5–9.

$$\phi = \text{tangent}^{-1}\left(\frac{\text{Real}}{\text{Imaginary}}\right) = -\text{tangent}^{-1}\left(\frac{\omega\tau}{1}\right) \qquad (5\text{–}9)$$

The phase shift is much harder to approximate because the tangent function is nonlinear. Normally the phase information is only required around the 0 dB intercept point for an active circuit, so the calculations are minimized. The phase is shown in Figure 5–9, and it is approximated by remembering that the tangent of 90° is 1, the tangent of 60° is $\sqrt{3}$, and the tangent of 30° is $\sqrt{3}/3$.

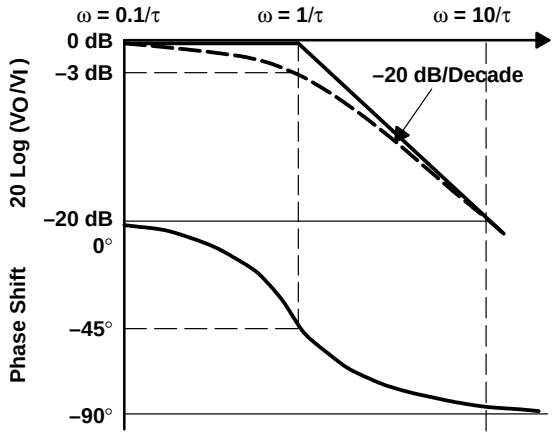

Figure 5–9. Bode Plot of Low-Pass Filter Transfer Function

A breakpoint occurring in the denominator is called a pole, and it slopes down. Conversely, a breakpoint occurring in the numerator is called a zero, and it slopes up. When the transfer function has multiple poles and zeros, each pole or zero is plotted independently, and the individual poles/zeros are added graphically. If multiple poles, zeros, or a pole/zero combination have the same breakpoint, they are plotted on top of each other. Multiple poles or zeros cause the slope to change by multiples of 20 dB/decade.

An example of a transfer function with multiple poles and zeros is a band reject filter (see Figure 5–10). The transfer function of the band reject filter is given in Equation 5–10.

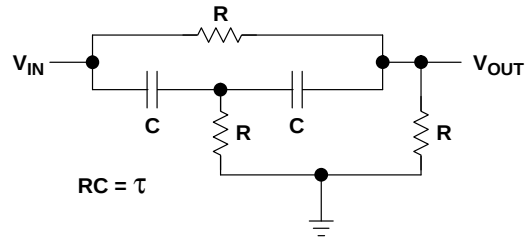

Figure 5–10. Band Reject Filter

$$G = \frac{V_{OUT}}{V_{IN}} = \frac{(1 + \tau s)(1 + \tau s)}{2\left(1 + \frac{\tau s}{0.44}\right)\left(1 + \frac{\tau s}{4.56}\right)} \qquad (5–10)$$

The pole zero plot for each individual pole and zero is shown in Figure 5–11, and the combined pole zero plot is shown in Figure 5–12.

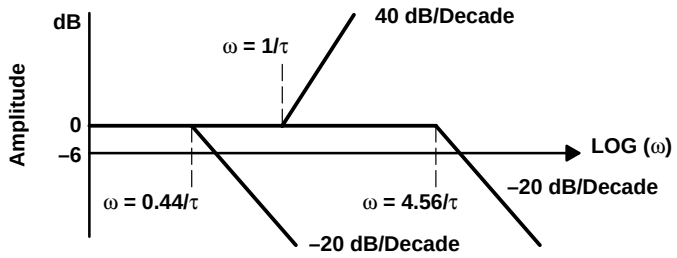

Figure 5–11. Individual Pole Zero Plot of Band Reject Filter

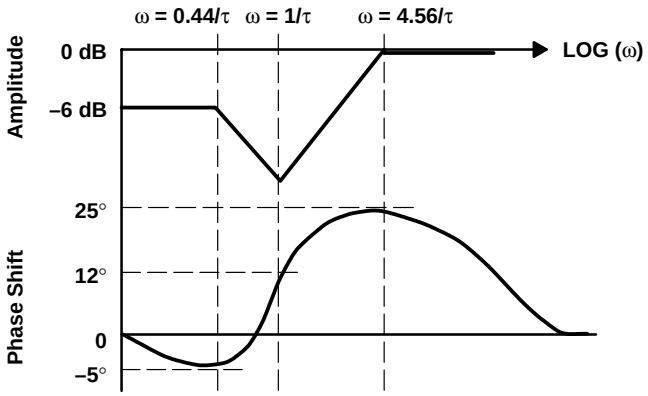

Figure 5–12. Combined Pole Zero Plot of Band Reject Filter

The individual pole zero plots show the dc gain of 1/2 plotting as a straight line from the –6 dB intercept. The two zeros occur at the same break frequency, thus they add to a 40-dB/decade slope. The two poles are plotted at their breakpoints of $\omega = 0.44/\tau$ and $\omega = 4.56/\tau$. The combined amplitude plot intercepts the amplitude axis at –6 dB because of the dc gain, and then breaks down at the first pole. When the amplitude function gets to the double zero, the first zero cancels out the first pole, and the second zero breaks up. The upward slope continues until the second pole cancels out the second zero, and the amplitude is flat from that point out in frequency.

When the separation between all the poles and zeros is great, a decade or more in frequency, it is easy to draw the Bode plot. As the poles and zeros get closer together, the plot gets harder to make. The phase is especially hard to plot because of the tangent function, but picking a few salient points and sketching them in first gets a pretty good approximation.[3] The Bode plot enables the designer to get a good idea of pole zero placement, and it is valuable for fast evaluation of possible compensation techniques. When the situation gets critical, accurate calculations must be made and plotted to get an accurate result.

Consider Equation 5–11.

$$\frac{V_{OUT}}{V_{IN}} = \frac{A}{1 + A\beta} \tag{5–11}$$

Taking the log of Equation 5–11 yields Equation 5–12.

$$20\text{Log}\left(\frac{V_{OUT}}{V_{IN}}\right) = 20\text{Log}(A) - 20\text{Log}(1 + A\beta) \tag{5–12}$$

If A and β do not contain any poles or zeros there will be no break points. Then the Bode plot of Equation 5–12 looks like that shown in Figure 5–13, and because there are no poles to contribute negative phase shift, the circuit cannot oscillate.

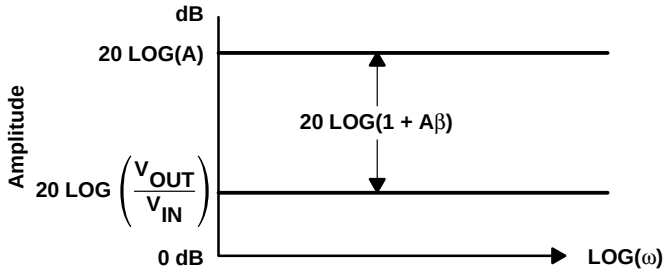

Figure 5–13. When No Pole Exists in Equation (5–12)

All real amplifiers have many poles, but they are normally internally compensated so that they appear to have a single pole. Such an amplifier would have an equation similar to that given in Equation 5–13.

$$A = \frac{a}{1 + j\frac{\omega}{\omega_a}} \tag{5–13}$$

The plot for the single pole amplifier is shown in Figure 5–14.

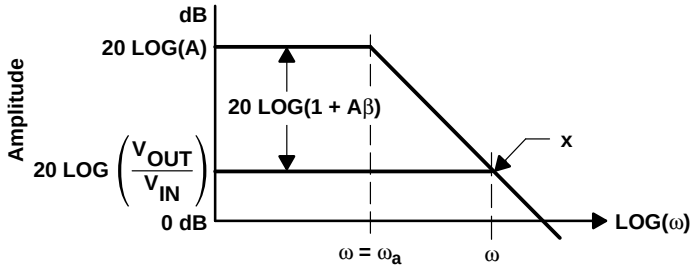

Figure 5–14. When Equation 5–12 has a Single Pole

The amplifier gain, A, intercepts the amplitude axis at 20Log(A), and it breaks down at a slope of –20 dB/decade at $\omega = \omega_a$. The negative slope continues for all frequencies greater than the breakpoint, $\omega = \omega_a$. The closed loop circuit gain intercepts the amplitude axis at $20\text{Log}(V_{OUT}/V_{IN})$, and because β does not have any poles or zeros, it is constant until its projection intersects the amplifier gain at point X. After intersection with the amplifier gain curve, the closed loop gain follows the amplifier gain because the amplifier is the controlling factor.

Actually, the closed loop gain starts to roll off earlier, and it is down 3 dB at point X. At point X the difference between the closed loop gain and the amplifier gain is –3 dB, thus according to Equation 5–12 the term $-20\text{Log}(1+A\beta) = -3$ dB. The magnitude of 3 dB is $\sqrt{2}$, hence $\sqrt{1 + (A\beta)^2} = \sqrt{2}$, and elimination of the radicals shows that $A\beta = 1$. There is a method [4] of relating phase shift and stability to the slope of the closed loop gain curves, but only the Bode method is covered here. An excellent discussion of poles, zeros, and their interaction is given by M. E Van Valkenberg,[5] and he also includes some excellent prose to liven the discussion.

5.5 Loop Gain Plots are the Key to Understanding Stability

Stability is determined by the loop gain, and when $A\beta = -1 = |1| \angle -180^\circ$ instability or oscillation occurs. If the magnitude of the gain exceeds one, it is usually reduced to one by circuit nonlinearities, so oscillation generally results for situations where the gain magnitude exceeds one.

Consider oscillator design, which depends on nonlinearities to decrease the gain magnitude; if the engineer designed for a gain magnitude of one at nominal circuit conditions, the gain magnitude would fall below one under worst case circuit conditions causing oscillation to cease. Thus, the prudent engineer designs for a gain magnitude of one under worst case conditions knowing that the gain magnitude is much more than one under optimistic conditions. The prudent engineer depends on circuit nonlinearities to reduce the gain magnitude to the appropriate value, but this same engineer pays a price of poorer distortion performance. Sometimes a design compromise is reached by putting a nonlinear component, such as a lamp, in the feedback loop to control the gain without introducing distortion.

Some high gain control systems always have a gain magnitude greater than one, but they avoid oscillation by manipulating the phase shift. The amplifier designer who pushes the amplifier for superior frequency performance has to be careful not to let the loop gain phase shift accumulate to 180°. Problems with overshoot and ringing pop up before the loop gain reaches 180° phase shift, thus the amplifier designer must keep a close eye on loop dynamics. Ringing and overshoot are handled in the next section, so preventing oscillation is emphasized in this section. Equation 5–14 has the form of many loop gain transfer functions or circuits, so it is analyzed in detail.

$$(A)\beta = \frac{(K)}{\left(1 + \tau_1(s)\right)\left(1 + \tau_2(s)\right)} \tag{5–14}$$

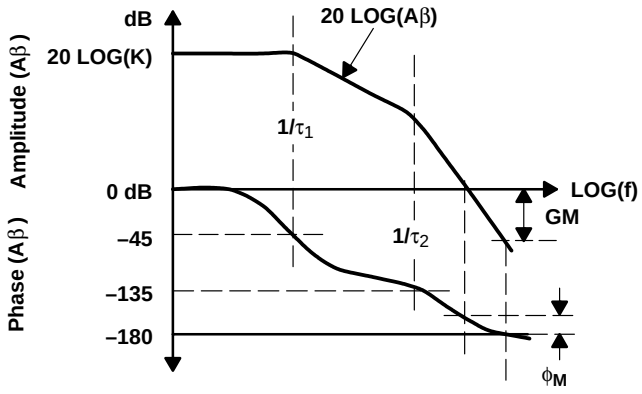

Figure 5–15. Magnitude and Phase Plot of Equation 5–14

The quantity, K, is the dc gain, and it plots as a straight line with an intercept of 20Log(K). The Bode plot of Equation 5–14 is shown in Figure 5–15. The two break points, $\omega = \omega_1 = 1/\tau_1$ and $\omega = \omega_2 = 1/\tau_2$, are plotted in the Bode plot. Each breakpoint adds –20 dB/decade slope to the plot, and 45° phase shift accumulates at each breakpoint. This transfer function is referred to as a two slope because of the two breakpoints. The slope of the curve when it crosses the 0 dB intercept indicates phase shift and the ability to oscillate. Notice that a one slope can only accumulate 90° phase shift, so when a transfer function passes through 0 dB with a one slope, it cannot oscillate. Furthermore, a two-slope system can accumulate 180° phase shift, therefore a transfer function with a two or greater slope is capable of oscillation.

A one slope crossing the 0 dB intercept is stable, whereas a two or greater slope crossing the 0 dB intercept may be stable or unstable depending upon the accumulated phase shift. Figure 5–15 defines two stability terms; the phase margin, ϕ_M, and the gain margin, G_M. Of these two terms the phase margin is much more important because phase shift is critical for stability. Phase margin is a measure of the difference in the actual phase shift and the theoretical 180° required for oscillation, and the phase margin measurement or calculation is made at the 0 dB crossover point. The gain margin is measured or calculated at the 180° phase crossover point. Phase margin is expressed mathematically in Equation 5–15.

$$\phi_M = 180 - \text{tangent}^{-1}(A\beta) \tag{5–15}$$

The phase margin in Figure 5–15 is very small, 20°, so it is hard to measure or predict from the Bode plot. A designer probably doesn't want a 20° phase margin because the system overshoots and rings badly, but this case points out the need to calculate small phase margins carefully. The circuit is stable, and it does not oscillate because the phase margin is positive. Also, the circuit with the smallest phase margin has the highest frequency response and bandwidth.

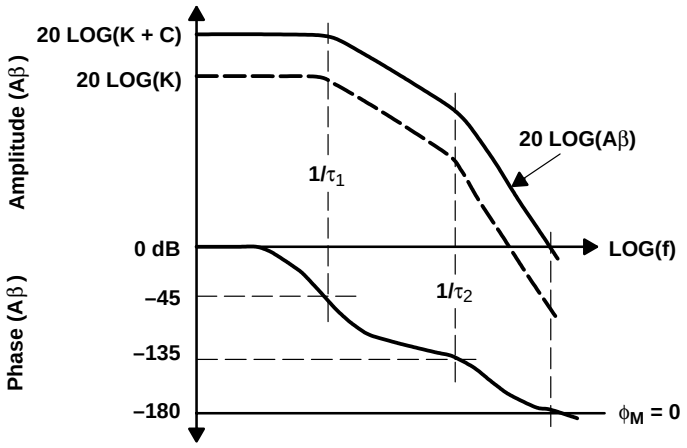

Figure 5–16. Magnitude and Phase Plot of the Loop Gain Increased to (K+C)

Increasing the loop gain to (K+C) as shown in Figure 5–16 shifts the magnitude plot up. If the pole locations are kept constant, the phase margin reduces to zero as shown, and the circuit will oscillate. The circuit is not good for much in this condition because production tolerances and worst case conditions ensure that the circuit will oscillate when you want it to amplify, and vice versa.

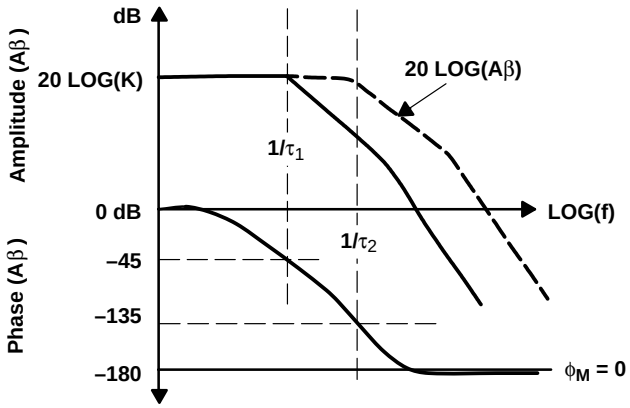

Figure 5–17. Magnitude and Phase Plot of the Loop Gain With Pole Spacing Reduced

The circuit poles are spaced closer in Figure 5–17, and this results in a faster accumulation of phase shift. The phase margin is zero because the loop gain phase shift reaches 180° before the magnitude passes through 0 dB. This circuit oscillates, but it is not a very stable oscillator because the transition to 180° phase shift is very slow. Stable oscillators have a very sharp transition through 180°.

When the closed loop gain is increased the feedback factor, β, is decreased because $V_{OUT}/V_{IN} = 1/\beta$ for the ideal case. This in turn decreases the loop gain, $A\beta$, thus the stability increases. In other words, increasing the closed loop gain makes the circuit more stable. Stability is not important except to oscillator designers because overshoot and ringing become intolerable to linear amplifiers long before oscillation occurs. The overshoot and ringing situation is investigated next.

5.6 The Second Order Equation and Ringing/Overshoot Predictions

The second order equation is a common approximation used for feedback system analysis because it describes a two-pole circuit, which is the most common approximation used. All real circuits are more complex than two poles, but except for a small fraction, they can be represented by a two-pole equivalent. The second order equation is extensively described in electronic and control literature [6].

$$(1 + A\beta) = 1 + \frac{K}{(1 + \tau_1 s)(1 + \tau_2 s)} \tag{5–16}$$

After algebraic manipulation Equation 5–16 is presented in the form of Equation 5–17.

$$s^2 + S\frac{\tau_1 + \tau_2}{\tau_1 \tau_2} + \frac{1 + K}{\tau_1 \tau_2} = 0 \tag{5–17}$$

Equation 5–17 is compared to the second order control Equation 5–18, and the damping ratio, ζ, and natural frequency, w_N are obtained through like term comparisons.

$$s^2 + 2\zeta\omega_N s + \omega_N^2 \tag{5–18}$$

Comparing these equations yields formulas for the phase margin and per cent overshoot as a function of damping ratio.

$$\omega_N = \sqrt{\frac{1 + K}{\tau_1 \tau_2}} \tag{5–19}$$

$$\xi = \frac{\tau_1 + \tau_2}{2\omega_N \tau_1 \tau_2} \tag{5–20}$$

When the two poles are well separated, Equation 5–21 is valid.

$$\phi_M = \text{tangent}^{-1}(2\xi) \tag{5–21}$$

The salient equations are plotted in Figure 5–18, which enables a designer to determine the phase margin and overshoot when the gain and pole locations are known.

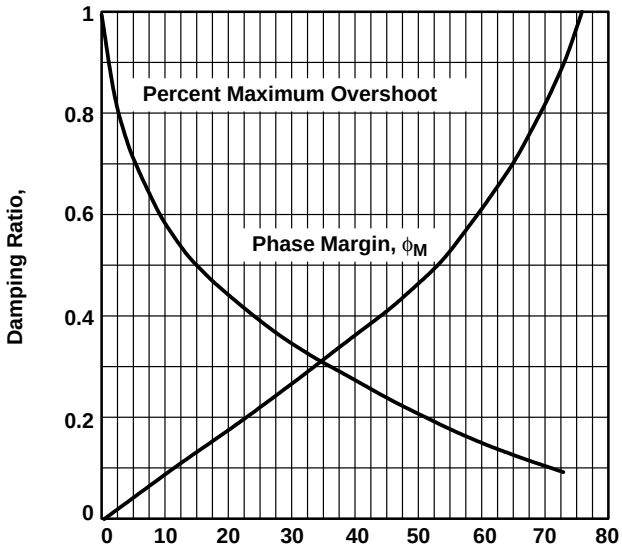

Figure 5–18. Phase Margin and Overshoot vs Damping Ratio

Enter Figure 5–18 at the calculated damping ratio, say 0.4, and read the overshoot at 25% and the phase margin at 42°. If a designer had a circuit specification of 5% maximum overshoot, then the damping ratio must be 0.78 with a phase margin of 62°.

Chapter 6

Development of the Non Ideal Op Amp Equations

Ron Mancini

6.1 Introduction

There are two types of error sources in op amps, and they fall under the general classification of dc and ac errors. Examples of dc errors are input offset voltage and input bias current. The dc errors stay constant over the usable op amp frequency range; therefore, the input bias current is 10 pA at 1 kHz and it is 10 pA at 10 kHz. Because of their constant and controlled behavior, dc errors are not considered until later chapters.

AC errors are flighty, so we address them here by developing a set of nonideal equations that account for ac errors. The ac errors may show up under dc conditions, but they get worse as the operating frequency increases. A good example of an ac error is common–mode rejection ration (CMRR). Most op amps have a guaranteed CMRR specification, but this specification is only valid at dc or very low frequencies. Further inspection of the data sheet reveals that CMRR decreases as operating frequency increases. Several other specifications that fall into the category of ac specifications are output impedance, power-supply rejection-ratio, peak-to-peak output voltage, differential gain, differential phase, and phase margin.

Differential gain is the most important ac specification because the other ac specifications are derived from the differential gain. Until now, differential gain has been called op amp gain or op amp open loop gain, and we shall continue with that terminology. Let the data sheet call it differential gain.

As shown in prior chapters, when frequency increases, the op amp gain decreases and errors increase. This chapter develops the equations that illustrate the effects of the gain changes. We start with a review of the basic canonical feedback system stability because the op amp equations are developed using the same techniques.

Amplifiers are built with active components such as transistors. Pertinent transistor parameters like transistor gain are subject to drift and initial inaccuracies from many sources, so amplifiers being built from these components are subject to drift and inaccura-

cies. The drift and inaccuracy is minimized or eliminated by using negative feedback. The op amp circuit configuration employs feedback to make the transfer equation of the circuit independent of the amplifier parameters (well almost), and while doing this, the circuit transfer function is made dependent on external passive components. The external passive components can be purchased to meet almost any drift or accuracy specification; only the cost and size of the passive components limit their use.

Once feedback is applied to the op amp it is possible for the op amp circuit to become unstable. Certain amplifiers belong to a family called internally compensated op amps; they contain internal capacitors that are sometimes advertised as precluding instabilities. Although internally compensated op amps should not oscillate when operated under specified conditions, many have relative stability problems that manifest themselves as poor phase response, ringing, and overshoot. The only absolutely stable internally compensated op amp is the one lying on the workbench without power applied! All other internally compensated op amps oscillate under some external circuit conditions.

Noninternally compensated or *externally* compensated op amps are unstable without the addition of external stabilizing components. This situation is a disadvantage in many cases because they require additional components, but the lack of internal compensation enables the top-drawer circuit designer to squeeze the last drop of performance from the op amp. You have two options: op amps internally compensated by the IC manufacturer, or op amps externally compensated by you. Compensation, except that done by the op amp manufacturer, must be done external to the IC. Surprisingly enough, internally compensated op amps require external compensation for demanding applications.

Compensation is achieved by adding external components that modify the circuit transfer function so that it becomes unconditionally stable. There are several different methods of compensating an op amp, and as you might suspect, there are pros and cons associated with each method of compensation. After the op amp circuit is compensated, it must be analyzed to determine the effects of compensation. The modifications that compensation have on the closed loop transfer function often determine which compensation scheme is most profitably employed.

6.2 Review of the Canonical Equations

A block diagram for a generalized feedback system is repeated in Figure 6–1. This simple block diagram is sufficient to determine the stability of any system.

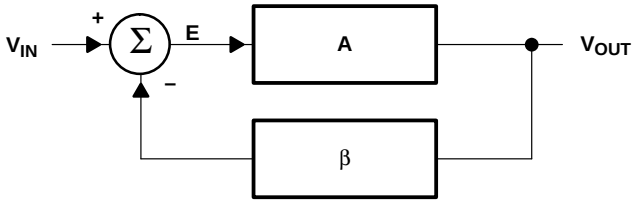

Figure 6–1. Feedback System Block Diagram

The output and error equation development is repeated below.

$$V_{OUT} = EA \tag{6–1}$$

$$E = V_{IN} - \beta V_{OUT} \tag{6–2}$$

Combining Equations 6–1 and 6–2 yields Equation 6–3:

$$\frac{V_{OUT}}{A} = V_{IN} - \beta V_{OUT} \tag{6–3}$$

Collecting terms yields Equation 6–4:

$$V_{OUT}\left(\frac{1}{A} + \beta\right) = V_{IN} \tag{6–4}$$

Rearranging terms yields the classic form of the feedback equation.

$$\frac{V_{OUT}}{V_{IN}} = \frac{A}{1 + A\beta} \tag{6–5}$$

Notice that Equation 6–5 reduces to Equation 6–6 when the quantity Aβ in Equation 6–5 becomes very large with respect to one. Equation 6–6 is called the ideal feedback equation because it depends on the assumption that Aβ >> 1, and it finds extensive use when amplifiers are assumed to have ideal qualities. Under the conditions that Aβ >>1, the system gain is determined by the feedback factor β. Stable passive circuit components are used to implement the feedback factor, thus the ideal closed loop gain is predictable and stable because β is predictable and stable.

$$\frac{V_{OUT}}{V_{IN}} = \frac{1}{\beta} \tag{6–6}$$

The quantity Aβ is so important that it has been given a special name, loop gain. Consider Figure 6–2; when the voltage inputs are grounded (current inputs are opened) and the loop is broken, the calculated gain is the loop gain, Aβ. Now, keep in mind that this is a mathematics of complex numbers, which have magnitude and direction. When the loop gain approaches minus one, or to express it mathematically $1 \angle -180°$, Equation 6–5 approaches infinity because $1/0 \Rightarrow \infty$. The circuit output heads for infinity as fast as it can

using the equation of a straight line. If the output were not energy limited the circuit would explode the world, but it is energy limited by the power supplies so the world stays intact.

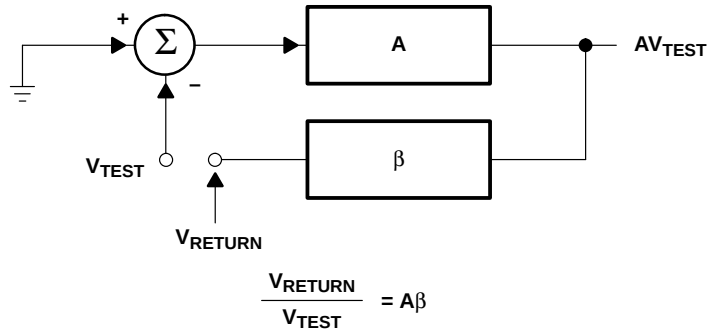

Figure 6–2. Feedback Loop Broken to Calculate Loop Gain

Active devices in electronic circuits exhibit nonlinear behavior when their output approaches a power supply rail, and the nonlinearity reduces the amplifier gain until the loop gain no longer equals $1\angle -180°$. Now the circuit can do two things: first, it could become stable at the power supply limit, or second, it can reverse direction (because stored charge keeps the output voltage changing) and head for the negative power supply rail.

The first state where the circuit becomes stable at a power supply limit is named lockup; the circuit will remain in the locked up state until power is removed. The second state where the circuit bounces between power supply limits is named oscillatory. Remember, the loop gain, $A\beta$, is the sole factor that determines stability for a circuit or system. Inputs are grounded or disconnected when the loop gain is calculated, so they have no effect on stability. The loop gain criteria is analyzed in depth later.

Equations 6–1 and 6–2 are combined and rearranged to yield Equation 6–7, which gives an indication of system or circuit error.

$$E = \frac{V_{IN}}{1 + A\beta} \tag{6–7}$$

First, notice that the error is proportional to the input signal. This is the expected result because a bigger input signal results in a bigger output signal, and bigger output signals require more drive voltage. Second, the loop gain is inversely proportional to the error. As the loop gain increases the error decreases, thus large loop gains are attractive for minimizing errors. Large loop gains also decrease stability, thus there is always a tradeoff between error and stability.

6.3 Noninverting Op Amps

A noninverting op amp is shown in Figure 6–3. The dummy variable, V_B, is inserted to make the calculations easier and a is the op amp gain.

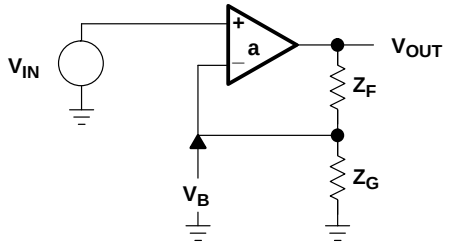

Figure 6–3. Noninverting Op Amp

Equation 6–8 is the amplifier transfer equation.

$$V_{OUT} = a\left(V_{IN} - V_B\right) \tag{6–8}$$

The output equation is developed with the aid of the voltage divider rule. Using the voltage divider rule assumes that the op amp impedance is low.

$$V_B = \frac{V_{OUT} Z_G}{Z_F + Z_G} \text{ for } I_B = 0 \tag{6–9}$$

Combining Equations 6–8 and 6–9 yields Equation 6–10.

$$V_{OUT} = aV_{IN} - \frac{aZ_G\, V_{OUT}}{Z_G + Z_F} \tag{6–10}$$

Rearranging terms in Equation 6–10 yields Equation 6–11, which describes the transfer function of the circuit.

$$\frac{V_{OUT}}{V_{IN}} = \frac{a}{1 + \frac{aZ_G}{Z_G + Z_F}} \tag{6–11}$$

Equation 6–5 is repeated as Equation 6–12 to make a term by term comparison of the equations easy.

$$\frac{V_{OUT}}{V_{IN}} = \frac{A}{1 + A\beta} \tag{6–12}$$

By virtue of the comparison we get Equation 6–13, which is the loop-gain equation for the noninverting op amp. The loop-gain equation determines the stability of the circuit. The

comparison also shows that the open loop gain, A, is equal to the op amp open loop gain, a, for the noninverting circuit.

$$A\beta = \frac{aZ_G}{Z_G + Z_F} \tag{6–13}$$

Equation 6–13 is also derived with the aid of Figure 6–4, which shows the open loop noninverting op amp.

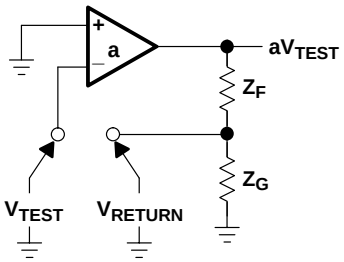

Figure 6–4. Open Loop Noninverting Op Amp

The test voltage, V_{TEST}, is multiplied by the op amp open loop gain to obtain the op amp output voltage, aV_{TEST}. The voltage divider rule is used to calculate Equation 6–15, which is identical to Equation 6–14 after some algebraic manipulation.

$$V_{RETURN} = \frac{aV_{TEST}\,Z_G}{Z_F + Z_G} \tag{6–14}$$

$$\frac{V_{RETURN}}{V_{TEST}} = A\beta = \frac{aZ_G}{Z_F + Z_G} \tag{6–15}$$

6.4 Inverting Op Amps

The inverting op amp circuit is shown in Figure 6–5. The dummy variable (V_A) is inserted to make the calculations easier, and a is the op amp open loop gain.

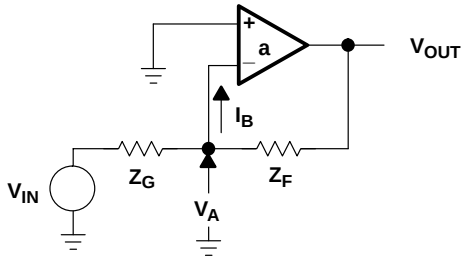

Figure 6–5. Inverting Op Amp

The transfer equation is given in Equation 6–16:

$$V_{OUT} = -aV_A \tag{6–16}$$

The node voltage (Equation 6–17) is obtained with the aid of superposition and the voltage divider rule. Equation 6–18 is obtained by combining Equations 6–16 and 6–17.

$$V_A = \frac{V_{IN} Z_F}{Z_G + Z_F} + \frac{V_{OUT} Z_G}{Z_G + Z_F} \quad \text{for } I_B = 0 \tag{6–17}$$

$$\frac{V_{OUT}}{V_{IN}} = \frac{\dfrac{-aZ_F}{Z_G + Z_F}}{1 + \dfrac{aZ_G}{Z_G + Z_F}} \tag{6–18}$$

Equation 6–16 is the transfer function of the inverting op amp. By virtue of the comparison between Equations 6–18 and 6–14, we get Equation 6–15 again, which is also the loop gain equation for the inverting op amp circuit. The comparison also shows that the open loop gain (A) is different from the op amp open loop gain (a) for the noninverting circuit.

The inverting op amp with the feedback loop broken is shown in Figure 6–6, and this circuit is used to calculate the loop-gain given in Equation 6–19.

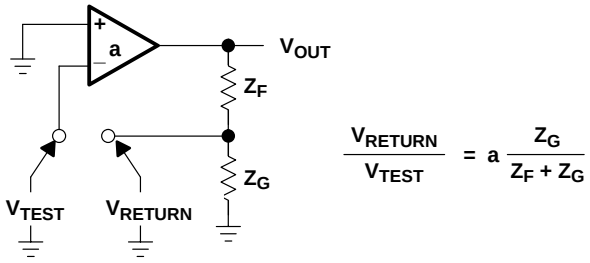

Figure 6–6. Inverting Op Amp: Feedback Loop Broken for Loop Gain Calculation

$$\frac{V_{RETURN}}{V_{TEST}} = \frac{aZ_G}{Z_G + Z_F} = A\beta \tag{6–19}$$

Several things must be mentioned at this point in the analysis. First, the transfer functions for the noninverting and inverting Equations, 6–13 and 6–18, are different. For a common set of Z_G and Z_F values, the magnitude and polarity of the gains are different. Second, the loop gain of both circuits, as given by Equations 6–15 and 6–19, is identical. Thus, the stability performance of both circuits is identical although their transfer equations are different. This makes the important point that *stability is not dependent on the circuit inputs*. Third, the A gain block shown in Figure 6–1 is different for each op amp circuit. By comparison of Equations 6–5, 6–11, and 6–18 we see that $A_{NON–INV} = a$ and $A_{INV} = aZ_F \div (Z_G + Z_F)$.

6.5 Differential Op Amps

The differential amplifier circuit is shown in Figure 6–7. The dummy variable, V_E, is inserted to make the calculations easier, and a is the open loop gain.

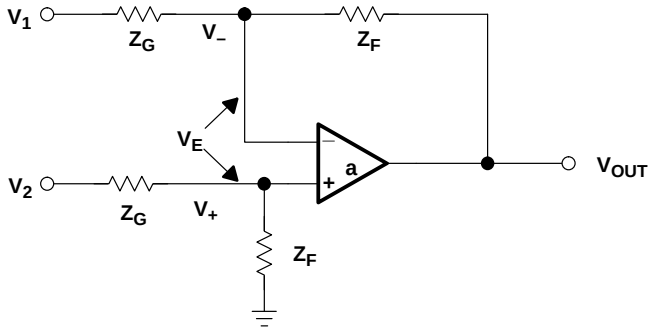

Figure 6–7. Differential Amplifier Circuit

Equation 6–20 is the circuit transfer equation.

$$V_{OUT} = a\,V_E = V_+ - V_- \tag{6–20}$$

The positive input voltage, V_+, is written in Equation 6–21 with the aid of superposition and the voltage divider rule.

$$V_+ = V_2 \frac{Z_F}{Z_F + Z_G} \tag{6–21}$$

The negative input voltage, V_-, is written in Equation 6–22 with the aid of superposition and the voltage divider rule.

$$V_- = V_1 \frac{Z_F}{Z_F + Z_G} - V_{OUT} \frac{Z_G}{Z_F + Z_G} \tag{6–22}$$

Combining Equations 6–20, 6–21, and 6–22 yields Equation 6–23.

$$V_{OUT} = a\left[\frac{V_2 Z_F}{Z_F + Z_G} - \frac{V_1 Z_F}{Z_F + Z_G} - \frac{V_{OUT} Z_G}{Z_F + Z_G}\right] \tag{6–23}$$

After algebraic manipulation, Equation 6–23 reduces to Equation 6–24.

$$\frac{V_{OUT}}{V_2 - V_1} = \frac{\frac{aZ_F}{Z_F + Z_G}}{1 + \frac{aZ_G}{Z_F + Z_G}} \tag{6–24}$$

The comparison method reveals that the loop gain as shown in Equation 6–25 is identical to that shown in Equations 6–13 and 6–19.

$$A\beta = \frac{aZ_G}{Z_G + Z_F} \tag{6–25}$$

Again, the loop gain, which determines stability, is only a function of the closed loop, and independent of the inputs.

Chapter 7

Voltage-Feedback Op Amp Compensation

Ron Mancini

7.1 Introduction

Voltage-feedback amplifiers (VFA) have been with us for about 60 years, and they have been problems for circuit designers since the first day. You see, the feedback that makes them versatile and accurate also has a tendency to make them unstable. The operational amplifier (op amp) circuit configuration uses a high-gain amplifier whose parameters are determined by external feedback components. The amplifier gain is so high that without these external feedback components, the slightest input signal would saturate the amplifier output. The op amp is in common usage, so this configuration is examined in detail, but the results are applicable to many other voltage-feedback circuits. Current-feedback amplifiers (CFA) are similar to VFAs, but the differences are important enough to warrant CFAs being handled separately.

Stability as used in electronic circuit terminology is often defined as achieving a nonoscillatory state. This is a poor, inaccurate definition of the word. Stability is a relative term, and this situation makes people uneasy because relative judgments are exhaustive. It is easy to draw the line between a circuit that oscillates and one that does not oscillate, so we can understand why some people believe that oscillation is a natural boundary between stability and instability.

Feedback circuits exhibit poor phase response, overshoot, and ringing long before oscillation occurs, and these effects are considered undesirable by circuit designers. This chapter is not concerned with oscillators; thus, relative stability is defined in terms of performance. By definition, when designers decide what tradeoffs are acceptable, they determine what the relative stability of the circuit is. A relative stability measurement is the damping ratio (ζ) and the damping ratio is discussed in detail in Reference 1. The damping ratio is related to phase margin, hence phase margin is another measure of relative stability. The most stable circuits have the longest response times, lowest bandwidth, highest accuracy, and least overshoot. The least stable circuits have the fastest response times, highest bandwidth, lowest accuracy, and some overshoot.

Op Amps left in their native state oscillate without some form of compensation. The first IC op amps were very hard to stabilize, but there were a lot of good analog designers

around in the ’60s, so we used them. Internally compensated op amps were introduced in the late ’60s in an attempt to make op amps easy for everyone to use. Unfortunately, internally compensated op amps sacrifice a lot of bandwidth and still oscillate under some conditions, so an understanding of compensation is required to apply op amps.

Internal compensation provides a worst-case trade-off between stability and performance. Uncompensated op amps require more attention, but they can do more work. Both are covered here.

Compensation is a process of applying a judicious patch in the form of an RC network to make up for a less than perfect op amp or circuit. There are many different problems that can introduce instability, thus there are many different compensation schemes.

7.2 Internal Compensation

Op amps are internally compensated to save external components and to enable their use by less knowledgeable people. It takes some measure of analog knowledge to compensate an analog circuit. Internally compensated op amps normally are stable when they are used in accordance with the applications instructions. Internally compensated op amps are not unconditionally stable. They are multiple pole systems, but they are internally compensated such that they appear as a single pole system over much of the frequency range. Internal compensation severely decreases the possible closed-loop bandwidth of the op amp.

Internal compensation is accomplished in several ways, but the most common method is to connect a capacitor across the collector-base junction of a voltage gain transistor (see Figure 7–1). The Miller effect multiplies the capacitor value by an amount approximately equal to the stage gain, thus the Miller effect uses small value capacitors for compensation.

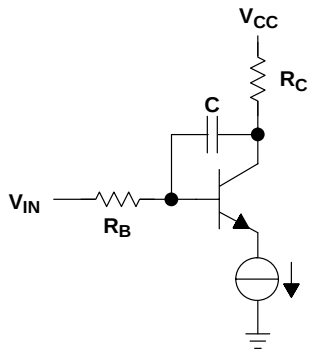

Figure 7–1. Miller Effect Compensation

Figure 7–2 shows the gain/phase diagram for an older op amp (TL03X). When the gain crosses the 0-dB axis (gain equal to one) the phase shift is approximately 108°, thus the op amp must be modeled as a second-order system because the phase shift is more than 90°.

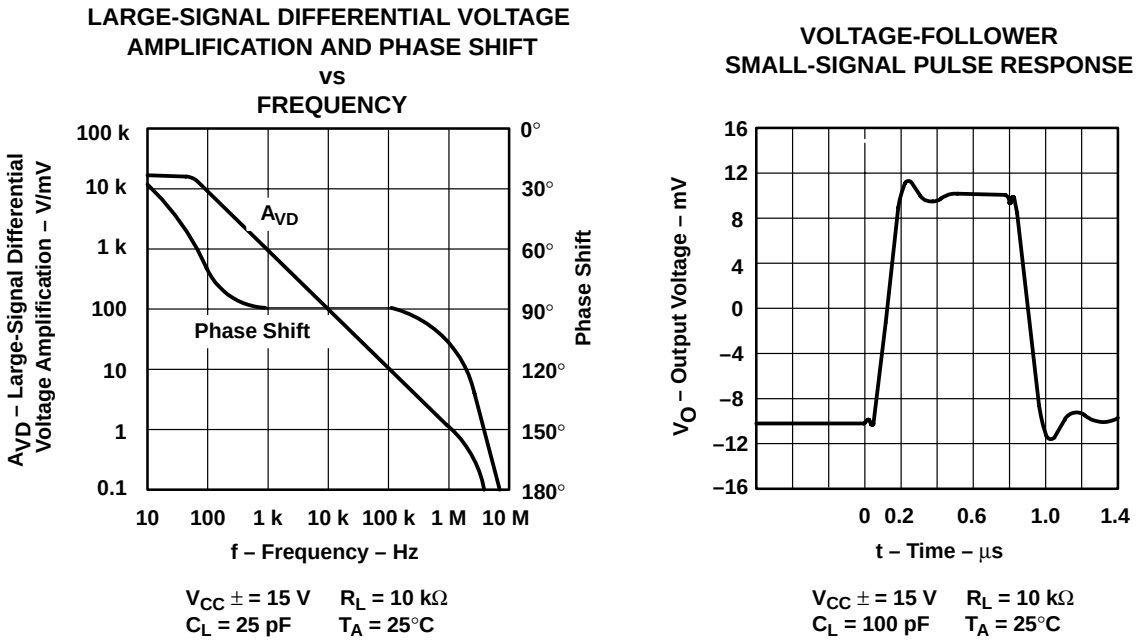

Figure 7–2. TL03X Frequency and Time Response Plots

This yields a phase margin of $\phi = 180° - 108° = 72°$, thus the circuit should be very stable. Referring to Figure 7–3, the damping ratio is one and the expected overshoot is zero. Figure 7–2 shows approximately 10% overshoot, which is unexpected, but inspecting Figure 7–2 further reveals that the loading capacitance for the two plots is different. The pulse response is loaded with 100 pF rather than 25 pF shown for the gain/phase plot, and this extra loading capacitance accounts for the loss of phase margin.

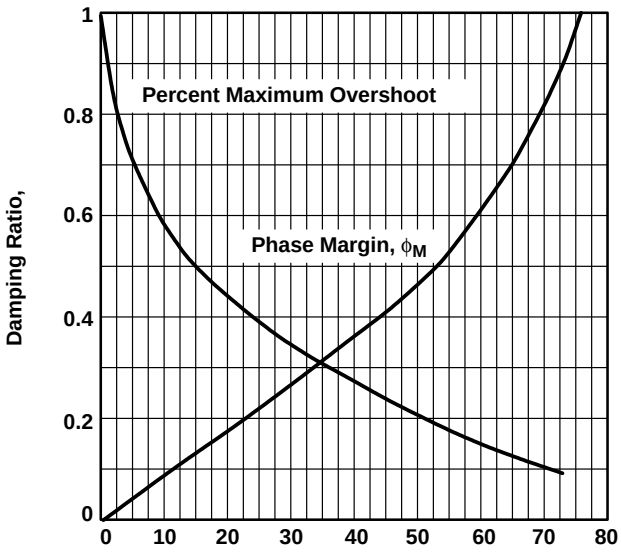

Figure 7–3. Phase Margin and Percent Overshoot Versus Damping Ratio

Why does the loading capacitance make the op amp unstable? Look closely at the gain/phase response between 1 MHz and 9 MHz, and observe that the gain curve changes slope drastically while the rate of phase change approaches 120°/decade. The radical gain/phase slope change proves that several poles are located in this area. The loading capacitance works with the op amp output impedance to form another pole, and the new pole reacts with the internal op amp poles. As the loading capacitor value is increased, its pole migrates down in frequency, causing more phase shift at the 0-dB crossover frequency. The proof of this is given in the TL03X data sheet where plots of ringing and oscillation versus loading capacitance are shown.

Figure 7–4 shows similar plots for the TL07X, which is the newer family of op amps. Notice that the phase shift is approximately 100° when the gain crosses the 0-dB axis. This yields a phase margin of 80°, which is close to unconditionally stable. The slope of the phase curve changes to 180°/decade about one decade from the 0-dB crossover point. The radical slope change causes suspicion about the 90° phase margin, furthermore the gain curve must be changing radically when the phase is changing radically. The gain/phase plot may not be totally false, but it sure is overly optimistic.

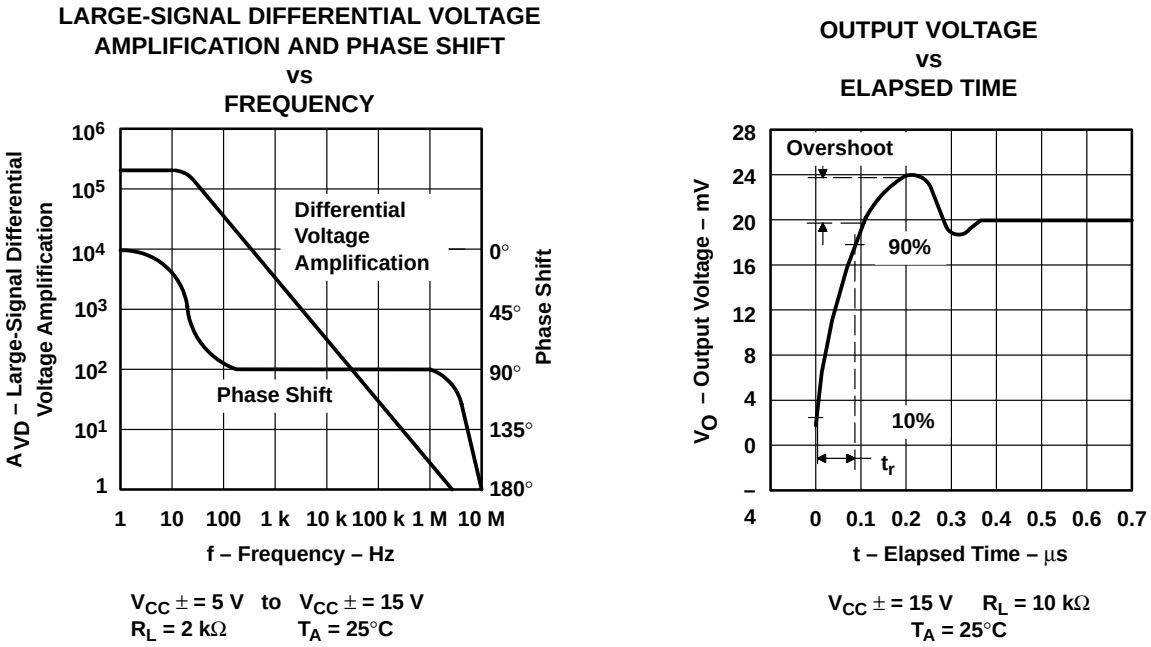

Figure 7–4. TL07X Frequency and Time Response Plots

The TL07X pulse response plot shows approximately 20% overshoot. There is no loading capacitance indicated on the plot to account for a seemingly unconditionally stable op amp exhibiting this large an overshoot. Something is wrong here: the analysis is wrong, the plots are wrong, or the parameters are wrong. Figure 7–5 shows the plots for the TL08X family of op amps, which are sisters to the TL07X family. The gain/phase curve and pulse response is virtually identical, but the pulse response lists a 100 pF loading capacitor. This little exercise illustrates three valuable points: first, if the data seems wrong it probably is wrong, second, even the factory people make mistakes, and third, the loading capacitor makes op amps ring, overshoot, or oscillate.

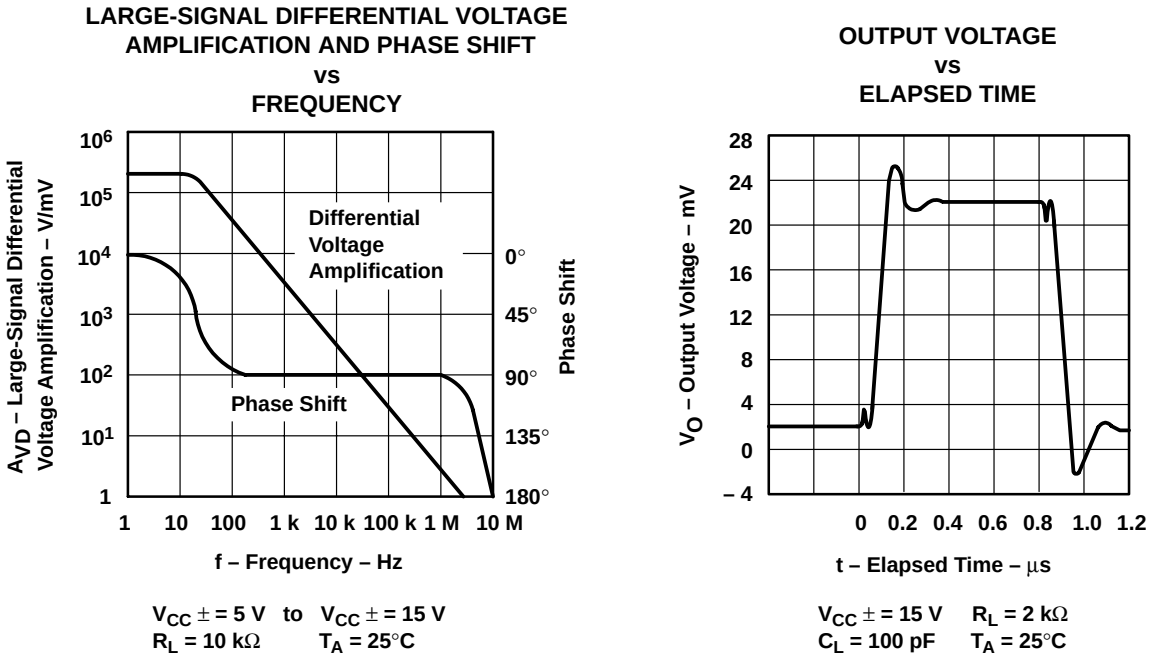

Figure 7–5. TL08X Frequency and Time Response Plots

The frequency and time-response plots for the TLV277X family of op amps is shown in Figures 7–6 and 7–7. First, notice that the information is more sophisticated because the phase response is given in degrees of phase margin; second, both gain/phase plots are done with substantial loading capacitors (600 pF), so they have some practical value; and third, the phase margin is a function of power supply voltage.

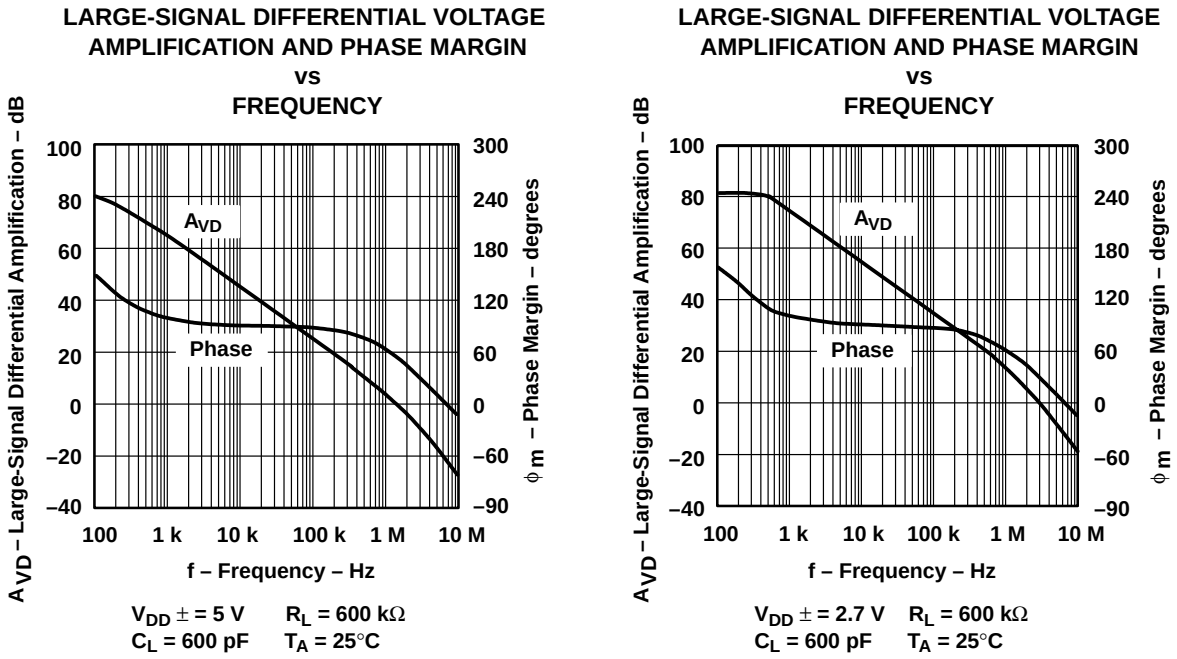

Figure 7–6. TLV277X Frequency Response Plots

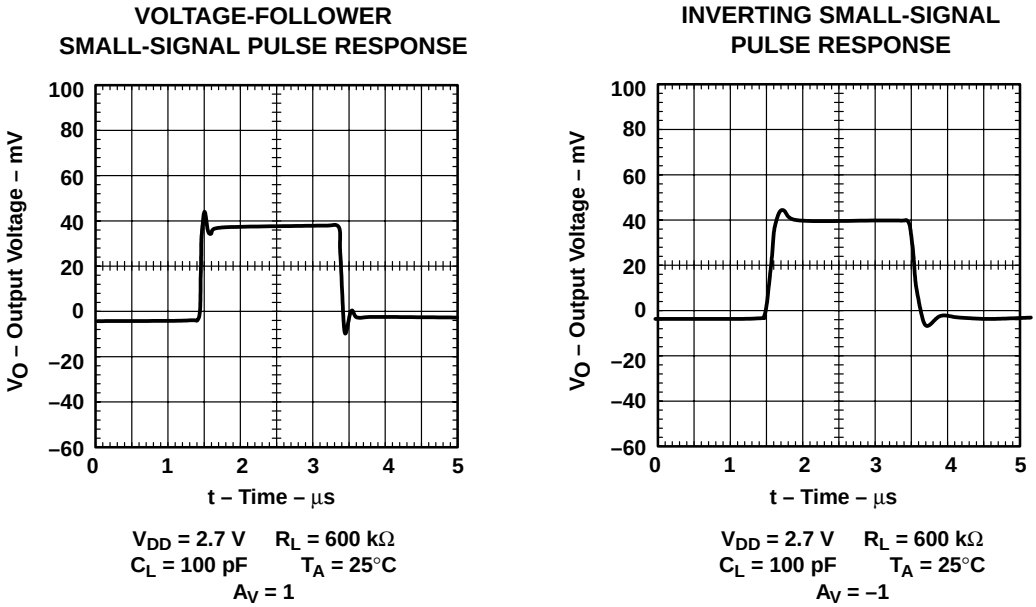

Figure 7–7. TLV227X Time Response Plots

At V_{CC} = 5 V, the phase margin at the 0-dB crossover point is 60°, while it is 30° at V_{CC} = 2.7 V. This translates into an expected overshoot of 18% at V_{CC} = 5 V, and 28% at V_{CC} = 2.7 V. Unfortunately the time response plots are done with 100-pF loading capacitance, hence we can not check our figures very well. The V_{CC} = 2.7 V overshoot is approximately 2%, and it is almost impossible to figure out what the overshoot would have been with a 600 pF loading capacitor. The small-signal pulse response is done with mV-signals, and that is a more realistic measurement than using the full signal swing.

Internally compensated op amps are very desirable because they are easy to use, and they do not require external compensation components. Their drawback is that the bandwidth is limited by the internal compensation scheme. The op amp open-loop gain eventually (when it shows up in the loop gain) determines the error in an op amp circuit. In a noninverting buffer configuration, the TL277X is limited to 1% error at 50 kHz (V_{CC} = 2.7 V) because the op amp gain is 40 dB at that point. Circuit designers can play tricks such as bypassing the op amp with a capacitor to emphasize the high-frequency gain, but the error is still 1%. Keep Equation 7–1 in mind because it defines the error. If the TLV277X were not internally compensated, it could be externally compensated for a lower error at 50 kHz because the gain would be much higher.

$$E = \frac{V_{IN}}{1 + A\beta} \tag{7–1}$$

7.3 External Compensation, Stability, and Performance

Nobody compensates an op amp just because it is there; they have a reason to compensate the op amp, and that reason is usually stability. They want the op amp to perform a function in a circuit where it is potentially unstable. Internally and noninternally compensated op amps are compensated externally because certain circuit configurations do cause oscillations. Several potentially unstable circuit configurations are analyzed in this section, and the reader can extend the external compensation techniques as required.

Other reasons for externally compensating op amps are noise reduction, flat amplitude response, and obtaining the highest bandwidth possible from an op amp. An op amp generates noise, and noise is generated by the system. The noise contains many frequency components, and when a high-pass filter is incorporated in the signal path, it reduces high frequency noise. Compensation can be employed to roll off the op amp's high frequency, closed-loop response, thus causing the op amp to act as a noise filter. Internally compensated op amps are modeled with a second order equation, and this means that the output voltage can overshoot in response to a step input. When this overshoot (or peaking) is undesirable, external compensation can increase the phase margin to 90° where there is no peaking. An uncompensated op amp has the highest bandwidth possible. External compensation is required to stabilize uncompensated op amps, but the compensation can be tailored to the specific circuit, thus yielding the highest possible bandwidth consistent with the pulse response requirements.

7.4 Dominant-Pole Compensation

We saw that capacitive loading caused potential instabilities, thus an op amp loaded with an output capacitor is a circuit configuration that must be analyzed. This circuit is called dominant pole compensation because if the pole formed by the op amp output impedance and the loading capacitor is located close to the zero frequency axis, it becomes dominant. The op amp circuit is shown in Figure 7–8, and the open loop circuit used to calculate the loop gain (Aβ) is shown in Figure 7–9.

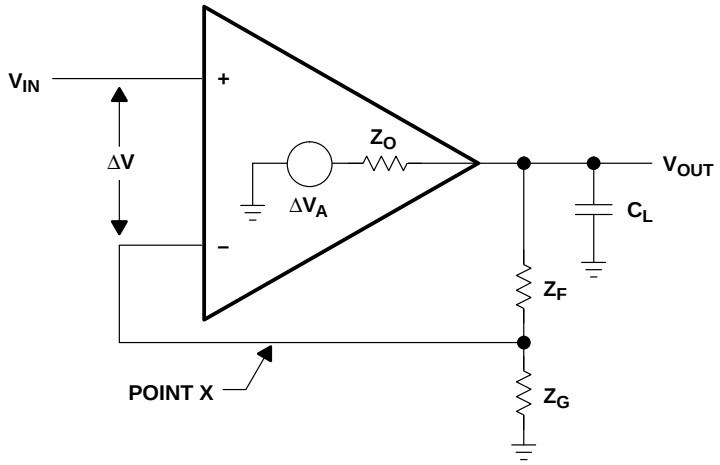

Figure 7–8. Capacitively-Loaded Op Amp

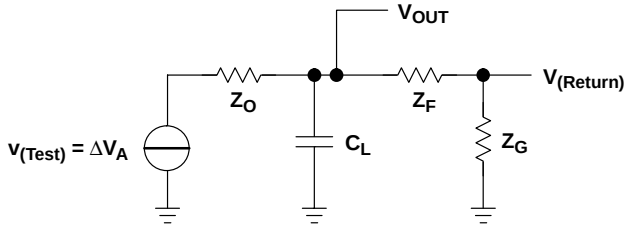

Figure 7–9. Capacitively-Loaded Op Amp With Loop Broken for Loop Gain (Aβ) Calculation

The analysis starts by looking into the capacitor and taking the Thevenin equivalent circuit.

$$V_{TH} = \frac{\Delta Va}{Z_O C_L s + 1} \tag{7–2}$$

$$Z_{TH} = \frac{Z_O}{Z_O C_L s + 1} \tag{7–3}$$

Then the output equation is written.

$$V_{RETURN} = \frac{V_{TH}Z_G}{Z_G + Z_F + Z_{TH}} = \frac{\Delta Va}{Z_O C_L s + 1}\left(\frac{Z_G}{Z_F + Z_G + \frac{Z_O}{Z_O C_L s + 1}}\right) \quad (7\text{–}4)$$

Rearranging terms yields Equation 7–5.

$$\frac{V_{RETURN}}{V_{TEST}} = A\beta = \frac{\frac{aZ_G}{Z_F + Z_G + Z_O}}{\frac{(Z_F + Z_G)Z_O C_L s}{Z_F + Z_G + Z_O} + 1} \quad (7\text{–}5)$$

When the assumption is made that $(Z_F + Z_G) >> Z_O$, Equation 7–5 reduces to Equation 7–6.

$$A\beta = \frac{aZ_G}{Z_F + Z_G}\left(\frac{1}{Z_O C_L s + 1}\right) \quad (7\text{–}6)$$

Equation 7–7 models the op amp as a second-order system. Hence, substituting the second-order model for *a* in Equation 7–6 yields Equation 7–8, which is the stability equation for the dominant-pole compensation circuit.

$$a = \frac{K}{(s + \tau_1)(s + \tau_2)} \quad (7\text{–}7)$$

$$A\beta = \frac{K}{(s + \tau_1)(s + \tau_2)} \frac{Z_G}{Z_F + Z_G} \frac{1}{Z_O C_L s + 1} \quad (7\text{–}8)$$

Several conclusions can be drawn from Equation 7–8 depending on the location of the poles. If the Bode plot of Equation 7–7, the op amp transfer function, looks like that shown in Figure 7–10, it only has 25° phase margin, and there is approximately 48% overshoot. When the pole introduced by Z_O and C_L moves towards the zero frequency axis it comes close to the τ_2 pole, and it adds phase shift to the system. Increased phase shift increases peaking and decreases stability. In the real world, many loads, especially cables, are capacitive, and an op amp like the one pictured in Figure 7–10 would ring while driving a capacitive load. The load capacitance causes peaking and instability in internally compensated op amps when the op amps do not have enough phase margin to allow for the phase shift introduced by the load.

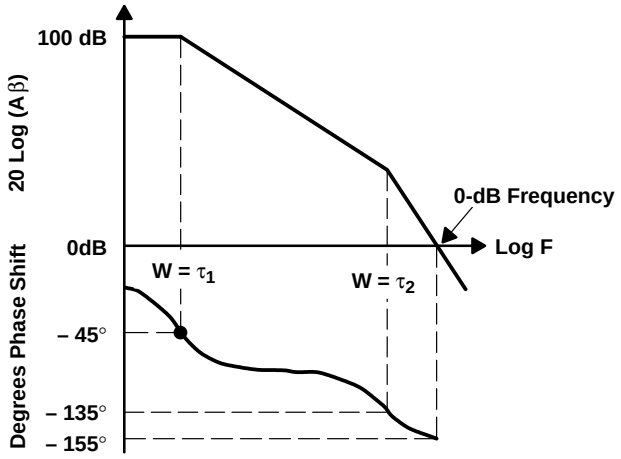

Figure 7–10. Possible Bode Plot of the Op Amp Described in Equation 7–7

Prior to compensation, the Bode plot of an uncompensated op amp looks like that shown in Figure 7–11. Notice that the break points are located close together thus accumulating about 180° of phase shift before the 0 dB crossover point; the op amp is not usable and probably unstable. Dominant pole compensation is often used to stabilize these op amps. If a dominant pole, in this case ω_D, is properly placed it rolls off the gain so that τ_1 introduces 45° phase at the 0-dB crossover point. After the dominant pole is introduced the op amp is stable with 45° phase margin, but the op amp gain is drastically reduced for frequencies higher than ω_D. This procedure works well for internally compensated op amps, but is seldom used for externally compensated op amps because inexpensive discrete capacitors are readily available.

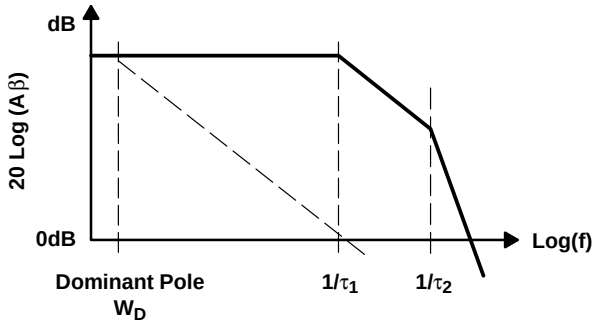

Figure 7–11. Dominant-Pole Compensation Plot

Assuming that $Z_O << Z_F$, the closed-loop transfer function is easy to calculate because C_L is enclosed in the feedback loop. The ideal closed-loop transfer equation is the same as Equation 6–11 for the noninverting op amp, and is repeated below as Equation 7–9.

$$\frac{V_{OUT}}{V_{IN}} = \frac{a}{1 + \frac{aZ_G}{Z_G + Z_F}} \tag{7–9}$$

When a $\Rightarrow \infty$ Equation 7–9 reduces to Equation 7–10.

$$\frac{V_{OUT}}{V_{IN}} = \frac{Z_F + Z_G}{Z_G} \tag{7–10}$$

As long as the op amp has enough compliance and current to drive the capacitive load, and Z_O is small, the circuit functions as though the capacitor was not there. When the capacitor becomes large enough, its pole interacts with the op amp pole causing instability. When the capacitor is huge, it completely kills the op amp's bandwidth, thus lowering the noise while retaining a large low-frequency gain.

7.5 Gain Compensation

When the closed-loop gain of an op amp circuit is related to the loop gain, as it is in voltage-feedback op amps, the closed-loop gain can be used to stabilize the circuit. This type of compensation can not be used in current-feedback op amps because the mathematical relationship between the loop gain and ideal closed-loop gain does not exist. The loop gain equation is repeated as Equation 7–11. Notice that the closed-loop gain parameters Z_G and Z_F are contained in Equation 7–11, hence the stability can be controlled by manipulating the closed-loop gain parameters.

$$A\beta = \frac{aZ_G}{Z_G + Z_F} \tag{7–11}$$

The original loop gain curve for a closed-loop gain of one is shown in Figure 7–12, and it is or comes very close to being unstable. If the closed-loop noninverting gain is changed to 9, then K changes from K/2 to K/10. The loop gain intercept on the Bode plot (Figure 7–12) moves down 14 dB, and the circuit is stabilized.

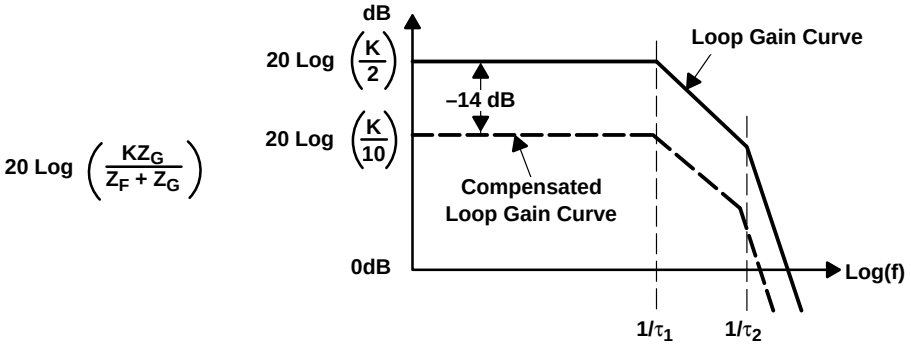

Figure 7–12. Gain Compensation

Gain compensation works for inverting or noninverting op amp circuits because the loop gain equation contains the closed-loop gain parameters in both cases. When the closed-loop gain is increased, the accuracy and the bandwidth decrease. As long as the application can stand the higher gain, gain compensation is the best type of compensation to use. Uncompensated versions of normally internally compensated op amps are offered for sale as stable op amps with minimum gain restrictions. As long as gain in the circuit you design exceeds the gain specified on the data sheet, this is economical and a safe mode of operation.

7.6 Lead Compensation

Sometimes lead compensation is forced on the circuit designer because of the parasitic capacitance associated with packaging and wiring op amps. Figure 7–13 shows the circuit for lead compensation; notice the capacitor in parallel with R_F. That capacitor is often made by parasitic wiring and the ground plane, and high frequency circuit designers go to great lengths to minimize or eliminate it. What is good in one sense is bad in another, because adding the parallel capacitor is a good way to stabilize the op amp and reduce noise. Let us analyze the stability first, and then we will analyze the closed-loop performance.

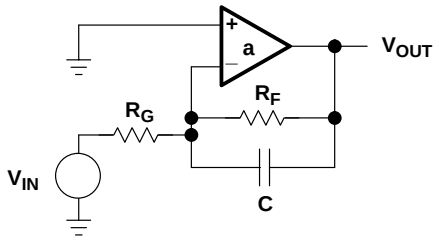

Figure 7–13. Lead-Compensation Circuit

The loop equation for the lead-compensation circuit is given by Equation 7–12.

$$A\beta = \left(\frac{R_G}{R_G + R_F}\right)\left(\frac{R_F Cs + 1}{R_G \parallel R_F Cs + 1}\right)\left[\frac{K}{(s + \tau_1)(s + \tau_2)}\right] \qquad (7\text{–}12)$$

The compensation capacitor introduces a pole and zero into the loop equation. The zero always occurs before the pole because $R_F > R_F || R_G$. When the zero is properly placed it cancels out the τ_2 pole along with its associated phase shift. The original transfer function is shown in Figure 7–14 drawn in solid lines. When the $R_F C$ zero is placed at $\omega = 1/\tau_2$, it cancels out the τ_2 pole causing the bode plot to continue on a slope of –20 dB/decade. When the frequency gets to $\omega = 1/(R_F||RG)C$, this pole changes the slope to –40 dB/decade. Properly placed, the capacitor aids stability, but what does it do to the closed-loop

transfer function? The equation for the inverting op amp closed-loop gain is repeated below.

$$\frac{V_{OUT}}{V_{IN}} = \frac{\frac{-aZ_F}{Z_G + Z_F}}{1 + \frac{aZ_G}{Z_G + Z_F}} \tag{7–13}$$

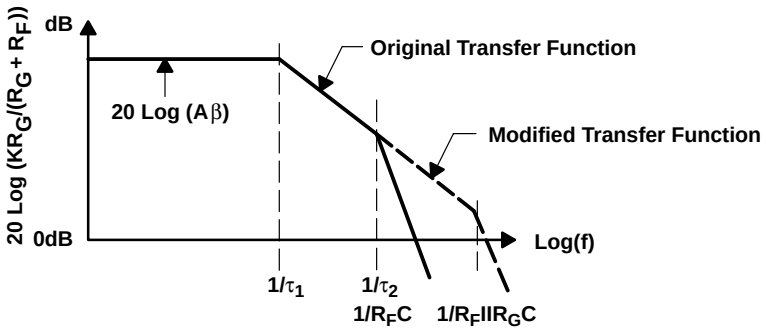

Figure 7–14. Lead-Compensation Bode Plot

When *a* approaches infinity, Equation 7–13 reduces to Equation 7–14.

$$\frac{V_{OUT}}{V_{IN}} = -\frac{Z_F}{Z_{IN}} \tag{7–14}$$

Substituting $R_F||C$ for Z_F and R_G for Z_G in Equation 7–14 yields Equation 7–15, which is the ideal closed-loop gain equation for the lead compensation circuit.

$$\frac{V_{OUT}}{V_{IN}} = -\frac{R_F}{R_G}\left(\frac{1}{R_F Cs + 1}\right) \tag{7–15}$$

The forward gain for the inverting amplifier is given by Equation 7–16. Compare Equation 7–13 with Equation 6–5 to determine A.

$$A = \frac{aZ_F}{Z_G + A_F} = \left(\frac{aR_F}{R_G + R_F}\right)\left(\frac{1}{R_F \parallel R_G Cs + 1}\right) \tag{7–16}$$

The op amp gain (a), the forward gain (A), and the ideal closed-loop gain are plotted in Figure 7–15. The op amp gain is plotted for reference only. The forward gain for the inverting op amp is not the op amp gain. Notice that the forward gain is reduced by the factor $R_F/(R_G + R_F)$, and it contains a high frequency pole. The ideal closed-loop gain follows the ideal curve until the $1/R_FC$ breakpoint (same location as $1/\tau_2$ breakpoint), and then it

slopes down at –20 dB/decade. Lead compensation sacrifices the bandwidth between the $1/R_FC$ breakpoint and the forward gain curve. The location of the $1/R_FC$ pole determines the bandwidth sacrifice, and it can be much greater than shown here. The pole caused by R_F, R_G, and C does not appear until the op amp's gain has crossed the 0-dB axis, thus it does not affect the ideal closed-loop transfer function.

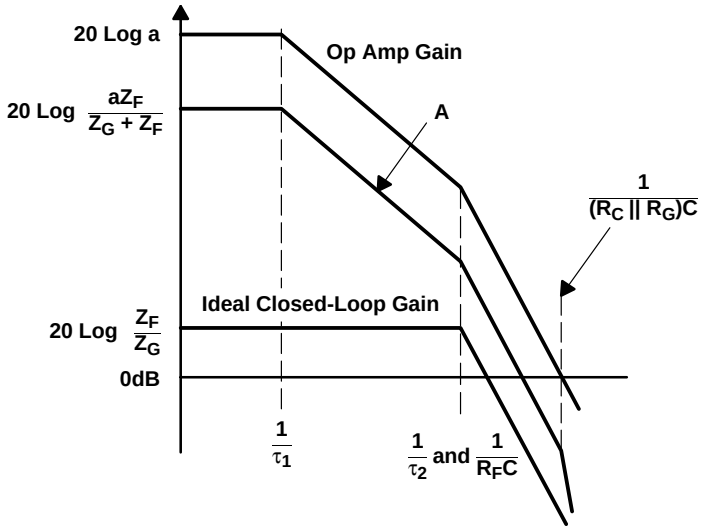

Figure 7–15. Inverting Op Amp With Lead Compensation

The forward gain for the noninverting op amp is *a*; compare Equation 6–11 to Equation 6–5. The ideal closed-loop gain is given by Equation 7–17.

$$\frac{V_{OUT}}{V_{IN}} = \frac{Z_F + Z_G}{Z_G} = \left(\frac{R_F + R_G}{R_G}\right)\left(\frac{R_F \parallel R_G Cs + 1}{R_F Cs + 1}\right) \qquad (7\text{–}17)$$

The plot of the noninverting op amp with lead compensation is shown in Figure 7–16. There is only one plot for both the op amp gain (a) and the forward gain (A), because they are identical in the noninverting circuit configuration. The ideal starts out as a flat line, but it slopes down because its closed-loop gain contains a pole and a zero. The pole always occurs closer to the low frequency axis because $R_F > R_F||R_G$. The zero flattens the ideal closed-loop gain curve, but it never does any good because it cannot fall on the pole. The pole causes a loss in the closed-loop bandwidth by the amount separating the closed-loop and forward gain curves.

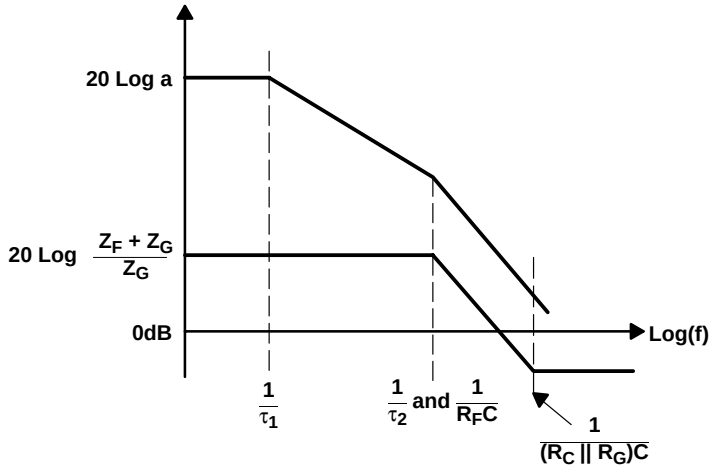

Figure 7–16. Noninverting Op Amp With Lead Compensation

Although the forward gain is different in the inverting and noninverting circuits, the closed-loop transfer functions take very similar shapes. This becomes truer as the closed-loop gain increases because the noninverting forward gain approaches the op amp gain. This relationship cannot be relied on in every situation, and each circuit must be checked to determine the closed-loop effects of the compensation scheme.

7.7 Compensated Attenuator Applied to Op Amp

Stray capacitance on op amp inputs is a problem that circuit designers are always trying to get away from because it decreases stability and causes peaking. The circuit shown in Figure 7–17 has some stray capacitance (C_G,) connected from the inverting input to ground. Equation 7–18 is the loop gain equation for the circuit with input capacitance.

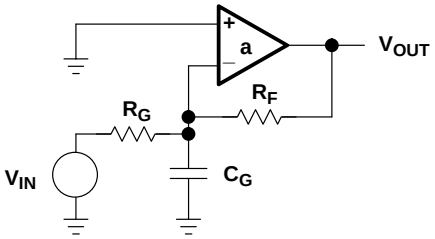

Figure 7–17. Op Amp With Stray Capacitance on the Inverting Input

$$A\beta = \left(\frac{R_G}{R_G + R_F}\right)\left(\frac{1}{R_G \| R_F Cs + 1}\right)\left[\frac{K}{(\tau_1 s + 1)(\tau_2 s + 1)}\right] \quad (7\text{–}18)$$

Op amps having high input and feedback resistors are subject to instability caused by stray capacitance on the inverting input. Referring to Equation 7–18, when the

$1/(R_F||R_GC_G)$ pole moves close to τ_2 the stage is set for instability. Reasonable component values for a CMOS op amp are R_F = 1 MΩ, R_G = 1 MΩ, and C_G = 10 pF. The resulting pole occurs at 318 kHz, and this frequency is lower than the breakpoint of τ_2 for many op amps. There is 90° of phase shift resulting from τ_1, the $1/(R_F||R_GC)$ pole adds 45° phase shift at 318 kHz, and τ_2 starts to add another 45° phase shift at about 600 kHz. This circuit is unstable because of the stray input capacitance. The circuit is compensated by adding a feedback capacitor as shown in Figure 7–18.

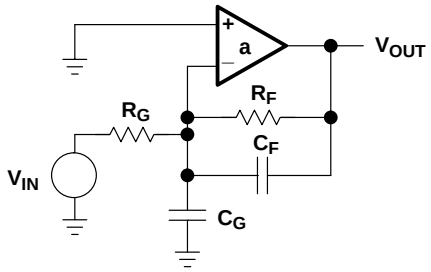

Figure 7–18. Compensated Attenuator Circuit

The loop gain with C_F added is given by Equation 7–19.

$$A\beta = \left[\frac{\frac{R_G}{R_GC_Gs+1}}{\frac{R_G}{R_GC_Gs+1}+\frac{R_F}{R_FC_Fs+1}}\right]\left[\frac{K}{(\tau_1 s+1)(\tau_2 s+1)}\right] \qquad (7\text{–}19)$$

If $R_GC_G = R_FC_F$ Equation 7–19 reduces to Equation 7–20.

$$A\beta = \left(\frac{R_G}{R_G+R_F}\right)\left[\frac{K}{(\tau_1 s+1)(\tau_2 s+1)}\right] \qquad (7\text{–}20)$$

The compensated attenuator Bode plot is shown in Figure 7–19. Adding the correct $1/R_FC_F$ breakpoint cancels out the $1/R_GC_G$ breakpoint; the loop gain is independent of the capacitors. Now is the time to take advantage of the stray capacitance. C_F can be formed by running a wide copper strip from the output of the op amp over the ground plane under R_F; do not connect the other end of this copper strip. The circuit is tuned by removing some copper (a razor works well) until all peaking is eliminated. Then measure the copper, and have an identical trace put on the printed-circuit board.

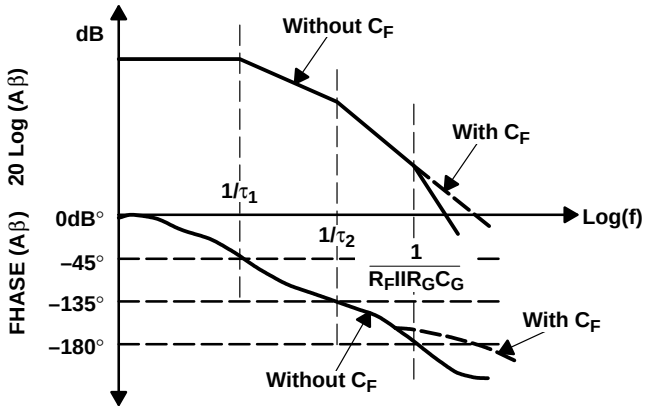

Figure 7–19. Compensated Attenuator Bode Plot

The inverting and noninverting closed-loop gain equations are a function of frequency. Equation 7–21 is the closed-loop gain equation for the inverting op amp. When $R_FC_F = R_GC_G$, Equation 7–21 reduces to Equation 7–22, which is independent of the breakpoint. This also happens to the noninverting op amp circuit. This is one of the few occasions when the compensation does not affect the closed-loop gain frequency response.

$$\frac{V_{OUT}}{V_{IN}} = - \frac{\frac{R_F}{R_FC_Fs+1}}{\frac{R_G}{R_GC_Gs+1}} \qquad (7–21)$$

When $R_FC_F = R_GC_G$ $\qquad \frac{V_{OUT}}{V_{IN}} = - \left(\frac{R_F}{R_G}\right)$ (7–22)

7.8 Lead-Lag Compensation

Lead-lag compensation stabilizes the circuit without sacrificing the closed-loop gain performance. It is often used with uncompensated op amps. This type of compensation provides excellent high-frequency performance. The circuit schematic is shown in Figure 7–20, and the loop gain is given by Equation 7–23.

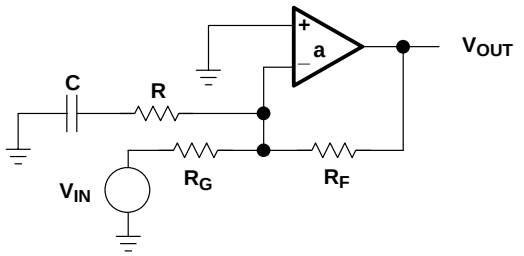

Figure 7–20. Lead-Lag Compensated Op Amp

$$A\beta = \frac{K}{(\tau_1 s + 1)(\tau_2 s + 1)} \frac{R_G}{R_G + R_F} \frac{RCs + 1}{\frac{(RR_G + RR_F + R_G R_F)}{(R_G + R_F)} Cs + 1} \quad (7\text{–}23)$$

Referring to Figure 7–21, a pole is introduced at $\omega = 1/RC$, and this pole reduces the gain 3 dB at the breakpoint. When the zero occurs prior to the first op amp pole it cancels out the phase shift caused by the $\omega = 1/RC$ pole. The phase shift is completely canceled before the second op amp pole occurs, and the circuit reacts as if the pole was never introduced. Nevertheless, $A\beta$ is reduced by 3 dB or more, so the loop gain crosses the 0-dB axis at a lower frequency. The beauty of lead lag compensation is that the closed-loop ideal gain is not affected as is shown below. The Thevenin equivalent of the input circuit is calculated in Equation 7–24, the circuit gain in terms of Thevenin equivalents is calculated in Equation 7–25, and the ideal closed-loop gain is calculated in Equation 7–26.

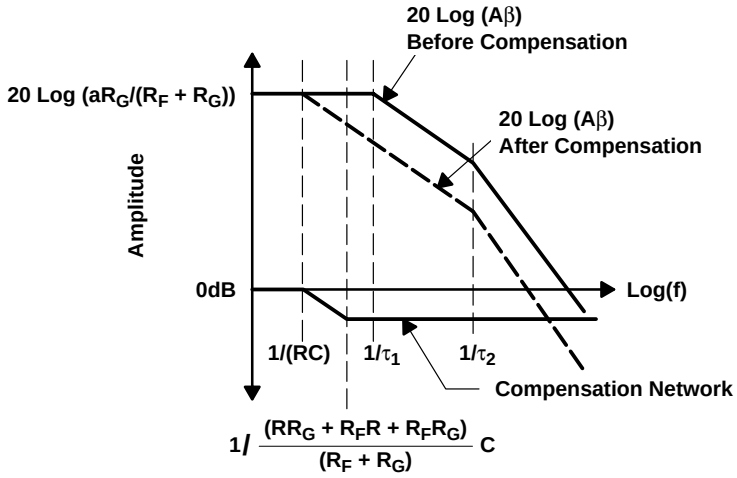

Figure 7–21. Bode Plot of Lead-Lag Compensated Op Amp

$$V_{TH} = V_{IN}\frac{R + \frac{1}{Cs}}{R + R_G + \frac{1}{Cs}} \qquad R_{TH} = \frac{R_G\left(R + \frac{1}{Cs}\right)}{R + R_G + \frac{1}{Cs}} \tag{7–24}$$

$$V_{OUT} = -V_{TH}\frac{R_F}{R_{TH}} \tag{7–25}$$

$$-\frac{V_{OUT}}{V_{IN}} = \frac{R + \frac{1}{Cs}}{R + R_G + \frac{1}{Cs}}\frac{R_F}{\frac{R_G\left(R+\frac{1}{Cs}\right)}{R+R_G+\frac{1}{Cs}}} = \frac{R_F}{R_G} \tag{7–26}$$

Equation 7–26 is intuitively obvious because the RC network is placed across a virtual ground. As long as the loop gain, Aβ, is large, the feedback will null out the closed-loop effect of RC, and the circuit will function as if it were not there. The closed-loop log plot of the lead-lag-compensated op amp is given in Figure 7–22. Notice that the pole and zero resulting from the compensation occur and are gone before the first amplifier poles come on the scene. This prevents interaction, but it is not required for stability.

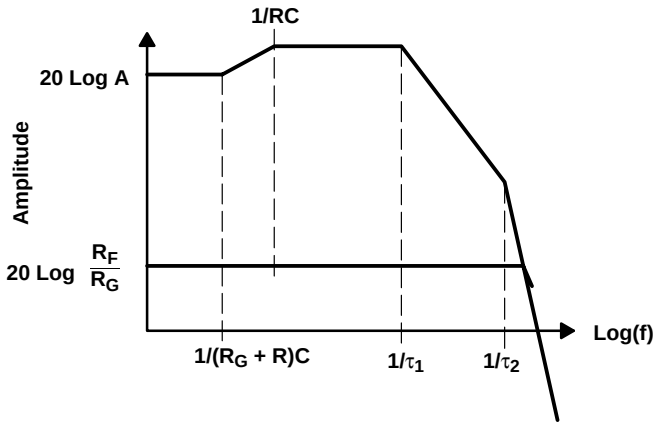

Figure 7–22. Closed-Loop Plot of Lead-Lag Compensated Op Amp

7.9 Comparison of Compensation Schemes

Internally compensated op amps can, and often do, oscillate under some circuit conditions. Internally compensated op amps need an external pole to get the oscillation or ringing started, and circuit stray capacitances often supply the phase shift required for instability. Loads, such as cables, often cause internally compensated op amps to ring severely.

Dominant pole compensation is often used in IC design because it is easy to implement. It rolls off the closed-loop gain early; thus, it is seldom used as an external form of compensation unless filtering is required. Load capacitance, depending on its pole location, usually causes the op amp to ring. Large load capacitance can stabilize the op amp because it acts as dominant pole compensation.

The simplest form of compensation is gain compensation. High closed-loop gains are reflected in lower loop gains, and in turn, lower loop gains increase stability. If an op amp circuit can be stabilized by increasing the closed-loop gain, do it.

Stray capacitance across the feedback resistor tends to stabilize the op amp because it is a form of lead compensation. This compensation scheme is useful for limiting the circuit bandwidth, but it decreases the closed-loop gain.

Stray capacitance on the inverting input works with the parallel combination of the feedback and gain setting resistors to form a pole in the Bode plot, and this pole decreases the circuit's stability. This effect is normally observed in high-impedance circuits built with CMOS op amps. Adding a feedback capacitor forms a compensated attenuator scheme that cancels out the input pole. The cancellation occurs when the input and feedback RC time constants are equal. Under the conditions of equal time constants, the op amp functions as though the stray input capacitance was not there. An excellent method of implementing a compensated attenuator is to build a stray feedback capacitor using the ground plane and a trace off the output node.

Lead-lag compensation stabilizes the op amp, and it yields the best closed-loop frequency performance. Contrary to some published opinions, no compensation scheme will increase the bandwidth beyond that of the op amp. Lead-lag compensation just gives the best bandwidth for the compensation.

7.10 Conclusions

The stability criteria often is not oscillation, rather it is circuit performance as exhibited by peaking and ringing.

The circuit bandwidth can often be increased by connecting an external capacitor in parallel with the op amp. Some op amps have hooks that enable a parallel capacitor to be connected in parallel with a portion of the input stages. This increases bandwidth because it shunts high frequencies past the low bandwidth g_m stages, but this method of compensation depends on the op amp type and manufacturer.

The compensation techniques given here are adequate for the majority of applications. When the new and challenging application presents itself, use the procedure outlined here to invent your own compensation technique.

Chapter 8

Current-Feedback Op Amp Analysis

Ron Mancini

8.1 Introduction

Current-feedback amplifiers (CFA) do not have the traditional differential amplifier input structure, thus they sacrifice the parameter matching inherent to that structure. The CFA circuit configuration prevents them from obtaining the precision of voltage-feedback amplifiers (VFA), but the circuit configuration that sacrifices precision results in increased bandwidth and slew rate. The higher bandwidth is relatively independent of closed-loop gain, so the constant gain-bandwidth restriction applied to VFAs is removed for CFAs. The slew rate of CFAs is much improved from their counterpart VFAs because their structure enables the output stage to supply slewing current until the output reaches its final value. In general, VFAs are used for precision and general purpose applications, while CFAs are restricted to high frequency applications above 100 MHz.

Although CFAs do not have the precision of their VFA counterparts, they are precise enough to be dc-coupled in video applications where dynamic range requirements are not severe. CFAs, unlike previous generation high-frequency amplifiers, have eliminated the ac coupling requirement; they are usually dc-coupled while they operate in the GHz range. CFAs have much faster slew rates than VFAs, so they have faster rise/fall times and less intermodulation distortion.

8.2 CFA Model

The CFA model is shown in Figure 8–1. The noninverting input of a CFA connects to the input of the input buffer, so it has very high impedance similar to that of a bipolar transistor noninverting VFA input. The inverting input connects to the input buffer's output, so the inverting input impedance is equivalent to a buffer's output impedance, which is very low. Z_B models the input buffer's output impedance, and it is usually less than 50 Ω. The input buffer gain, G_B, is as close to one as IC design methods can achieve, and it is small enough to neglect in the calculations.

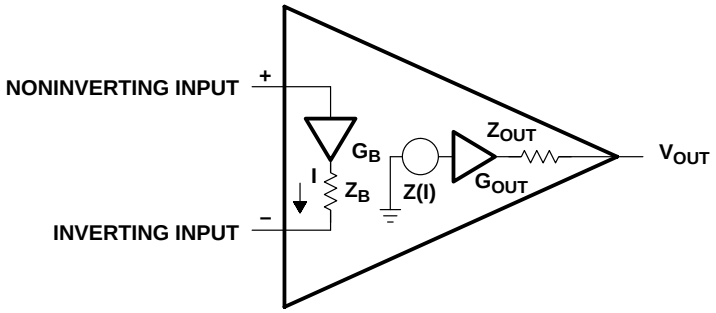

Figure 8–1. Current-Feedback Amplifier Model

The output buffer provides low output impedance for the amplifier. Again, the output buffer gain, G_{OUT}, is very close to one, so it is neglected in the analysis. The output impedance of the output buffer is ignored during the calculations. This parameter may influence the circuit performance when driving very low impedance or capacitive loads, but this is usually not the case. The input buffer's output impedance can't be ignored because affects stability at high frequencies.

The current-controlled current source, Z, is a transimpedance. The transimpedance in a CFA serves the same function as gain in a VFA; it is the parameter that makes the performance of the op amp dependent only on the passive parameter values. Usually the transimpedance is very high, in the MΩ range, so the CFA gains accuracy by closing a feedback loop in the same manner that the VFA does.

8.3 Development of the Stability Equation

The stability equation is developed with the aid of Figure 8–2. Remember, stability is independent of the input, and stability depends solely on the loop gain, Aβ. Breaking the loop at point *X*, inserting a test signal, V_{TI}, and calculating the return signal V_{TO} develops the stability equation.

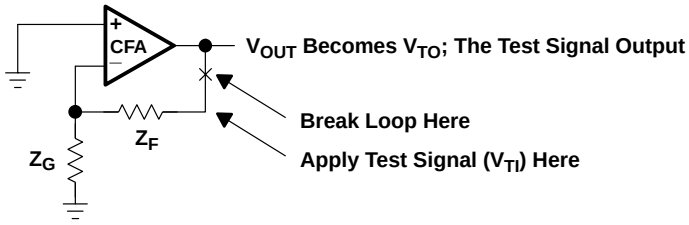

Figure 8–2. Stability Analysis Circuit

The circuit used for stability calculations is shown in Figure 8–3 where the model of Figure 8–1 is substituted for the CFA symbol. The input and output buffer gain, and output buffer

output impedance have been deleted from the circuit to simplify calculations. This approximation is valid for almost all applications.

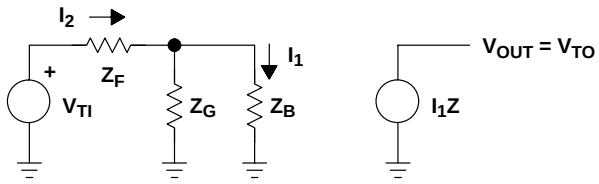

Figure 8–3. Stability Analysis Circuit

The transfer equation is given in Equation 8–1, and the Kirchoff"s law is used to write Equations 8–2 and 8–3.

$$V_{TO} = I_1 Z \tag{8–1}$$

$$V_{TI} = I_2\left(Z_F + Z_G \parallel Z_B\right) \tag{8–2}$$

$$I_2\left(Z_G \parallel Z_B\right) = I_1 Z_B \tag{8–3}$$

Equations 8–2 and 8–3 are combined to yield Equation 8–4.

$$V_{TI} = I_1\left(Z_F + Z_G \parallel Z_B\right)\left(1 + \frac{Z_B}{Z_G}\right) = I_1 Z_F\left(1 + \frac{Z_B}{Z_F \parallel Z_G}\right) \tag{8–4}$$

Dividing Equation 8–1 by Equation 8–4 yields Equation 8–5, and this is the open loop transfer equation. This equation is commonly known as the loop gain.

$$A\beta = \frac{V_{TO}}{V_{TI}} = \frac{Z}{\left(Z_F\left(1 + \frac{Z_B}{Z_F \parallel Z_G}\right)\right)} \tag{8–5}$$

8.4 The Noninverting CFA

The closed-loop gain equation for the noninverting CFA is developed with the aid of Figure 8–4, where external gain setting resistors have been added to the circuit. The buffers are shown in Figure 8–4, but because their gains equal one and they are included within the feedback loop, the buffer gain does not enter into the calculations.

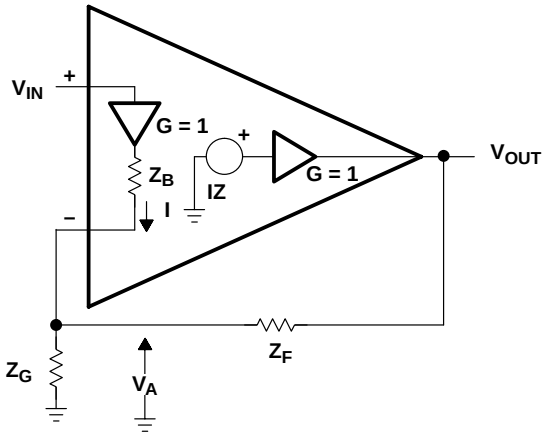

Figure 8–4. Noninverting CFA

Equation 8–6 is the transfer equation, Equation 8–7 is the current equation at the inverting node, and Equation 8–8 is the input loop equation. These equations are combined to yield the closed-loop gain equation, Equation 8–9.

$$V_{OUT} = IZ \tag{8–6}$$

$$I = \left(\frac{V_A}{Z_G}\right) - \left(\frac{V_{OUT} - V_A}{Z_F}\right) \tag{8–7}$$

$$V_A = V_{IN} - IZ_B \tag{8–8}$$

$$\frac{V_{OUT}}{V_{IN}} = \frac{\dfrac{Z\left(1 + \dfrac{Z_F}{Z_G}\right)}{Z_F\left(1 + \dfrac{Z_B}{Z_F \| Z_G}\right)}}{1 + \dfrac{Z}{Z_F\left(1 + \dfrac{Z_B}{Z_F \| Z_G}\right)}} \tag{8–9}$$

When the input buffer output impedance, Z_B, approaches zero, Equation 8–9 reduces to Equation 8–10.

$$\frac{V_{OUT}}{V_{IN}} = \frac{\frac{Z\left(1+\frac{Z_F}{Z_G}\right)}{Z_F}}{1+\frac{Z}{Z_F}} = \frac{1+\frac{Z_F}{Z_G}}{1+\frac{Z_F}{Z}} \qquad (8\text{–}10)$$

When the transimpedance, Z, is very high, the term Z_F/Z in Equation 8–10 approaches zero, and Equation 8–10 reduces to Equation 8–11; the ideal closed-loop gain equation for the CFA. The ideal closed-loop gain equations for the CFA and VFA are identical, and the degree to which they depart from ideal is dependent on the validity of the assumptions. The VFA has one assumption that the direct gain is very high, while the CFA has two assumptions, that the transimpedance is very high and that the input buffer output impedance is very low. As would be expected, two assumptions are much harder to meet than one, thus the CFA departs from the ideal more than the VFA does.

$$\frac{V_{OUT}}{V_{IN}} = 1 + \frac{Z_F}{Z_G} \qquad (8\text{–}11)$$

8.5 The Inverting CFA

The inverting CFA configuration is seldom used because the inverting input impedance is very low ($Z_B||Z_F + Z_G$). When Z_G is made dominant by selecting it as a high resistance value it overrides the effect of Z_B. Z_F must also be selected as a high value to achieve at least unity gain, and high values for Z_F result in poor bandwidth performance, as we will see in the next section. If Z_G is selected as a low value the frequency sensitive Z_B causes the gain to increase as frequency increases. These limitations restrict inverting applications of the inverting CFA.

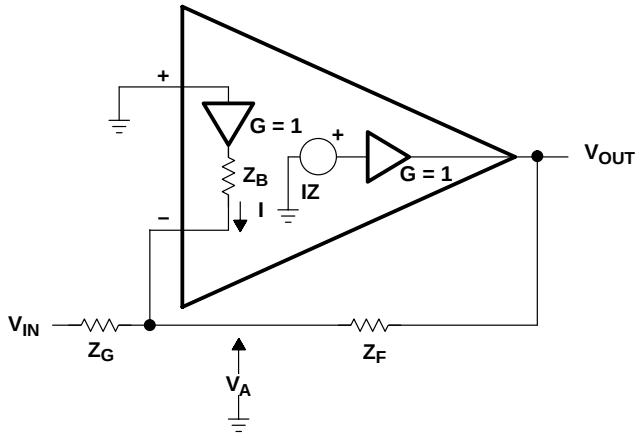

Figure 8–5. Inverting CFA

The current equation for the input node is written as Equation 8–12. Equation 8–13 defines the dummy variable, V_A, and Equation 8–14 is the transfer equation for the CFA. These equations are combined and simplified leading to Equation 8–15, which is the closed-loop gain equation for the inverting CFA.

$$I + \frac{V_{IN} - V_A}{Z_G} = \frac{V_A - V_{OUT}}{Z_F} \tag{8–12}$$

$$IZ_B = -V_A \tag{8–13}$$

$$IZ = V_{OUT} \tag{8–14}$$

$$\frac{V_{OUT}}{V_{IN}} = -\frac{\dfrac{Z}{Z_G\left(1 + \dfrac{Z_B}{Z_F \| Z_G}\right)}}{1 + \dfrac{Z}{Z_F\left(1 + \dfrac{Z_B}{Z_F \| Z_G}\right)}} \tag{8–15}$$

When Z_B approaches zero, Equation 8–15 reduces to Equation 8–16.

$$\frac{V_{OUT}}{V_{IN}} = -\frac{\dfrac{1}{Z_G}}{\dfrac{1}{Z} + \dfrac{1}{Z_F}} \tag{8–16}$$

When Z is very large, Equation 8–16 becomes Equation 8–17, which is the ideal closed-loop gain equation for the inverting CFA.

$$\frac{V_{OUT}}{V_{IN}} = -\frac{Z_F}{Z_G} \tag{8–17}$$

The ideal closed-loop gain equation for the inverting VFA and CFA op amps are identical. Both configurations have lower input impedance than the noninverting configuration has, but the VFA has one assumption while the CFA has two assumptions. Again, as was the case with the noninverting counterparts, the CFA is less ideal than the VFA because of the two assumptions. The zero Z_B assumption always breaks down in bipolar junction transistors as is shown later. The CFA is almost never used in the differential amplifier configuration because of the CFA's gross input impedance mismatch.

8.6 Stability Analysis

The stability equation is repeated as Equation 8–18.

$$A\beta = \frac{V_{TO}}{V_{TI}} = \frac{Z}{\left(Z_F\left(1 + \frac{Z_B}{Z_F \| Z_G}\right)\right)} \tag{8–18}$$

Comparing Equations 8–9 and 8–15 to Equation 8–18 reveals that the inverting and noninverting CFA op amps have identical stability equations. This is the expected result because stability of any feedback circuit is a function of the loop gain, and the input signals have no affect on stability. The two op amp parameters affecting stability are the transimpedance, Z, and the input buffer's output impedance, Z_B. The external components affecting stability are Z_G and Z_F. The designer controls the external impedance, although stray capacitance that is a part of the external impedance sometimes seems to be uncontrollable. Stray capacitance is the primary cause of ringing and overshoot in CFAs. Z and Z_B are CFA op amp parameters that can't be controlled by the circuit designer, so he has to live with them.

Prior to determining stability with a Bode plot, we take the log of Equation 8–18, and plot the logs (Equations 8–19 and 8–20) in Figure 8–6.

$$20 \text{ LOG } |A\beta| = 20 \text{ LOG } |Z| - 20 \text{ LOG } \left|Z_F\left(1 + \frac{Z_B}{Z_F \| Z_B}\right)\right| \tag{8–19}$$

$$\phi = \text{TANGENT}^{-1}(A\beta) \tag{8–20}$$

This enables the designer to add and subtract components of the stability equation graphically.

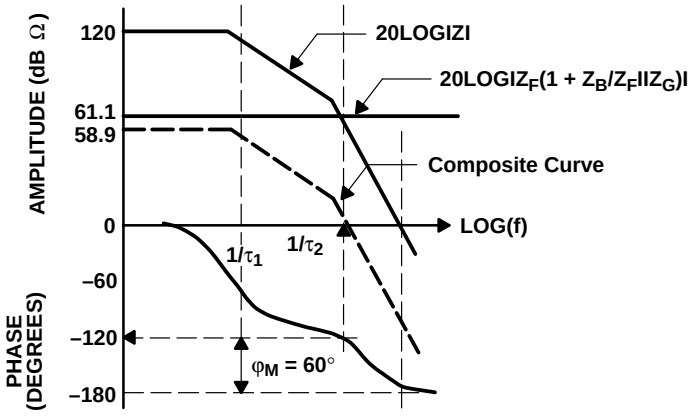

Figure 8–6. Bode Plot of Stability Equation

The plot in Figure 8–6 assumes typical values for the parameters:

$$Z = \frac{1M\Omega}{(1 + \tau_1 S)(1 + \tau_2 S)} \tag{8–21}$$

$$Z_B = 70\Omega \tag{8–22}$$

$$Z_G = Z_F = 1k\Omega \tag{8–23}$$

The transimpedance has two poles and the plot shows that the op amp will be unstable without the addition of external components because 20 LOG|Z| crosses the 0-dB axis after the phase shift is 180°. Z_F, Z_B, and Z_G reduce the loop gain 61.1 dB, so the circuit is stable because it has 60°-phase margin. Z_F is the component that stabilizes the circuit. The parallel combination of Z_F and Z_G contribute little to the phase margin because Z_B is very small, so Z_B and Z_G have little effect on stability.

The manufacturer determines the optimum value of R_F during the characterization of the IC. Referring to Figure 8–6, it is seen that when R_F exceeds the optimum value recommended by the IC manufacturer, stability increases. The increased stability has a price called decreased bandwidth. Conversely, when R_F is less than the optimum value recommended by the IC manufacturer, stability decreases, and the circuit response to step inputs is overshoot or possibly ringing. Sometimes the overshoot associated with less than optimum R_F is tolerated because the bandwidth increases as R_F decreases. The peaked response associated with less than optimum values of R_F can be used to compensate for cable droop caused by cable capacitance.

When $Z_B = 0\ \Omega$ and $Z_F = R_F$ the loop gain equation is; $A\beta = Z/R_F$. Under these conditions Z and R_F determine stability, and a value of R_F can always be found to stabilize the circuit. The transimpedance and feedback resistor have a major impact on stability, and the input buffer's output impedance has a minor effect on stability. Since Z_B increases with an increase in frequency, it tends to increase stability at higher frequencies. Equation 8–18 is rewritten as Equation 8–24, but it has been manipulated so that the ideal closed-loop gain is readily apparent.

$$A\beta = \frac{Z}{Z_F + Z_B\left(1 + \frac{R_F}{R_G}\right)} \tag{8–24}$$

The closed-loop ideal gain equation (inverting and noninverting) shows up in the denominator of Equation 8–24, so the closed-loop gain influences the stability of the op amp. When Z_B approaches zero, the closed-loop gain term also approaches zero, and the op amp becomes independent of the ideal closed-loop gain. Under these conditions R_F determines stability, and the bandwidth is independent of the closed-loop gain. Many people claim that the CFA bandwidth is independent of the gain, and that claim's validity is dependent on the ratios Z_B/Z_F being very low.

Z_B is important enough to warrant further investigation, so the equation for Z_B is given below.

$$Z_B \cong h_{ib} + \frac{R_B}{\beta_0 + 1}\left(\frac{1 + \frac{s\beta_0}{\omega_T}}{1 + \frac{S\beta_0}{(\beta_0+1)\omega_T}}\right) \quad (8\text{–}25)$$

At low frequencies $h_{ib} = 50\ \Omega$ and $R_B/(\beta_0+1) = 25\ \Omega$, so $Z_B = 75\ \Omega$. Z_B varies in accordance with Equation 8–25 at high frequencies. Also, the transistor parameters in Equation 8–25 vary with transistor type; they are different for NPN and PNP transistors. Because Z_B is dependent on the output transistors being used, and this is a function of the quadrant the output signal is in, Z_B has an extremely wide variation. Z_B is a small factor in the equation, but it adds a lot of variability to the current-feedback op amp.

8.7 Selection of the Feedback Resistor

The feedback resistor determines stability, and it affects closed-loop bandwidth, so it must be selected very carefully. Most CFA IC manufacturers employ applications and product engineers who spend a great deal of time and effort selecting R_F. They measure each noninverting gain with several different feedback resistors to gather data. Then they pick a compromise value of R_F that yields stable operation with acceptable peaking, and that value of R_F is recommended on the data sheet for that specific gain. This procedure is repeated for several different gains in anticipation of the various gains their customer applications require (often G = 1, 2, or 5). When the value of R_F or the gain is changed from the values recommended on the data sheet, bandwidth and/or stability is affected.

When the circuit designer must select a different R_F value from that recommended on the data sheet he gets into stability or low bandwidth problems. Lowering R_F decreases stability, and increasing R_F decreases bandwidth. What happens when the designer needs to operate at a gain not specified on the data sheet? The designer must select a new value of R_F for the new gain, but there is no guarantee that new value of R_F is an optimum value. One solution to the R_F selection problem is to assume that the loop gain, $A\beta$, is a linear function. Then the assumption can be made that $(A\beta)_1$ for a gain of one equals $(A\beta)_N$ for a gain of N, and that this is a linear relationship between stability and gain. Equations 8–26 and 8–27 are based on the linearity assumption.

$$\frac{Z}{Z_{F1} + Z_B\left(1 + \frac{Z_{F1}}{Z_{G1}}\right)} = \frac{Z}{Z_{FN} + Z_B\left(1 + \frac{Z_{FN}}{Z_{GN}}\right)} \quad (8\text{–}26)$$

$$Z_{FN} = Z_{F1} + Z_B\left(\left(1 + \frac{Z_{F1}}{Z_{G1}}\right) - \left(1 + \frac{Z_{FN}}{Z_{GN}}\right)\right) \quad (8\text{–}27)$$

Equation 8–27 leads one to believe that a new value for Z_F can easily be chosen for each new gain. This is not the case in the real world; the assumptions don't hold up well enough to rely on them. When you change to a new gain not specified on the data sheet, Equation 8–27, at best, supplies a starting point for R_F, but you must test to determine the final value of R_F.

When the R_F value recommended on the data sheet can't be used, an alternate method of selecting a starting value for R_F is to use graphical techniques. The graph shown in Figure 8–7 is a plot of the typical 300-MHz CFA data given in Table 8–1.

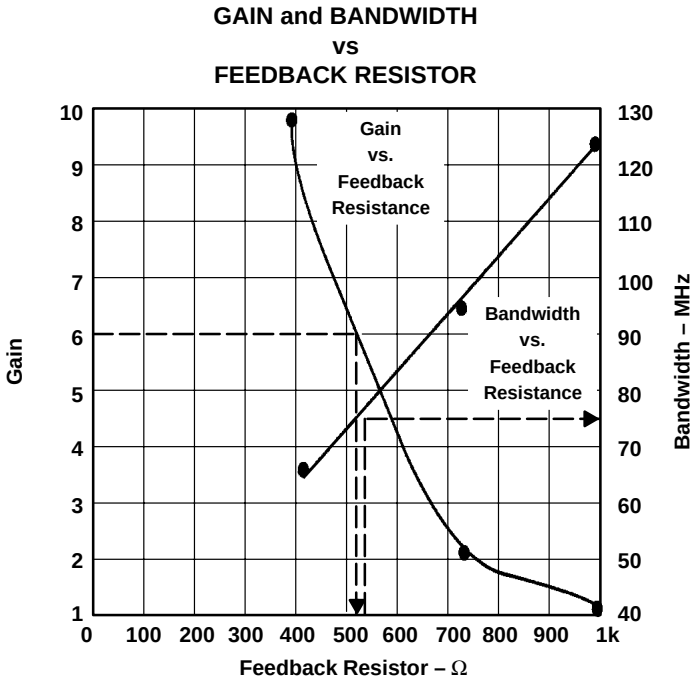

Figure 8–7. Plot of CFA R_F, G, and BW

Table 8–1. Data Set for Curves in Figure 8–7

GAIN (A_{CL})	R_F (Ω)	BANDWIDTH (MHz)
+ 1	1000	125
+ 2	681	95
+ 10	383	65

Enter the graph at the new gain, say A_{CL} = 6, and move horizontally until you reach the intersection of the gain versus feedback resistance curve. Then drop vertically to the resistance axis and read the new value of R_F (500 Ω in this example). Enter the graph at the new value of R_F, and travel vertically until you intersect the bandwidth versus feedback resistance curve. Now move to the bandwidth axis to read the new bandwidth (75 MHz in this example). As a starting point you should expect to get approximately 75 MHz BW with a gain of 6 and R_F = 500 Ω. Although this technique yields more reliable solutions than Equation 8–27 does, op amp peculiarities, circuit board stray capacitances, and wiring make extensive testing mandatory. The circuit must be tested for performance and stability at each new operating point.

8.8 Stability and Input Capacitance

When designer lets the circuit board introduce stray capacitance on the inverting input node to ground, it causes the impedance Z_G to become reactive. The new impedance, Z_G, is given in Equation 8–28, and Equation 8–29 is the stability equation that describes the situation.

$$Z_G = \frac{R_G}{1 + R_G C_G s} \tag{8–28}$$

$$A\beta = \frac{Z}{Z_B + \dfrac{Z_F}{Z_G^2 + Z_B Z_G}} \tag{8–29}$$

$$A\beta = \frac{Z}{R_F\left(1 + \dfrac{R_B}{R_F \| R_G}\right)\left(1 + R_B \parallel R_F \parallel R_G C_G s\right)} \tag{8–30}$$

Equation 8–29 is the stability equation when Z_G consists of a resistor in parallel with stray capacitance between the inverting input node and ground. The stray capacitance, C_G, is a fixed value because it is dependent on the circuit layout. The pole created by the stray capacitance is dependent on R_B because it dominates R_F and R_G. R_B fluctuates with manufacturing tolerances, so the $R_B C_G$ pole placement is subject to IC manufacturing tolerances. As the $R_B C_G$ combination becomes larger, the pole moves towards the zero fre-

quency axis, lowering the circuit stability. Eventually it interacts with the pole contained in Z, $1/\tau_2$, and instability results.

The effects of stray capacitance on CFA closed-loop performance are shown in Figure 8–8.

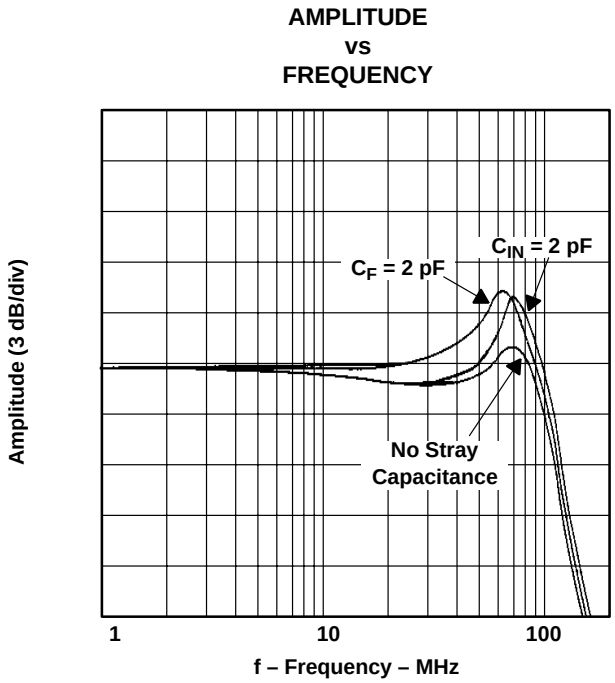

Figure 8–8. Effects of Stray Capacitance on CFAs

Notice that the introduction of C_G causes more than 3 dB peaking in the CFA frequency response plot, and it increases the bandwidth about 18 MHz. Two picofarads are not a lot of capacitance because a sloppy layout can easily add 4 or more picofarads to the circuit.

8.9 Stability and Feedback Capacitance

When a stray capacitor is formed across the feedback resistor, the feedback impedance is given by Equation 8–31. Equation 8–32 gives the loop gain when a feedback capacitor has been added to the circuit.

$$Z_F = \frac{R_F}{1 + R_F C_F s} \tag{8–31}$$

$$A\beta = \frac{Z\left(1 + R_F C_F s\right)}{R_F\left(1 + \frac{R_B}{R_F \| R_G}\right)\left(1 + R_B \| R_F \| R_G C_F s\right)} \tag{8–32}$$

This loop gain transfer function contains a pole and zero, thus, depending on the pole/zero placement, oscillation can result. The Bode plot for this case is shown in Figure 8–9. The original and composite curves cross the 0-dB axis with a slope of –40 dB/decade, so either curve can indicate instability. The composite curve crosses the 0-dB axis at a higher frequency than the original curve, hence the stray capacitance has added more phase shift to the system. The composite curve is surely less stable than the original curve. Adding capacitance to the inverting input node or across the feedback resistor usually results in instability. R_B largely influences the location of the pole introduced by C_F, thus here is another case where stray capacitance leads to instability.

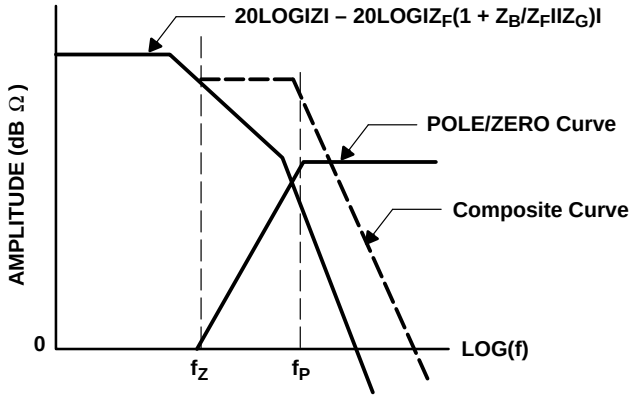

Figure 8–9. Bode Plot with C_F

Figure 8–8 shows that C_F = 2 pF adds about 4 dB of peaking to the frequency response plot. The bandwidth increases about 10 MHz because of the peaking. C_F and C_G are the major causes of overshoot, ringing, and oscillation in CFAs, and the circuit board layout must be carefully done to eliminate these stray capacitances.

8.10 Compensation of C_F and C_G

When C_F and C_G both are present in the circuit they may be adjusted to cancel each other out. The stability equation for a circuit with C_F and C_G is Equation 8–33.

$$A\beta = \frac{Z\left(1 + R_F C_F s\right)}{R_F\left(1 + \frac{R_B}{R_F \| R_G}\right)\left(R_B \| R_F \| R_G \left(C_F + C_G\right) s + 1\right)} \quad (8\text{–}33)$$

If the zero and pole in Equation 8–33 are made to cancel each other, the only poles remaining are in Z. Setting the pole and zero in Equation 8–33 equal yields Equation 8–34 after some algebraic manipulation.

$$R_F C_F = C_G\left(R_G \| R_B\right) \quad (8\text{–}34)$$

R_B dominates the parallel combination of R_B and R_G, so Equation 8–34 is reduced to Equation 8–35.

$$R_F C_F = R_B C_G \quad (8\text{–}35)$$

R_B is an IC parameter, so it is dependent on the IC process. R_B it is an important IC parameter, but it is not important enough to be monitored as a control variable during the manufacturing process. R_B has widely spread, unspecified parameters, thus depending on R_B for compensation is risky. Rather, the prudent design engineer assures that the circuit will be stable for any reasonable value of R_B, and that the resulting frequency response peaking is acceptable.

8.11 Summary

Constant gain-bandwidth is not a limiting criterion for the CFA, so the feedback resistor is adjusted for maximum performance. Stability is dependent on the feedback resistor; as R_F is decreased, stability is decreased, and when R_F goes to zero the circuit becomes unstable. As R_F is increased stability increases, but the bandwidth decreases.

The inverting input impedance is very high, but the noninverting input impedance is very low. This situation precludes CFAs from operation in the differential amplifier configuration. Stray capacitance on the inverting input node or across the feedback resistor always leads to peaking, usually to ringing, and sometimes to oscillations. A prudent circuit designer scans the PC board layout for stray capacitances, and he eliminates them. Breadboarding and lab testing are a must with CFAs. The CFA performance can be improved immeasurably with a good layout, good decoupling capacitors, and low inductance components.

Chapter 9

Voltage- and Current-Feedback Op Amp Comparison

Ron Mancini and James Karki

9.1 Introduction

The name, operational amplifier, was given to voltage-feedback amplifiers (VFA) when they were the only op amps in existence. These new (they were new in the late ’40s) amplifiers could be programmed with external components to perform various math operations on a signal; thus, they were nicknamed op amps. Current-feedback amplifiers (CFA) have been around approximately twenty years, but their popularity has only increased in the last several years. Two factors limiting the popularity of CFAs is their application difficulty and lack of precision.

The VFA is familiar component, and there are several variations of internally compensated VFAs that can be used with little applications work. Because of its long history, the VFA comes in many varieties and packages, so there are VFAs applicable to almost any job. VFA bandwidth is limited, so it can’t function as well at high signal frequencies as the CFA can. For now, the signal frequency and precision separates the applications of the two op amp configurations.

The VFA has some other redeeming virtues, such as excellent precision, that makes it the desirable amplifier in low frequency applications. Many functions other than signal amplification are accomplished at low frequencies, and functions like level-shifting a signal require precision. Fortunately, precision is not required in most high frequency applications where amplification or filtering of a signal is predominant, so CFAs are suitable to high frequency applications. The lack of precision coupled with the application difficulties prevents the CFA from replacing the VFA.

9.2 Precision

The long-tailed pair input structure gives the VFA its precision; the long-tailed pair is shown in Figure 9–1

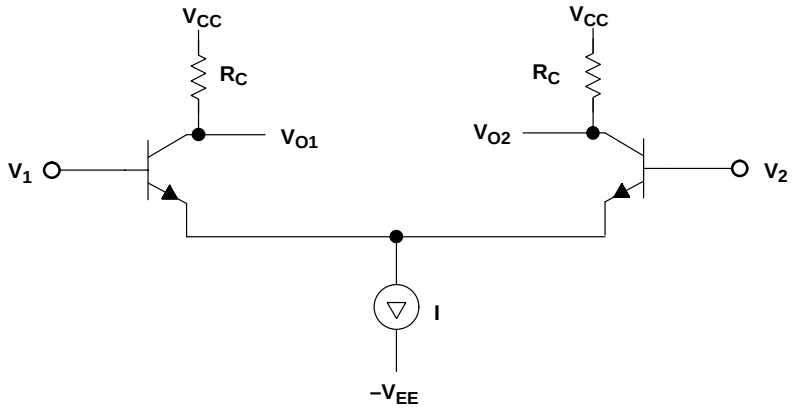

Figure 9–1. Long-Tailed Pair

The transistors, Q_1 and Q_2, are very carefully matched for initial and drift tolerances. Careful attention is paid to detail in the transistor design to insure that parameters like current gain, β, and base-emitter voltage, V_{BE}, are matched between the input transistors, Q_1 and Q_2. When $V_{B1} = V_{B2,}$ the current, I, splits equally between the transistors, and $V_{O1} = V_{O2}$. As long as the transistor parameters are matched, the collector currents stay equal. The slightest change of V_{B1} with respect to V_{B2} causes a mismatch in the collector currents and a differential output voltage $|V_{B1}–V_{B2}|$.

When temperature or other outside influences change transistor parameters like current gain or base-emitter voltage, as long as the change is equal, it causes no change in the differential output voltage. IC designers go to great lengths to ensure that transistor parameter changes due to external influences do not cause a differential output voltage change. Now, the slightest change in either base voltage causes a differential output voltage change, and gross changes in external conditions do not cause a differential output voltage change. This is the formula for a precision amplifier because it can amplify small input changes while ignoring changes in the parameters or ambient conditions.

This is a simplified explanation, and there are many different techniques used to ensure transistor matching. Some of the techniques used to match input transistors are parameter trimming, special layout techniques, thermal balancing, and symmetrical layouts. The long-tailed pair is an excellent circuit configuration for obtaining precision in the input circuit, but the output circuit has one fault. The output circuit collector impedance has to be high to achieve high gain in the first stage. High impedance coupled with the Miller capacitance discussed in Chapter 7 forms a quasidominant pole compensation circuit that has poor high frequency response.

The noninverting input of the CFA (see Figure 9–2) connects to a buffer input inside the op amp. The inverting input of the CFA connects to a buffer output inside the CFA. Buffer inputs and outputs have dramatically different impedance levels, so any matching becomes a moot point. The buffer can't reject common-mode voltages introduced by parameter drifts because it has no common-mode rejection capability. The input current causes a voltage drop across the input buffer's output impedance, R_B, and there is no way that this voltage drop can be distinguished from an input signal.

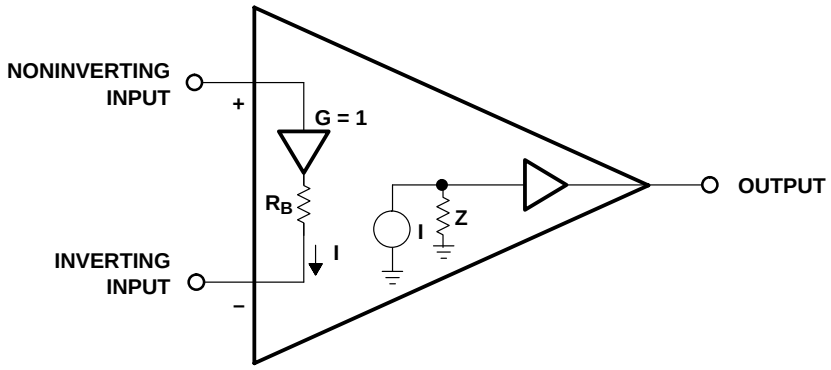

Figure 9–2. Ideal CFA

The CFA circuit configuration was selected for high frequency amplification because it has current-controlled gain and a current-dominant input. Being a current device, the CFA does not have the Miller-effect problem that the VFA has. The input structure of the CFA sacrifices precision for bandwidth, but CFAs achieve usable bandwidths ten times the usable VFA bandwidth.

9.3 Bandwidth

The bandwidth of a circuit is defined by high frequency errors. When the gain falls off at high frequencies unequal frequency amplification causes the signal to become distorted. The signal loses its high frequency components; an example of high frequency signal degradation is a square wave with sharp corners that is amplified and turned into slump cornered semi sine wave. The error equation for any feedback circuit is repeated in Equation 9–1.

$$E = \frac{V_{IN}}{1 + A\beta} \tag{9–1}$$

This equation is valid for any feedback circuit, so it applies equally to a VFA or a CFA. The loop gain equation for any VFA is repeated as Equation 9–2.

$$A\beta = \frac{aR_G}{R_F + R_G} \tag{9–2}$$

Equation 9–2 is rewritten below as Equations 9–3 and 9–4 for the noninverting and inverting circuits respectively. In each case, the symbol G_{CLNI} and G_{CLI} represent the closed loop gain for the noninverting and inverting circuits respectively.

$$A\beta = \frac{a}{\frac{R_F + R_G}{R_G}} = \frac{a}{G_{CLNI}} \tag{9–3}$$

$$A\beta = \frac{a}{\frac{R_F + R_G}{R_G}} = \frac{a}{G_{CLI} + 1} \tag{9–4}$$

In both cases the loop gain decreases as the closed loop gain increases, thus all VFA errors increase as the closed loop gain increases. The error increase is mathematically coupled to the closed loop gain equation, so there is no working around this fact. For the VFA, effective bandwidth decreases as the closed loop gain increases because the loop gain decreases as the closed loop gain increases.

A plot of the VFA loop gain, closed loop gain, and error is given in Figure 9–3. Referring to Figure 9–3, the direct gain, A, is the op amp open loop gain, a, for a noninverting op amp. The direct gain for an inverting op amp is $(a(Z_F/(Z_G + Z_F)))$. The Miller effect causes the direct gain to fall off at high frequencies, thus error increases as frequency increases because the effective loop gain decreases. At a given frequency, the error also increases when the closed loop gain is increased.

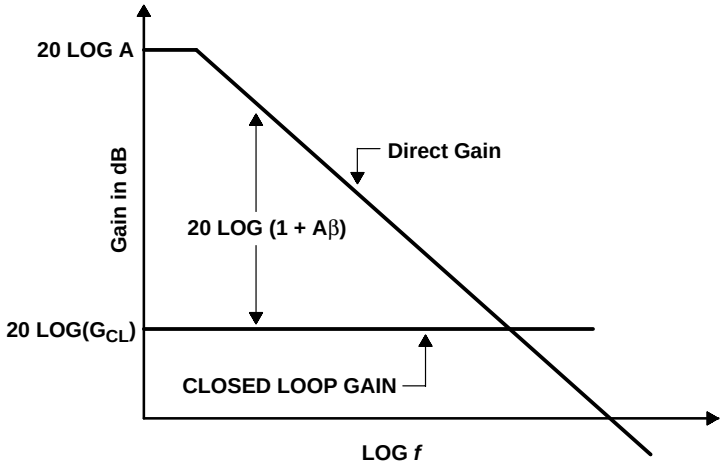

Figure 9–3. VFA Gain versus Frequency

The CFA is a current operated device; hence, it not nearly as subject to the Miller effect resulting from stray capacitance as the VFA is. The absence of the Miller effect enables the CFA's frequency response to hold up far better than the VFA's does. A plot of the CFA loop gain, transimpedance, and error is given in Figure 9–4. Notice that the transimpedance stays at the large low frequency intercept value until much higher frequencies than the VFA does.

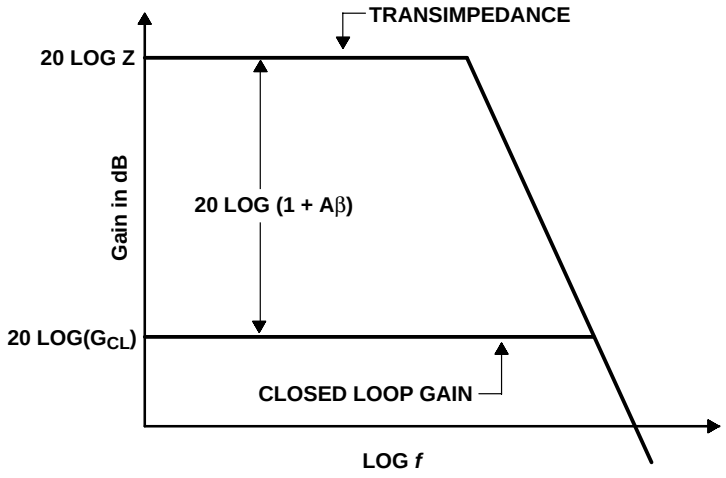

Figure 9–4. CFA Gain vs Frequency

The loop gain equation for the CFA is repeated here as Equation 9–5.

$$A\beta = \frac{Z}{R_F\left(1 + \frac{R_B}{R_F \| R_G}\right)} \tag{9–5}$$

When the input buffer output resistance approaches zero, Equation 9–5 reduces to Equation 9–6.

$$A\beta = \frac{Z}{R_F} \tag{9–6}$$

Equation 9–6 shows that the closed-loop gain has no effect on the loop gain when R_B = 0, so under ideal conditions one would expect the transimpedance to fall off with a zero slope. Figure 9–4 shows that there is a finite slope, but much less than that of a VFA, and the slope is caused by R_B not being equal to zero. For example, R_B is usually 50 Ω when R_F = 1000 Ω at A_{CL} = 1. If we let $R_F = R_G$, then $R_F||R_G$ = 500 Ω, and $R_B/R_F||R_G$ = 50/500 = 0.1.

Substituting this value into Equation 9–6 yields Equation 9–7, and Equation 9–7 is almost identical to Equation 9–6. R_B does cause some interaction between the loop gain and the transimpedance, but because the interaction is secondary the CFA gain falls off with a faster slope.

$$A\beta = \frac{Z}{1.1\ R_F} \tag{9–7}$$

The direct gain of a VFA starts falling off early, often at 10 Hz or 100 Hz, but the transimpedance of a CFA does not start falling off until much higher frequencies. The VFA is constrained by the gain-bandwidth limitation imposed by the closed loop gain being incorporated within the loop gain. The CFA, with the exception of the effects of R_B, does not have this constraint. This adds up to the CFA being the superior high frequency amplifier.

9.4 Stability

Stability in a feedback system is defined by the loop gain, and no other factor, including the inputs or type of inputs, affects stability. The loop gain for a VFA is given in Equation 9–2. Examining Equation 9–2 we see that the stability of a VFA is depends on two items; the op amp transfer function, a, and the gain setting components, Z_F/Z_G.

The op amp contains many poles, and if it is not internally compensated, it requires external compensation. The op amp always has at least one dominant pole, and the most phase margin that an op amp has is 45°. Phase margins beyond 60° are a waste of op amp bandwidth. When poles and zeros are contained in Z_F and Z_G, they can compensate for the op amp phase shift or add to its instability. In any case, the gain setting components always affect stability. When the closed-loop gain is high, the loop gain is low, and low loop gain circuits are more stable than high loop gain circuits.

Wiring the op amp to a printed circuit board always introduces components formed from stray capacitance and inductance. Stray inductance becomes dominant at very high frequencies, hence, in VFAs, it does not interfere with stability as much as it does with signal handling properties. Stray capacitance causes stability to increase or decrease depending on its location. Stray capacitance from the input or output lead to ground induces instability, while the same stray capacitance in parallel with the feedback resistor increases stability.

The loop gain for a CFA with no input buffer output impedance, R_B, is given in Equation 9–6. Examining Equation 9–6 we see that the stability of a CFA depends on two items: the op amp transfer function, Z, and the gain setting component, Z_F. The op amp contains many poles, thus they require external compensation. Fortunately, the external compensation for a CFA is done with Z_F. The factory applications engineer does extensive testing to determine the optimum value of R_F for a given gain. This value should be used in all applications at that gain, but increased stability and less peaking can be obtained by increasing R_F. Essentially this is sacrificing bandwidth for lower frequency performance, but in applications not requiring the full bandwidth, it is a wise tradeoff.

The CFA stability is not constrained by the closed-loop gain, thus a stable operating point can be found for any gain, and the CFA is not limited by the gain-bandwidth constraint. If the optimum feedback resistor value is not given for a specific gain, one must test to find the optimum feedback resistor value.

Stray capacitance from any node to ground adversely affects the CFA performance. Stray capacitance of just a couple of pico Farads from any node to ground causes 3 dB or more of peaking in the frequency response. Stray capacitance across the CFA feedback resistor, quite unlike that across the VFA feedback resistor, always causes some form of instability. CFAs are applied at very high frequencies, so the printed circuit board inductance associated with the trace length and pins adds another variable to the stability equation. Inductance cancels out capacitance at some frequency, but this usually seems to happen in an adverse manner. The wiring of VFAs is critical, but the wiring of CFAs is a science. Stay with the layout recommended by the manufacturer whenever possible.

9.5 Impedance

The input impedance of a VFA and CFA differ dramatically because their circuit configurations are very different. The VFA input circuit is a long-tailed pair, and this configuration gives the advantages that both input impedances match. Also, the input signal looks into an emitter-follower circuit that has high input impedance. The emitter-follower input impedance is $\beta(r_e + R_E)$ where R_E is a discrete emitter resistor. At low input currents, R_E is very high and the input impedance is very high. If a higher input impedance is required, the op amp uses a Darlington circuit that has an input impedance of $\beta^2(r_e + R_E)$.

So far, the implicit assumption is that the VFA is made with a bipolar semiconductor process. Applications requiring very high input impedances often use a FET process. Both BIFET and CMOS processes offer very high input impedance in any long-tailed pair configuration. It is easy to get matched and high input impedances at the amplifier inputs. Do not confuse the matched input impedance at the op amp leads with the overall circuit input impedance. The input impedance looking into the inverting input is R_G, and the impedance looking into the noninverting input is the input impedance of the op amp. While these are two different impedances, they are mismatched because of the circuit not the op amp.

The CFA has a radically different input structure that causes it to have mismatched input impedances. The noninverting input lead of the CFA is the input of a buffer that has very high input impedance. The inverting input lead is the output of a buffer that has very low impedance. There is no possibility that these two input impedances can be matched.

Again, because of the circuit, the inverting circuit input impedance is R_G. Once the circuit gain is fixed, the only way to increase R_G is to increase R_F. But, R_F is determined by a tradeoff between stability and bandwidth. The circuit gain and bandwidth requirements fix R_F, hence there is no room to further adjust R_F to raise the resistance of R_G. If the manufacturer's data sheet says that $R_F = 100\ \Omega$ when the closed-loop gain is two, then

R_G = 100 Ω or 50 Ω depending on the circuit configuration. This sets the circuit input impedance at 100 Ω. This analysis is not entirely accurate because R_B adds to the input impedance, but this addition is very small and dependent on IC parameters. CFA op amp circuits are usually limited to noninverting voltage applications, but they serve very well in inverting applications that are current-driven.

The CFA is limited to the bipolar process because that process offers the highest speed. The option of changing process to BIFET or CMOS to gain increased input impedance is not attractive today. Although this seems like a limiting factor, it is not because CFAs are often used in low impedance where the inputs are terminated in 50 Ω or 75 Ω. Also, most very high-speed applications require low impedances.

9.6 Equation Comparison

The pertinent VFA and CFA equations are repeated in Table 9–1. Notice that the ideal closed-loop gain equations for the inverting and noninverting circuits are identical. The ideal equations for the VFA depend on the op amp gain, a, being very large thus making Aβ large compared to one. The CFA needs two assumptions to be valid to obtain the ideal equations. First, the ideal equations for the CFA depend on the op amp transimpedance, Z, being very large thus making Aβ large compared to one. Second, R_B must be very small compared to $Z_F||Z_G$.

The ideal gain equations are identical, but the applications are very different because the VFA is best applied to lower frequency precision jobs while the CFA applications are in the very high frequency realm. The transimpedance in a CFA acts much like the gain does in a VFA. In each case, transimpedance or gain, it is the parameter that enables the use of feedback.

Table 9–1. Tabulation of Pertinent VFA and CFA Equations

Chapter 10

Op Amp Noise Theory and Applications

Bruce Carter

10.1 Introduction

The purpose of op amp circuitry is the manipulation of the input signal in some fashion. Unfortunately in the real world, the input signal has unwanted noise superimposed on it.

Noise is not something most designers get excited about. In fact, they probably wish the whole topic would go away. It can, however, be a fascinating study by itself. A good understanding of the underlying principles can, in some cases, be used to reduce noise in the design.

10.2 Characterization

Noise is a purely random signal, the instantaneous value and/or phase of the waveform cannot be predicted at any time. Noise can either be generated internally in the op amp, from its associated passive components, or superimposed on the circuit by external sources. External noise is covered in Chapter 17, and is usually the dominant effect.

10.2.1 rms versus P-P Noise

Instantaneous noise voltage amplitudes are as likely to be positive as negative. When plotted, they form a random pattern centered on zero. Since noise sources have amplitudes that vary randomly with time, they can only be specified by a probability density function. The most common probability density function is Gaussian. In a Gaussian probability function, there is a mean value of amplitude, which is most likely to occur. The probability that a noise amplitude will be higher or lower than the mean falls off in a bell-shaped curve, which is symmetrical around the center (Figure 10–1).

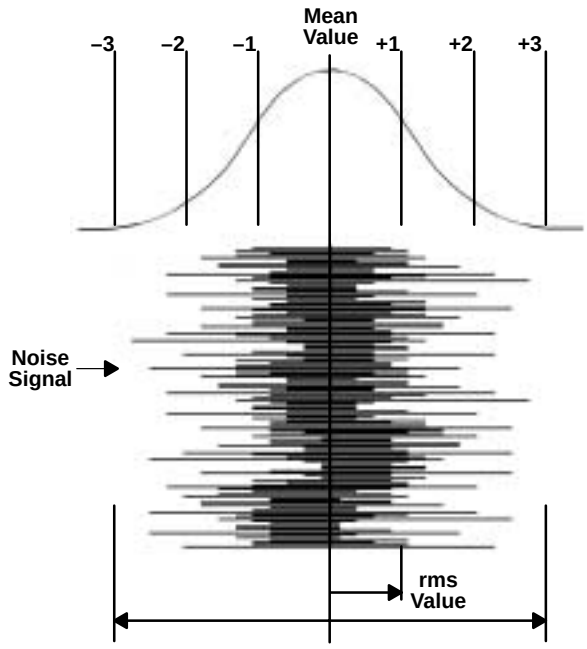

Figure 10–1. Gaussian Distribution of Noise Energy

σ is the standard deviation of the Gaussian distribution and the rms value of the noise voltage and current. The instantaneous noise amplitude is within $\pm 1\sigma$ 68% of the time. Theoretically, the instantaneous noise amplitude can have values approaching infinity. However, the probability falls off rapidly as amplitude increases. The instantaneous noise amplitude is within $\pm 3\sigma$ of the mean 99.7% of the time. If more or less assurance is desired, it is between $\pm 2\sigma$ 95.4% of the time and $\pm 3.4\sigma$ 99.94% of the time.

σ^2 is the average mean-square variation about the average value. This also means that the average mean-square variation about the average value, $\overline{i^2}$ or $\overline{e^2}$, is the same as the variance σ^2.

Thermal noise and shot noise (see below) have Gaussian probability density functions. The other forms of noise do not.

10.2.2 Noise Floor

When all input sources are turned off and the output is properly terminated, there is a level of noise called the *noise floor* that determines the smallest signal for which the circuit is useful. The objective for the designer is to place the signals that the circuit processes above the noise floor, but below the level where the signals will clip.

10.2.3 Signal-to-Noise Ratio

The noisiness of a signal is defined as:

$$\frac{S_{(f)}}{N_{(f)}} = \frac{\text{rms signal voltage}}{\text{rms noise voltage}} \quad (10\text{–}1)$$

In other words, it is a ratio of signal voltage to noise voltage (hence the name *signal-to-noise ratio*).

10.2.4 Multiple Noise Sources

When there are multiple noise sources in a circuit, the total root-mean-square (rms) noise signal that results is the square root of the sum of the average mean-square values of the individual sources:

$$E_{Totalrms} = \sqrt{e_{1rms}^2 + e_{2rms}^2 + \ldots e_{nrms}^2} \quad (10\text{–}2)$$

Put another way, this is the only “break” that the designer gets when dealing with noise. If there are two noise sources of equal amplitude in the circuit, the total noise is not doubled (increased by 6 dB). It only increases by 3 dB. Consider a very simple case, two noise sources with amplitudes of 2 V_{rms}:

$$E_{Totalrms} = \sqrt{2^2 + 2^2} = \sqrt{8} = 2.83\ V_{rms} \quad (10\text{–}3)$$

Therefore, when there are two equal sources of noise in a circuit, the noise is $20 \times \log\frac{2.83}{2} = 3.01$ dB higher than if there were only one source of noise — instead of double (6 dB) as would be intuitively expected.

This relationship means that the worst noise source in the system will tend to dominate the total noise. Consider a system in which one noise source is 10 V_{rms} and another is 1 V_{rms}:

$$E_{Totalrms} = \sqrt{10^2 + 1^2} = \sqrt{101} = 10.05\ V_{rms} \quad (10\text{–}4)$$

There is hardly any effect from the 1-V noise source at all!

10.2.5 Noise Units

Noise is normally specified as a spectral density in rms volts or amps per root Hertz, $V/\sqrt{Hz}$ or $A/\sqrt{Hz}$. These are not very “user-friendly” units. A frequency range is needed to relate these units to actual noise levels that will be observed.

For example:

- A TLE2027 op amp with a noise specification of 2.5 $nV/\sqrt{Hz}$ is used over an audio frequency range of 20 Hz to 20 kHz, with a gain of 40 dB. The output voltage is 0 dBV (1 V).
- To begin with, calculate the *root Hz* part: $\sqrt{20000 - 20} = 141.35$.
- Multiplying this by the noise spec: $2.5 \times 141.35 = 353.38$ nV, which is the equivalent input noise (EIN). The output noise equals the input noise multiplied by the gain, which is 100 (40 dB).

The signal-to-noise ratio can be now be calculated:

- $353.38\ nV \times 100 = 35.3\ \mu V$
- Signal-to-noise (dB) =

$$20 \times \log(1V \div 35.3\ \mu V) = 20 \times \log(28329) = 89\ dB \qquad (10–5)$$

The TLE2027 op amp is an excellent choice for this application. Remember, though, that passive components and external noise sources can degrade performance. There is also a slight increase in noise at low frequencies, due to the 1/f effect (see below).

10.3 Types of Noise

There are five types of noise in op amps and associated circuitry:

1) Shot noise
2) Thermal noise
3) Flicker noise
4) Burst noise
5) Avalanche noise

Some or all of these noises may be present in a design, presenting a noise spectrum unique to the system. It is not possible in most cases to separate the effects, but knowing general causes may help the designer optimize the design, minimizing noise in a particular bandwidth of interest. Proper design for low noise may involve a “balancing act” between these sources of noise and external noise sources.

10.3.1 Shot Noise

The name *shot noise* is short for Schottky noise. Sometimes it is referred to as *quantum noise*. It is caused by random fluctuations in the motion of charge carriers in a conductor. Put another way, current flow is not a continuous effect. Current flow is electrons, charged particles that move in accordance with an applied potential. When the electrons encounter a barrier, potential energy builds until they have enough energy to cross that barrier. When they have enough potential energy, it is abruptly transformed into kinetic energy as they cross the barrier. A good analogy is stress in an earthquake fault that is suddenly released as an earthquake.

As each electron randomly crosses a potential barrier, such as a pn junction in a semiconductor, energy is stored and released as the electron encounters and then shoots across the barrier. Each electron contributes a little *pop* as its stored energy is released when it crosses the barrier (Figure 10–2).

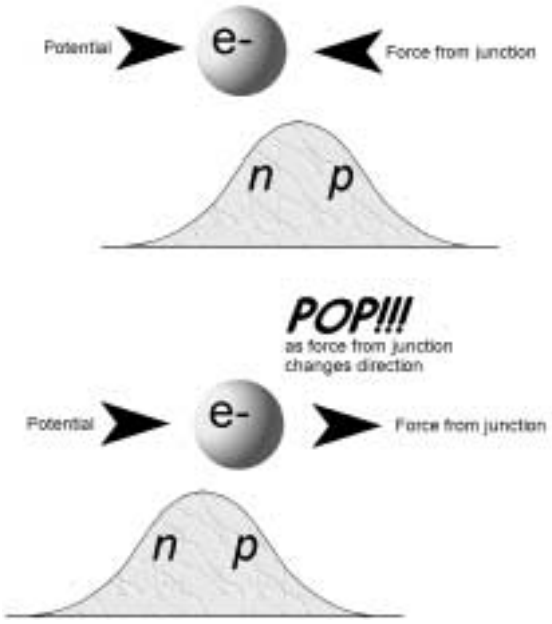

Figure 10–2. Shot Noise Generation

The aggregate effect of all of the electrons shooting across the barrier is the shot noise. Amplified shot noise has been described as sounding like lead shot hitting a concrete wall.

Some characteristics of shot noise:

- Shot noise is always associated with current flow. It stops when the current flow stops.
- Shot noise is independent of temperature.

- Shot noise is spectrally flat or has a uniform power density, meaning that when plotted versus frequency it has a constant value.
- Shot noise is present in any conductor — not just a semiconductor. Barriers in conductors can be as simple as imperfections or impurities in the metal. The level of shot noise, however, is very small due to the enormous numbers of electrons moving in the conductor, and the relative size of the potential barriers. Shot noise in semiconductors is much more pronounced.

The rms shot noise current is equal to:

$$I_{sh} = \sqrt{(2qI_{dc} + 4qI_0)B} \qquad (10–6)$$

Where:

q = Electron charge (1.6×10^{-19} coulombs)
I_{dc} = Average forward dc current in A
I_o = Reverse saturation current in A
B = Bandwidth in Hz

If the pn junction is forward biased, I_o is zero, and the second term disappears. Using Ohm's law and the dynamic resistance of a junction,

$$r_d = \frac{kT}{qI_{dc}} \qquad (10–7)$$

the rms shot noise voltage is equal to:

$$E_{sh} = kT\sqrt{\frac{2B}{qI_{dc}}} \qquad (10–8)$$

Where:

k = Boltzmann's constant (1.38×10^{-23} Joules/°K)
q = Electron charge (1.6×10^{-19} coulombs)
T = Temperature in °K
I_{dc} = Average dc current in A
B = Bandwidth in Hz

For example, a junction carries a current of 1 mA at room temperature. Its noise over the audio bandwidth is:

$$E_{sh} = 1.38 \times 10^{-23} \times 298 \sqrt{\frac{2(20000 - 20)}{(1.6 \times 10^{-19}) \times (1 \times 10^{-3})}} = 65 \text{ nV} = -144 \text{ dBV} \qquad (10–9)$$

Obviously, it is not much of a problem in this example.

Look closely at the formula for shot noise voltage. Notice that the shot noise voltage is inversely proportional to the current. Stated another way, shot noise voltage decreases

as average dc current increases, and increases as average dc current decreases. This can be an elegant way of determining if shot noise is a dominant effect in the op amp circuit being designed. If possible, decrease the average dc current by a factor of 100 and see if the overall noise increases by a factor of 10. In the example above:

$$E_{sh} = 1.38 \times 10^{-23} \times 298 \sqrt{\frac{2(20000 - 20)}{(1.6 \times 10^{-19}) \times (1 \times 10^{-5})}} = 650 \text{ nV} = -124 \text{ dBV} \qquad (10\text{–}10)$$

The shot noise voltage does increase by a factor of 10, or 20 dB.

10.3.2 Thermal Noise

Thermal noise is sometimes referred to as Johnson noise after its discoverer. It is generated by thermal agitation of electrons in a conductor. Simply put, as a conductor is heated, it will become noisy. Electrons are never at rest; they are always in motion. Heat disrupts the electrons' response to an applied potential. It adds a random component to their motion (Figure 10–3). Thermal noise only stops at absolute zero.

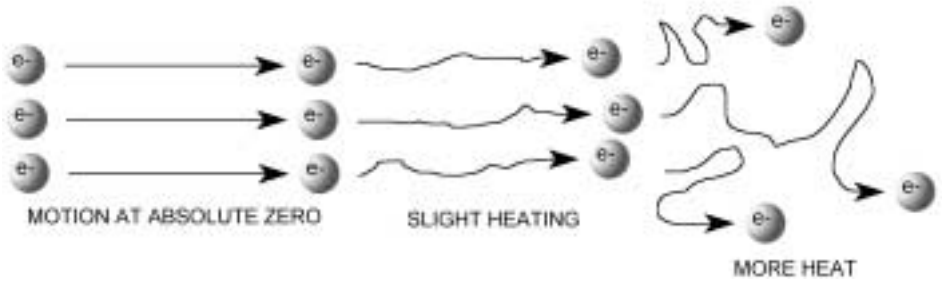

Figure 10–3. Thermal Noise

Like shot noise, thermal noise is spectrally flat or has a uniform power density (it is *white*), but thermal noise is independent of current flow.

At frequencies below 100 MHz, thermal noise can be calculated using Nyquist's relation:

$$E_{th} = \sqrt{4kTRB} \qquad (10\text{–}11)$$

or

$$I_{th} = \sqrt{\frac{4kTB}{R}} \qquad (10–12)$$

Where:

E_{th} =	Thermal noise voltage in Volts rms
I_{th} =	Thermal noise current in Amps rms
k =	Boltzmann's constant (1.38×10^{-23})
T =	Absolute temperature (Kelvin)
R =	Resistance in ohms
B =	Noise bandwidth in Hertz ($f_{max}–f_{min}$)

The noise from a resistor is proportional to its resistance and temperature. It is important not to operate resistors at elevated temperatures in high gain input stages. Lowering resistance values also reduces thermal noise.

For example:

The noise in a 100 kΩ resistor at 25°C (298°K) over the audio frequency range of 20 Hz to 20 kHz is:

$$\begin{aligned} E_{th} &= \sqrt{4kTRB} \\ &= \sqrt{4 \times (1.38 \times 10^{-23}) \times 298 \times 100,000 \times (20,000 - 20)} \\ &= 5.73\ \mu V \\ &= -104.8\ dBV \end{aligned} \qquad (10–13)$$

Decreasing the temperature would reduce the noise slightly, but scaling the resistor down to 1 kΩ (a factor of 100) would reduce the thermal noise by 20 dB. Similarly, increasing the resistor to 10 MΩ would increase the thermal noise to –84.8 dBV, a level that would affect a 16-bit audio circuit. The noise from multiple resistors adds according to the root-mean-square law in Paragraph 10.2.4. Beware of large resistors used as the input resistor of an op amp gain circuit, their thermal noise will be amplified by the gain in the circuit (Paragraph 10.4). Thermal noise in resistors is often a problem in portable equipment, where resistors have been scaled up to get power consumption down.

10.3.3 Flicker Noise

Flicker noise is also called *1/f noise*. Its origin is one of the oldest unsolved problems in physics. It is pervasive in nature and in many human endeavors. It is present in all active and many passive devices. It may be related to imperfections in crystalline structure of semiconductors, as better processing can reduce it.

Some characteristics of flicker noise:

- It increases as the frequency decreases, hence the name *1/f*
- It is associated with a dc current in electronic devices
- It has the same power content in each octave (or decade)

$$E_n = K_v \sqrt{\left(\ln \frac{f_{max}}{f_{min}}\right)} \qquad I_n = K_i \sqrt{\left(\ln \frac{f_{max}}{f_{min}}\right)} \tag{10–14}$$

Where:
K_e and K_i are proportionality constants (volts or amps) representing E_n and I_n at 1 Hz
f_{max} and f_{min} are the minimum and maximum frequencies in Hz

Flicker noise is found in carbon composition resistors, where it is often referred to as excess noise because it appears in addition to the thermal noise that is there. Other types of resistors also exhibit flicker noise to varying degrees, with wire wound showing the least. Since flicker noise is proportional to the dc current in the device, if the current is kept low enough, thermal noise will predominate and the type of resistor used will not change the noise in the circuit.

Reducing power consumption in an op amp circuit by scaling up resistors may reduce the 1/f noise, at the expense of increased thermal noise.

10.3.4 Burst Noise

Burst noise, also called popcorn noise, is related to imperfections in semiconductor material and heavy ion implants. It is characterized by discrete high-frequency pulses. The pulse rates may vary, but the amplitudes remain constant at several times the thermal noise amplitude. Burst noise makes a popping sound at rates below 100 Hz when played through a speaker — it sounds like popcorn popping, hence the name. Low burst noise is achieved by using clean device processing, and therefore is beyond the control of the designer. Modern processing techniques at Texas Instruments has all but eliminated its occurrence.

10.3.5 Avalanche Noise

Avalanche noise is created when a pn junction is operated in the reverse breakdown mode. Under the influence of a strong reverse electric field within the junction's depletion region, electrons have enough kinetic energy that, when they collide with the atoms of the crystal lattice, additional electron-hole pairs are formed (Figure 10–4). These collisions are purely random and produce random current pulses similar to shot noise, but much more intense.

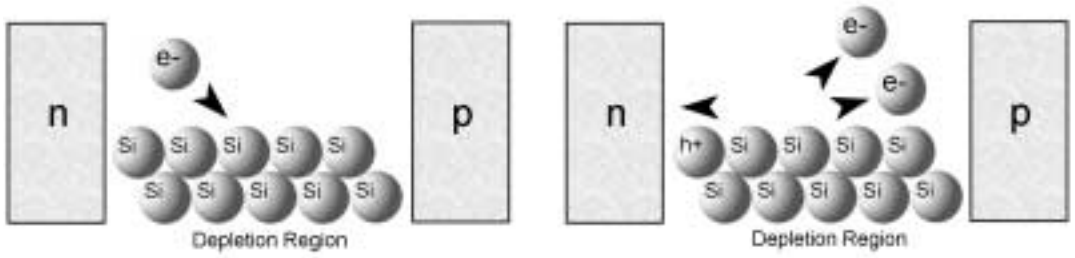

Figure 10–4. Avalanche Noise

When electrons and holes in the depletion region of a reversed-biased junction acquire enough energy to cause the avalanche effect, a random series of large noise spikes will be generated. The magnitude of the noise is difficult to predict due to its dependence on the materials.

Because the zener breakdown in a pn junction causes avalanche noise, it is an issue with op amp designs that include zener diodes. The best way of eliminating avalanche noise is to redesign a circuit to use no zener diodes.

10.4 Noise Colors

While the noise types are interesting, real op amp noise will appear as the summation of some or all of them. The various noise types themselves will be difficult to separate. Fortunately, there is an alternative way to describe noise, which is called *color*. The colors of noise come from rough analogies to light, and refer to the frequency content. Many colors are used to describe noise, some of them having a relationship to the real world, and some of them more attuned to the field of psycho-acoustics.

White noise is in the middle of a *spectrum* that runs from purple to blue to white to pink and red/brown. These colors correspond to powers of the frequency to which their spectrum is proportional, as shown in Table 10–1.

Table 10–1. Noise Colors

COLOR	FREQUENCY CONTENT
Purple	f^2
Blue	f
White	1
Pink	$\frac{1}{f}$
Red/Brown	$\frac{1}{f^2}$

There are an infinite number of variations between the colors. All inverse powers of frequency are possible, as are noises that are narrowband or appear only at one discrete frequency. Those, however, are primarily external sources of noise, so their presence is an important clue that the noise is external, not internal. There are no pure colors; at high frequencies, all of them begin to roll off and become pinkish. The op amp noise sources described above appear in the region between white noise and red/brown noise (Figure 10–5).

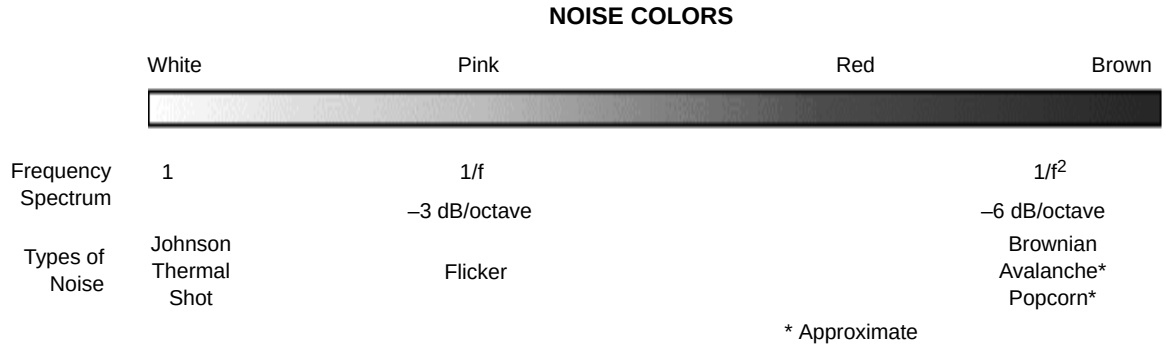

Figure 10–5. Noise Colors

10.4.1 White Noise

White noise is noise in which the frequency and power spectrum is constant and independent of frequency. The signal power for a constant bandwidth (centered at frequency f_o), does not change if f_o is varied. Its name comes from a similarity to white light, which has equal quantities of all colors.

When plotted versus frequency, white noise is a horizontal line of constant value.

Shot and thermal (Johnson) noise sources are approximately white, although there is no such thing as pure white noise. By definition, white noise would have infinite energy at infinite frequencies. White noise always becomes pinkish at high frequencies.

Steady rainfall or radio static on an unused channel approximate a white noise characteristic.

10.4.2 Pink Noise

Pink noise is noise with a 1/f frequency and power spectrum excluding dc. It has equal energy per octave (or decade for that matter). This means that the amplitude decreases logarithmically with frequency. Pink noise is pervasive in nature — many supposedly random events show a 1/f characteristic.

Flicker noise displays a 1/f characteristic, which also means that it rolls off at 3 dB/octave.

10.4.3 Red/Brown Noise

Red noise is not universally accepted as a noise type. Many sources omit it and go straight to brown, attributing red characteristics to brown. This has more to do with aesthetics than it does anything else (if brown noise is the low end of the spectrum, then pink noise should be named tan). So if pink noise is pink, then the low end of the spectrum should be red. Red noise is named for a connection with red light, which is on the low end of the visible light spectrum. But then this noise simulates Brownian motion, so perhaps it should be called Brown. Red/brown noise has a –6 dB/octave frequency response and a frequency spectrum of $1/f^2$ excluding dc.

Red/brown noise is found in nature. The acoustic characteristics of large bodies of water approximate red/brown noise frequency response.

Popcorn and avalanche noise approximate a red/brown characteristic, but they are more correctly defined as pink noise where the frequency characteristic has been shifted down as far as possible in frequency.

10.5 Op Amp Noise

This section describes the noise in op amps and associated circuits.

10.5.1 The Noise Corner Frequency and Total Noise

Op amp noise is never specified as shot, thermal, or flicker, or even white and pink. Noise for audio op amps is specified with a graph of equivalent input noise versus frequency. These graphs usually show two distinct regions:

- Lower frequencies where pink noise is the dominant effect
- Higher frequencies where white noise is the dominant effect

Actual measurements for the TLV2772 show that the noise has both white and pink characteristics (Figure 10–6). Therefore, the noise equations for each type of noise are not able to approximate the total noise out of the TLV2772 over the entire range shown on the graph. It is necessary to break the noise into two parts — the pink part and the white part — and then add those parts together to get the total op amp noise using the root-mean-square law of Paragraph 10.2.4.

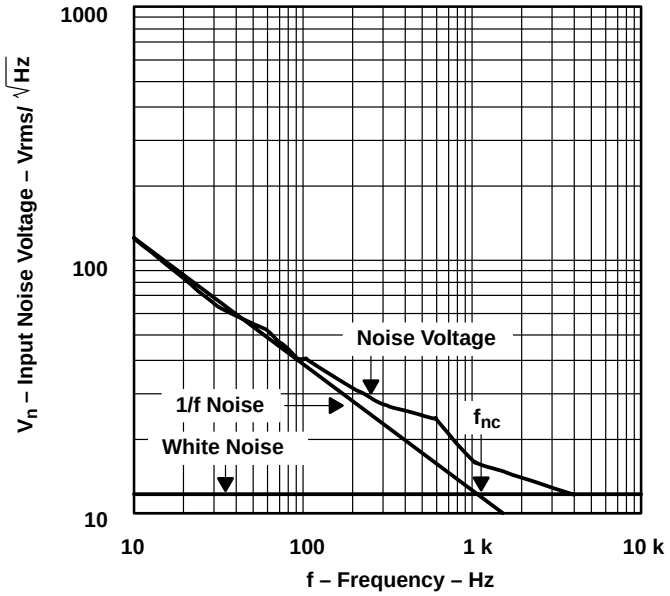

Figure 10–6. TLV2772 Op Amp Noise Characteristics

10.5.2 The Corner Frequency

The point in the frequency spectrum where 1/f noise and white noise are equal is referred to as the noise corner frequency, f_{nc}. Note on the graph in Figure 10–6 that the actual noise voltage is higher at f_{nc} due to the root-mean-square addition of noise sources as defined in Paragraph 10.2.4.

f_{nc} can be determined visually from the graph in Figure 10–6. It appears a little above 1 kHz. This was done by:

- Taking the white noise portion of the curve, and extrapolating it down to 10 Hz as a horizontal line.
- Taking the portion of the pink noise from 10 Hz to 100 Hz, and extrapolating it as a straight line.
- The point where the two intercept is $f_{nc,}$ the point where the white noise and pink noise are equal in amplitude. The total noise is then $\sqrt{2}$ x white noise specification (from Paragraph 10.2.4). This would be about 17 nV/ $\sqrt{Hz}$ for the TLV2772.

This is good enough for most applications. As can be seen from the actual noise plot in Figure 10–6, small fluctuations make precise calculation impossible. There is a precise method, however:

- Determine the 1/f noise at the lowest possible frequency.

- Square it.
- Subtract the white noise voltage squared (subtracting noise with root-mean-squares is just as valid as adding).
- Multiply by the frequency. This will give the noise contribution from the 1/f noise.
- Then divide by the white noise specification squared. The answer is f_{nc}.

For example:

The TLV2772 has a typical noise voltage of 130 nV/$\sqrt{\text{Hz}}$ at 10 Hz (from 5-V plot on data sheet).

The typical white noise specification for the TLV2772 is 12 nV/$\sqrt{\text{Hz}}$ (from data sheet)

$$1/f\ \text{noise}^2@10\text{Hz} = \left[\left(\frac{130\ \text{nV}}{\sqrt{\text{Hz}}}\right)^2 - \left(\frac{12\ \text{nV}}{\sqrt{\text{Hz}}}\right)^2\right] \times 10\ \text{Hz} = 167560(\text{nV})^2 \quad (10\text{–}15)$$

$$f_{nc} = \frac{1/f\ \text{noise}^2@10\text{Hz}}{\text{white noise}^2} = \frac{167560(\text{nV})^2}{\left(\frac{12\ \text{nV}}{\sqrt{\text{Hz}}}\right)^2} = 1164\ \text{Hz} \quad (10\text{–}16)$$

Once the corner frequency is known, the individual noise components can be added together as shown in Paragraph 10.2.2. Continuing the example above for a frequency range of 10 Hz to 10 kHz:

$$E_n = E_{\text{whitenoise}} \sqrt{f_{nc} \times 1n\frac{f_{max}}{f_{min}} + (f_{max} - f_{min})} \quad (10\text{–}17)$$

$$E_n = \frac{12\ \text{nV}}{\sqrt{\text{Hz}}} \sqrt{1164\ \text{Hz} \times 1n\frac{10^4}{10} + (10^4\ \text{Hz} - 10\ \text{Hz})} = 1.611\ \mu\text{V} = -116\ \text{dBV} \quad (10\text{–}18)$$

The example above presupposed that the bandwidth includes f_{nc}. If it does not, all of the contribution will be from either the 1/f noise or the white noise. Similarly, if the bandwidth is very large, and extends to three decades or so above f_{nc}, the contribution of the 1/f noise can be ignored.

10.5.3 Op Amp Circuit Noise Model

Texas Instruments measures the noise characteristics of a large sampling of devices. This information is compiled and used to determine the typical noise performance of the device. These noise specifications refer the input noise of the op amp. Some noise portions

can be represented better by a voltage source, and some by a current source. Input voltage noise is always represented by a voltage source in series with the noninverting input. Input current noise is always represented by current sources from both inputs to ground (Figure 10–7).

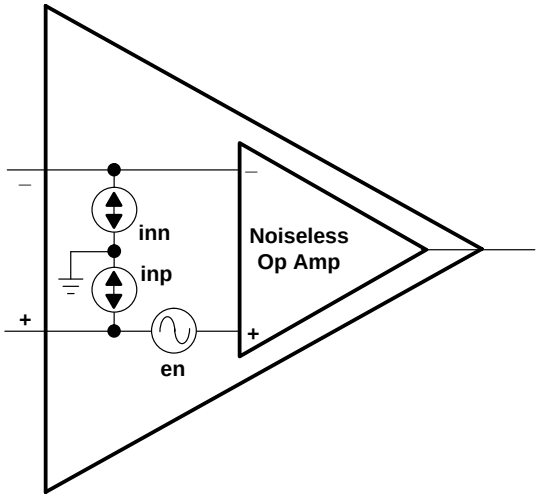

Figure 10–7. Op Amp Circuit Noise Model

In practice, op amp circuits are designed with low source impedance on the inverting and noninverting inputs. For low source impedances and CMOS JFET inputs, only the noise voltage is important; the current sources are insignificant in the calculations because they are swamped in the input impedances.

The equivalent circuit, therefore, reduces to that shown in Figure 10–8:

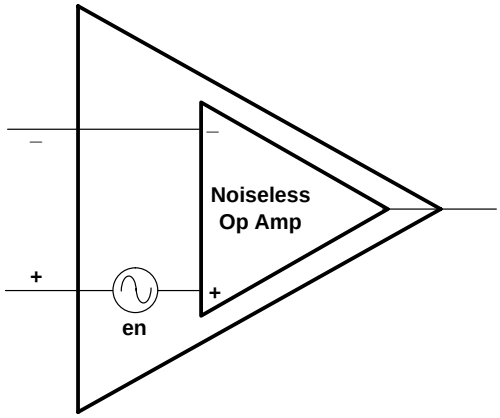

Figure 10–8. Equivalent Op Amp Circuit Noise Model

10.5.4 Inverting Op Amp Circuit Noise

If the previous circuit is operated in an inverting gain stage, the equivalent circuit becomes that shown in Figure 10–9:

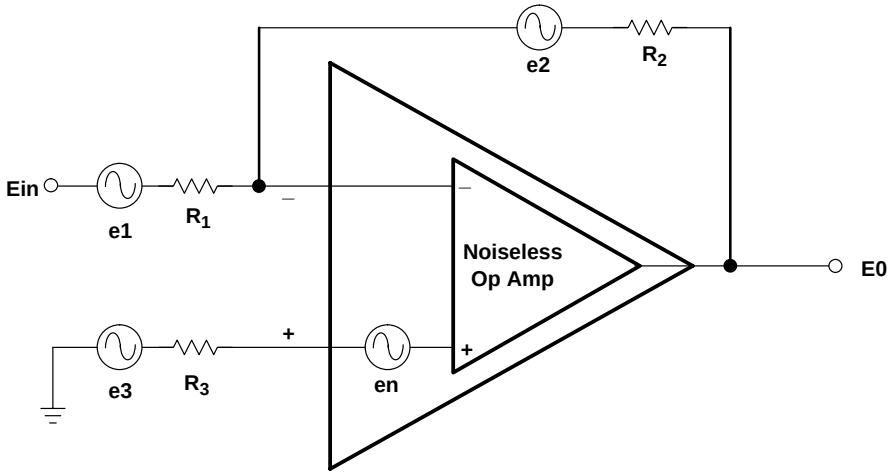

Figure 10–9. Inverting Op Amp Circuit Noise Model

The additional voltage sources e1 through e3 represent the thermal noise contribution from the resistors. As stated in Paragraph 10.3.2, the resistor noise can also be discounted if the values are low. Resistor noise will be omitted in the examples that follow. R3 is also not usually present, unless low common-mode performance is important. Deleting it and connecting the noninverting input directly to (virtual) ground makes the common mode response of the circuit worse, but may improve the noise performance of some circuits. There will be one less noise source to worry about. Therefore, the equivalent circuit becomes that shown in Figure 10–10:

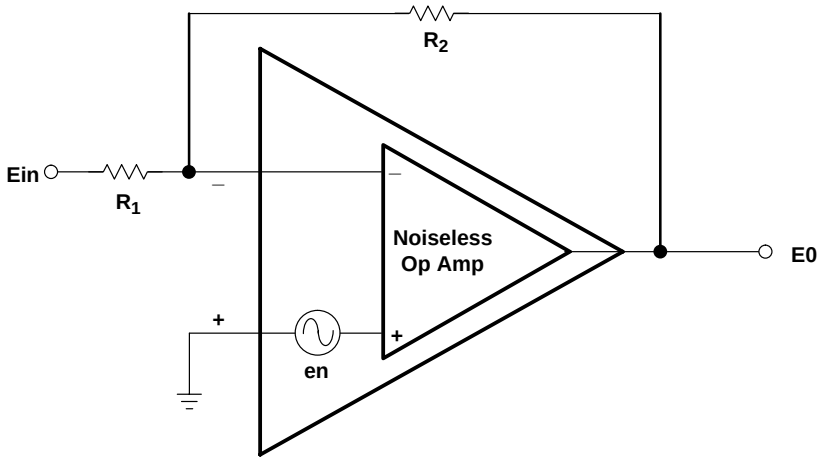

Figure 10–10. Inverting Equivalent Op Amp Circuit Noise Model

This simplifies the gain calculation:

$$E_0 = \sqrt{\left(E_{in}\frac{R_2}{R_1}\right)^2 + \left(e_n\left(1 + \frac{R_2}{R_1}\right)\right)^2} \qquad (10\text{–}19)$$

where e_n = the total noise over the bandwidth of interest.

10.5.5 Noninverting Op Amp Circuit Noise

Taking the simplified equivalent op amp circuit from Paragraph 10.5.2 as the base, the noise equivalent of a noninverting op amp circuit is shown in Figure 10–11:

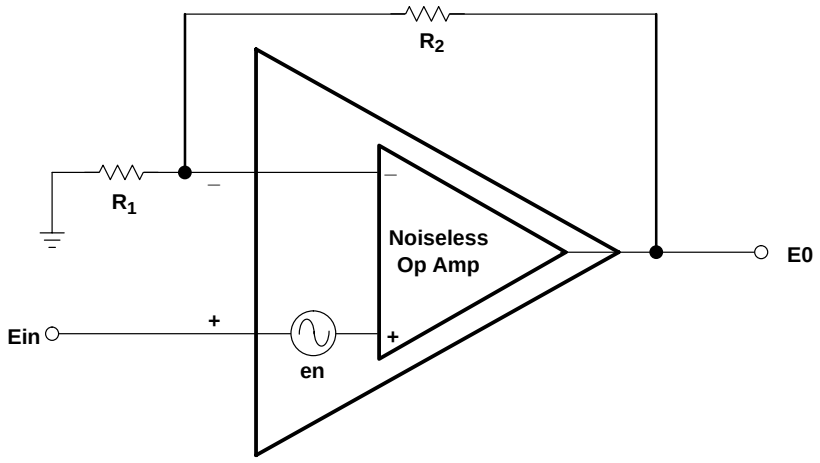

Figure 10–11. Noninverting Equivalent Op Amp Circuit Noise Model

The gain of this circuit is:

$$E_0 = \sqrt{\left(E_{in}\left(1 + \frac{R_2}{R_1}\right)\right)^2 + \left(e_n\left(1 + \frac{R_2}{R_1}\right)\right)^2} \qquad (10\text{–}20)$$

10.5.6 Differential Op Amp Circuit Noise

Taking the simplified equivalent op amp circuit from Paragraph 10.5.2 as the base, the noise equivalent of a differential op amp circuit is shown in Figure 10–12:

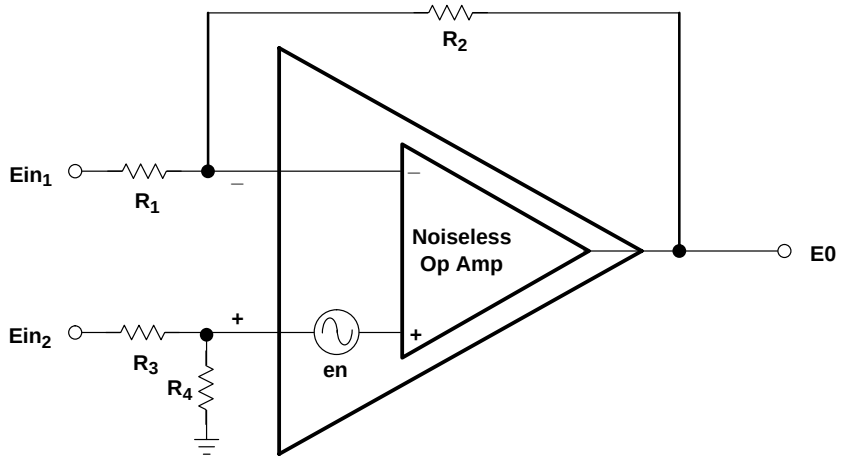

Figure 10–12. Differential Equivalent Op Amp Circuit Noise Model

Assuming that R1 = R3 and R2 = R4, the gain of this circuit is:

$$E_0 = \sqrt{\left((E_{in2} - E_{in1})\frac{R_2}{R_1}\right)^2 + \left(e_n\left(1 + \frac{R_2}{R_1}\right)\right)^2} \qquad (10\text{–}21)$$

10.5.7 Summary

The previous examples, though trivial, illustrate that noise always adds to the overall output of the op amp circuit. Reference 1 provides a much more in-depth derivation of op amp noise in circuits, including resistive effects.

10.6 Putting It All Together

This example is provided for analysis only — actual results depend on a number of other factors. Expanding on the techniques of Paragraph 10.2.5:

A low-noise op amp is needed over an audio frequency range of 20 Hz to 20 kHz, with a gain of 40 dB. The output voltage is 0 dBV (1V). The schematic is shown in Figure 10–13:

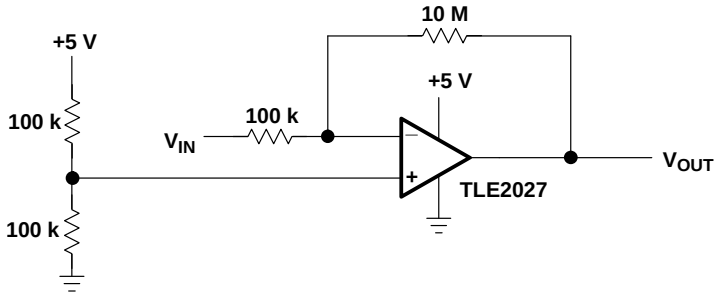

Figure 10–13. Split Supply Op Amp Circuit

It would be nice to use a TLE2027 with a noise figure of 2.5 $nV/\sqrt{Hz}$. The data sheet, however, reveals that this is a ±15-V part, and that noise figure is only specified at ±15 V. Furthermore, the specification for V_{OM+} and V_{OM-} (see Chapter 11) show that it can only swing to within approximately 2 V of its voltage rails. If they are +5 V and ground, the op amp is close to clipping with a 1-V output signal. This illustrates a common fallacy: the designer chooses an op amp based on one parameter only, without checking others that affect the circuit. An expert analog designer must develop an attention to details or be prepared to spend a lot of time in the lab with false starts and unexpected problems.

So, the only choice is to select a different op amp. The TLC2201 is an excellent choice. It is a low-noise op amp optimized for single supply operation. Figure 10–14 appears right on the first page of the data sheet, which should be extremely significant to the designer.

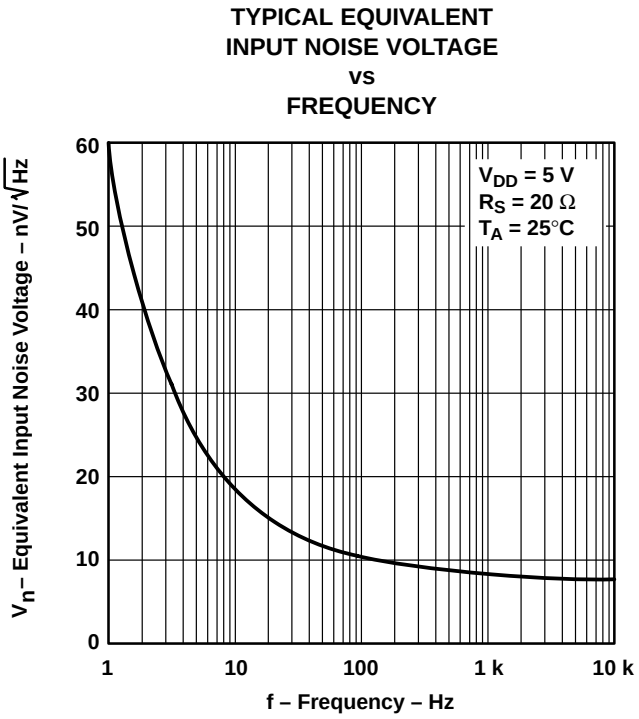

Figure 10–14. TLC2201 Op Amp Noise Performance

The first circuit change in this example is to change the TLE2027 to a TLC2201. Visually, the corner frequency f_{nc} appears to be somewhere around 20 Hz (from Paragraph 10.5.2), the lower frequency limit of the band we are interested in. This is good, it means for all practical purposes the 1/f noise can be discounted. It has 8 nV/$\sqrt{\text{Hz}}$ noise instead of 2.5 nV/$\sqrt{\text{Hz}}$, and from Paragraph 10.2.5:

- To begin with, calculate the *root Hz* part: $\sqrt{20000 - 20} = 141.35$.
- Multiplying this by the noise spec: $8 \times 141.35 = 1.131$ μV, which is the equivalent input noise (E_{IN}). The output noise equals the input noise multiplied by the gain, which is 100 (40 dB).

The signal-to-noise ratio can be now be calculated:

- $1.131\ \mu V \times 100 = 113.1\ \mu V$
- Signal-to-noise (dB) =

$$20 \times \log(1V \div 113.1\ \mu V) = 20 \times \log(8842) = 78.9\ \text{dB} \qquad (10\text{–}22)$$

Pretty good, but 10 dB less than would have been possible with a TLE2027. If this is not acceptable (lets say for 16-bit accuracy), one is forced to generate a ±15-V supply. Let's suppose for now that 78.9 dB signal-to-noise is acceptable, and build the circuit.

When it is assembled, it oscillates. What went wrong?

To begin with, it is important to look for potential sources of external noise. The way the schematic in Figure 10–14 is drawn provides a visual clue to the culprit: a long connection from the half-supply voltage reference to the high-impedance noninverting input. Added to that is a 50-kΩ source impedance, which does not effectively swamp external noise sources from entering the noninverting input. There is a big difference between simply providing a correct dc operating point, and providing one that has low impedances where they are needed. Most designers know the “fix”, which is to decouple the noninverting input as shown in Figure 10–15:

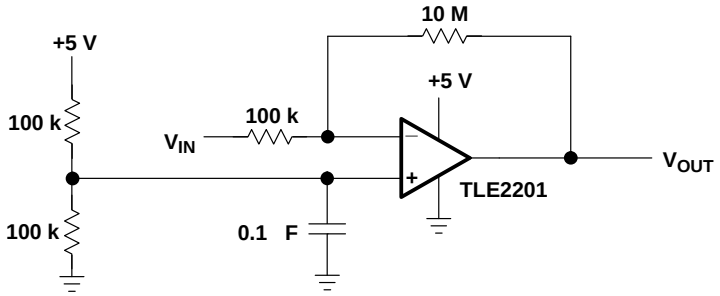

Figure 10–15. TLC2201 Op Amp Circuit

Better — it stopped oscillating. Probably a nearby noise source radiating into the noninverting input was providing enough noise to put the circuit into oscillation. The capacitor lowers the input impedance of the noninverting input and stops the oscillation. There is much more information on this topic in Chapter 17, including layout effects and component selection. For now, it is assumed that all of these have been taken into account.

The circuit is still slightly noisier than the 78.9 dB signal-to-noise ratio given above, especially at lower frequencies. This is where the real work of this example begins: that of eliminating component noise.

The circuit in Figure 10–15 has 4 resistors. Assuming that the capacitor is noiseless (not always a good assumption), that means four noise sources. For now, only the two resistors in the voltage divider that forms the voltage reference will be considered. The capacitor, however, has transformed the white noise from the resistors into pink (1/f) noise. From Paragraph 10.3.2 and 10.2.5, the noise from the resistors and the amplifier itself is:

$$E_{Totalrms} = \sqrt{5.73\ \mu V^2 + 5.73\ \mu V^2 + 113.1\ \mu V^2} = 113.1\ \mu V_{rms} \qquad (10–23)$$

Signal-to-noise (dB) =

$$20 \times \log(1V \div 113.1\ \mu V) = 20 \times \log(8842) = 78.9\ dB \qquad (10–24)$$

So far, so good. The amplifier noise is swamping the resistor noise, which will only add a very slight pinkish component at low frequencies. Remember, however, that this noise

voltage is multiplied by 101 through the circuit, but that was previously taken into account for the 78.9 dB signal-to-noise calculation above.

Reducing the value of the resistors to decrease their noise is an option. Changing the voltage divider resistors from 100 kΩ to 1 kΩ while leaving the 0.1 μV capacitor the same, changes the corner frequency from 32 Hz to 796 Hz, right in the middle of the audio band.

> **Note:**
>
> Resist the temptation to make the capacitor larger to move the pinkish effect below the lower limits of human hearing. The resulting circuit must charge the large capacitor up during power up, and down during power down. This may cause unexpected results.

If the noise from the half-supply generator is critical, the best possible solution is to use a low-noise, low-impedance half-supply source. Remember, however, that its noise will be multiplied by 101 in this application.

The effect of the 100-kΩ resistor on the inverting input is whitish, and will appear across the entire bandwidth of the circuit. Compared to the amplifier noise, it is still small, just like the noise from the noninverting resistors on the input. The noise contribution of resistors will be discounted.

Of much more concern, however, is the 10-MΩ resistor used as the feedback resistor. The noise associated with it appears as a voltage source at the inverting input of the op amp, and, therefore, is multiplied by a factor of 100 through the circuit. From Paragraph 10.3.2, the noise of a 10-MΩ resistor is –84.8 dBV, or 57.3 μV. Adding this and the 100-kΩ resistor noise to the amplifier noise:

$$E_{Totalrms} = \sqrt{5.73\ \mu V^2 + 113.1\ \mu V^2} = 126.8\ \mu V_{rms} = -77.9\ dBV \qquad (10–25)$$

Signal-to-noise (dB) =

$$20 \times \log(1V \div 126.8\ \mu V) = 20 \times \log(7887) = 77.9\ dB \qquad (10–26)$$

The noise contribution from the 10-MΩ resistor subtracts 1 dB from the signal-to-noise ratio. Changing the 10-MΩ resistor to 100 kΩ, and the input resistor from 100 kΩ to 1 kΩ preserves the overall gain of the circuit. The redesigned circuit is shown in Figure 10–16:

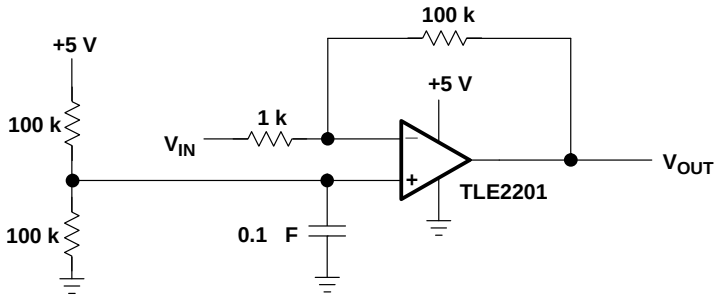

Figure 10–16. Improved TLC2201 Op Amp Circuit

For frequencies above 100 Hz, where the 1/f noise from the op amp and the reference resistors is negligible, the total noise of the circuit is:

$$E_{Totalrms} = \sqrt{0.57\ \mu V^2 + 5.73\ \mu V^2 + 113.1\ \mu V^2} = 113.2\ \mu V_{rms} = -78.9\ dBV \qquad (10–27)$$

Signal-to-noise (dB) =

$$20 \times \log(1V \div 113.2\ \mu V) = 20 \times \log(8830) = 78.9\ dB \qquad (10–28)$$

Proper selection of resistors, therefore, has yielded a signal-to-noise ratio close to the theoretical limit for the op amp itself. The power consumption of the circuit, however, has increased slightly, which may be unacceptable in a portable application. Remember, too, that this signal-to-noise ratio is only at an output level of 0 dBV, an input level of –40 dBV. If the input signal is reduced, the signal-to-noise ratio is reduced proportionally.

Music, in particular almost never sustains peak levels. The average amplitude may be down 20 dB to 40 dB from the peak values. This erodes a 79 dB signal-to-noise ratio to 39 dB in quiet passages. If someone “cranks up the volume” during the quiet passages, noise will become audible. This is done automatically with automatic volume controls. The only way a designer can combat this is to increase the voltage levels through the individual stages. If the preceding audio stages connecting to this example, for instance, could be scaled to provide 10 dB more gain, the TLC2201 would be handling an output level of 3.16 V instead of 1 V, which is well within its rail-to-rail limit of 0 V to 4.7 V. This would increase the signal-to-noise gain of this circuit to 88.9 dB — almost the same as would have been possible with a TLE2027 operated off of ±15V! But noise in the preceding stages would also increase. Combatting noise is a difficult problem, and there are always trade-offs involved.

Chapter 11

Understanding Op Amp Parameters

Bruce Carter

11.1 Introduction

This chapter is about op amp data sheet parameters. The designer must have a clear understanding of what op amp parameters mean and their impact on circuit design. The chapter is arranged for speedy access to parameter information. Their definitions, typical abbreviations, and units appear in Section 11.2. Section 11.3 digs deeper into important parameters for the designer needing more in-depth information.

While these parameters are the ones most commonly used at Texas Instruments, the same parameter may go by different names and abbreviations at other manufacturers. Not every parameter listed here may appear in the data sheet for a given op amp. An op amp that is intended only for ac applications may omit dc offset information. The omission of information is not an attempt to “hide” anything. It is merely an attempt to highlight the parameters of most interest to the designer who is using the part the way it was intended. There is no such thing as an ideal op amp — or one that is universally applicable. The selection of any op amp must be based on an understanding of what particular parameters are most important to the application.

If a particular parameter cannot be found in the data sheet, a review of the application may well be in order and another part, whose data sheet contains the pertinent information, might be more suitable. Texas Instruments manufactures a broad line of op amps that can implement almost any application. The inexperienced designer could easily select an op amp that is totally wrong for the application. Trying to use an audio op amp with low total harmonic distortion in a high-speed video circuit, for example, will not work — no matter how superlative the audio performance might be.

Some parameters have a statistically normal distribution. The typical value published in the data sheet is the mean or average value of the distribution. The typical value listed is the 1σ value. This means that in 68% of the devices tested, the parameter is found to be $\pm$ the typical value or better. Texas Instruments currently uses 6σ to define minimum and maximum values. Usually, typical values are set when the part is characterized and never changes.

11.2 Operational Amplifier Parameter Glossary

There are usually three main sections of electrical tables in op amp data sheets. The *absolute maximum ratings* table and the *recommended operating conditions* table list constraints placed upon the circuit in which the part will be installed. *Electrical characteristics* tables detail device performance.

Absolute maximum ratings are those limits beyond which the life of individual devices may be impaired and are never to be exceeded in service or testing. Limits, by definition, are maximum ratings, so if double-ended limits are specified, the term will be defined as a range (e.g., operating temperature range).

Recommended operating conditions have a similarity to maximum ratings in that operation outside the stated limits could cause unsatisfactory performance. Recommended operating conditions, however, do not carry the implication of device damage if they are exceeded.

Electrical characteristics are measurable electrical properties of a device inherent in its design. They are used to predict the performance of the device as an element of an electrical circuit. The measurements that appear in the electrical characteristics tables are based on the device being operated within the recommended operating conditions.

Table 11–1 is a list of parameters and operating conditions that are commonly used in TI op amp data sheets. The glossary is arranged alphabetically by parameter name. An abbreviation cross-reference is provided after the glossary in Table 11–2 to help the designer find information when only an abbreviation is given. More detail is given about important parameters in Section 11.3.

Table 11–1. Op Amp Parameter GLossary

PARAMETER	ABBV	UNITS	DEFINITION	INFO
Bandwidth for 0.1 dB flatness		MHz	The range of frequencies within which the gain is ± 0.1 dB of the nominal value.	
Case temperature for 60 seconds		°C	Usually specified as an absolute maximum — It is meant to be used as guide for automated soldering processes.	
Common-mode input capacitance	C_{ic}	pF	Input capacitance a common-mode source would see to ground.	11.3.7.1
Common-mode input impedance	Z_{ic}	Ω	The parallel sum of the small-signal impedance between each input terminal and ground.	
Common-mode input voltage	V_{IC}	V	The average voltage at the input pins.	11.3.3
Common-mode rejection ratio	CMRR or k_{CMR}	dB	The ratio of differential voltage amplification to common-mode voltage amplification. Note: This is measured by determining the ratio of a change in input common-mode voltage to the resulting change in input offset voltage.	11.3.9

PARAMETER	ABBV	UNITS	DEFINITION	INFO
Continuous total dissipation		mW	Usually specified as an absolute maximum. It is the power that can be dissipated by the op amp package, including the load power. This parameter may be broken down by ambient temperature and package style in a table.	
Crosstalk	X_T	dBc	The ratio of the change in output voltage of a driven channel to the resulting change in output voltage from another channel that is not driven.	
Differential gain error	A_D	%	The change in ac gain with change in dc level. The ac signal is 40 IRE (0.28 V_{PK}) and the dc level change is ±100 IRE (±0.7 V). Typically tested at 3.58 MHz (NTSC) or 4.43 MHz (PAL) carrier frequencies.	
Differential input capacitance	C_{ic}	pF	(see common mode input capacitance)	11.3.7.1
Differential input resistance	r_{id}	Ω	The small-signal resistance between two ungrounded input terminals.	
Differential input voltage	V_{ID}	V	The voltage at the noninverting input with respect to the inverting input.	
Differential phase error	Φ_D	°	The change in ac phase with change in dc level. The ac signal is 40 IRE (0.28 V_{PK}) and the dc level change is ±100 IRE (±0.7 V). Typically tested at 3.58 MHz (NTSC) or 4.43 MHz (PAL) carrier frequencies.	
Differential voltage amplification	A_{VD}	dB	(see open loop voltage gain)	11.3.6
Fall time	t_f	ns	The time required for an output voltage step to change from 90% to 10% of its final value.	
Duration of short-circuit current			Amount of time that the output can be shorted to network ground — usually specified as an absolute maximum.	
Input common-mode voltage range	V_{ICR}	V	The range of common-mode input voltage that, if exceeded, may cause the operational amplifier to cease functioning properly. This is sometimes is taken as the voltage range over which the input offset voltage remains within a set limit.	11.3.3
Input current	I_I	mA	The amount of current that can be sourced or sinked by the op amp input — usually specified as an absolute maximum rating.	
Input noise current	I_n	$\frac{pA}{\sqrt{Hz}}$	The internal noise current reflected back to an ideal current source in parallel with the input pins.	11.3.13
Input noise voltage	V_n	$\frac{nV}{\sqrt{Hz}}$	The internal noise voltage reflected back to an ideal voltage source in parallel with the input pins.	11.3.13
Gain bandwidth product	GBW	MHz	The product of the open-loop voltage gain and the frequency at which it is measured.	11.3.13
Gain margin	A_m	dB	The reciprocal of the open-loop voltage gain at the frequency where the open-loop phase shift first reaches –180°.	
High-level output voltage	V_{OH}	V	The highest positive op amp output voltage for the bias conditions applied to the power pins.	11.3.5
Input bias current	I_{IB}	μA	The average of the currents into the two input terminals with the output at a specified level.	11.3.2

PARAMETER	ABBV	UNITS	DEFINITION	INFO
Input capacitance	c_i	pF	The capacitance between the input terminals with either input grounded.	11.3.7.1
Input offset current	I_{IO}	µA	The difference between the currents into the two input terminals with the output at the specified level.	11.3.2
Input offset voltage	$V_{IO,}$ V_{OS}	mV	The dc voltage that must be applied between the input terminals to cancel dc offsets within the op amp.	11.3.1
Input offset voltage long-term drift		$\frac{\mu V}{month}$	The ratio of the change in input offset voltage to the change time. It is the average value for the month.	11.3.1
Input resistance	r_i	MΩ	The dc resistance between the input terminals with either input grounded.	11.3.7.1
Input voltage range	V_I	V	The range of input voltages that may be applied to either the IN+ or IN– inputs	11.3.15
Large-signal voltage amplification	A_V	dB	(see open loop voltage gain)	
Lead temperature for 10 or 60 seconds		°C	Usually specified as an absolute maximum. It is meant to be used as guide for automated and hand soldering processes.	
Low-level output current	I_{OL}	mA	The current into an output with input conditions applied that according to the product parameter will establish a low level at the output.	
Low-level output voltage	V_{OL}	V	The smallest positive op amp output voltage for the bias conditions applied to the power pins.	11.3.5
Maximum peak output voltage swing	$V_{OM\pm}$	V	The maximum peak-to-peak output voltage that can be obtained without clipping when the op amp is operated from a bipolar supply.	11.3.5
Maximum peak-to-peak output voltage swing	$V_{O(PP)}$	V	The maximum peak-to-peak voltage that can be obtained without waveform clipping when the dc output voltage is zero.	
Maximum-output-swing bandwidth	B_{OM}	MHz	The range of frequencies within which the maximum output voltage swing is above a specified value or the maximum frequency of an amplifier in which the output amplitude is at the extents of it's linear range. Also called full power bandwidth.	11.3.15
Noise figure	NF	dB	The ratio of the total noise power at the output of an amplifier, referred to the input, to the noise power of the signal source.	
Open-loop transimpedance	Z_t	MΩ	In a transimpedance or current feedback amplifier, it is the frequency dependent ratio of change in output voltage to the frequency dependent change in current at the inverting input.	
Open-loop transresistance	R_t	MΩ	In a transimpedance or current feedback amplifier, it is the ratio of change in dc output voltage to the change in dc current at the inverting input.	
Open -loop voltage gain	A_{OL}	dB	The ratio of change in output voltage to the change in voltage across the input terminals. Usually the dc value and a graph showing the frequency dependence are shown in the data sheet.	
Operating temperature	T_A	°C	Temperature over which the op amp may be operated. Some of the other parameters may change with temperature, leading to degraded operation at temperature extremes.	

PARAMETER	ABBV	UNITS	DEFINITION	INFO
Output current	I_O	mA	The amount of current that is drawn from the op amp output. Usually specified as an absolute maximum rating — not for long term operation at the specified level.	
Output impedance	Z_o	Ω	The frequency dependent small-signal impedance that is placed in series with an ideal amplifier and the output terminal.	11.3.8
Output resistance	r_o	Ω	The dc resistance that is placed in series with an ideal amplifier and the output terminal.	
Overshoot factor	–	–	The ratio of the largest deviation of the output voltage from its final steady-state value to the absolute value of the step after a step change at the output.	
Phase margin	Φ_m	°	The absolute value of the open-loop phase shift at the frequency where the open-loop amplification first equals one.	11.3.15
Power supply rejection ratio	PSRR	dB	The absolute value of the ratio of the change in supply voltages to the change in input offset voltage. Typically both supply voltages are varied symmetrically. Unless otherwise noted, both supply voltages are varied symmetrically.	11.3.10
Rise time	t_r	nS	The time required for an output voltage step to change from 10% to 90% of its final value.	
Settling time	t_s	nS	With a step change at the input, the time required for the output voltage to settle within the specified error band of the final value. Also known as total response time, $t_{tot.}$	
Short-circuit output current	I_{OS}	mA	The maximum continuous output current available from the amplifier with the output shorted to ground, to either supply, or to a specified point. Sometimes a low value series resistor is specified.	
Slew rate	SR	V/µs	The rate of change in the output voltage with respect to time for a step change at the input.	11.3.12
Storage temperature	T_S	°C	Temperature over which the op amp may be stored for long periods of time without damage.	
Supply current	I_{CC}/I_{DD}	mA	The current into the V_{CC+}/V_{DD+} or $V_{CC–}/V_{DD–}$ terminal of the op amp while it is operating.	
Supply current (shutdown)	$I_{CC–}/I_{DD–}$ SHDN	mA	The current into the V_{CC+}/V_{DD+} or $V_{CC–}/V_{DD–}$ terminal of the amplifier while it is turned off.	
Supply rejection ratio	k_{SVR}	dB	(see power supply rejection ratio)	11.3.10
Supply voltage sensitivity	k_{SVS}, $\Delta V_{CC±}$, $\Delta V_{DD±}$, or ΔV_{IO}	dB	The absolute value of the ratio of the change in input offset voltage to the change in supply voltages.	11.3.10
Supply voltage	V_{CC}/V_{DD}	V	Bias voltage applied to the op amp power supply pin(s). Usually specified as a ± value, referenced to network ground.	
Temperature coefficient of input offset current	αI_{IO}	µA/°C	The ratio of the change in input offset current to the change in free-air temperature. This is an average value for the specified temperature range.	11.3.2

PARAMETER	ABBV	UNITS	DEFINITION	INFO
Temperature coefficient of input offset voltage	αV_{IO}	µV/°C	The ratio of the change in input offset voltage to the change in free-air temperature. This is an average value for the specified temperature range.	11.3.1
Total current into $V_{CC}+$/ V_{DD+}		mA	Maximum current that can be supplied to the positive power terminal of the op amp — usually specified as an absolute maximum.	
Total current out of V_{DD-}		mA	Maximum current that can be drawn from the negative power terminal of the op amp — usually specified as an absolute maximum.	
Total harmonic distortion	THD	dB	The ratio of the RMS voltage of the first nine harmonics of the fundamental signal to the total RMS voltage at the output.	
Total harmonic distortion plus noise	THD+N	dB	The ratio of the RMS noise voltage and RMS harmonic voltage of the fundamental signal to the total RMS voltage at the output.	11.3.14
Total power dissipation	P_D	mW	The total dc power supplied to the device less any power delivered from the device to a load. Note: At no load: $P_D = V_{CC+} \times I$ or $P_D = V_{DD+} \times I$	
Turn-on voltage (shutdown)	$V_{IH-SHDN}$	V	The voltage required on the shutdown pin to turn the device on.	
Turn-off voltage (shutdown)	$V_{IL-SHDN}$	V	The voltage required on the shutdown pin to turn the device off.	
Turn-on time (shutdown)	t_{EN}	µs	The time from when the turn-on voltage is applied to the shutdown pin to when the supply current has reached half of its final value.	
Turn-off time (shutdown)	t_{DIS}	µs	The time from when the turn-off voltage is applied to the shutdown pin to when the supply current has reached half of its final value.	
Unity gain bandwidth	B_1	MHz	The range of frequencies within which the open-loop voltage amplification is greater that unity.	11.3.15

11.3 Additional Parameter Information

Depending on the application, some op amp parameters are more important than others. This section contains additional information for parameters that impact a broad range of designs.

11.3.1 Input Offset Voltage

All op amps require a small voltage between their inverting and noninverting inputs to balance mismatches due to unavoidable process variations. The required voltage is known as the input offset voltage and is abbreviated V_{IO}. V_{IO} is normally modeled as a voltage source driving the noninverting input.

Figure 11–1 shows two typical methods for measuring input offset voltage — *DUT* stands for device under test. Test circuit (a) is simple, but since Vout is not at zero volts, it does not really meet the definition of the parameter. Test circuit (b) is referred to as a *servo loop*. The action of the loop is to maintain the output of the DUT at zero volts.

Bipolar input op amps typically offer better offset parameters than JFET or CMOS input op amps.

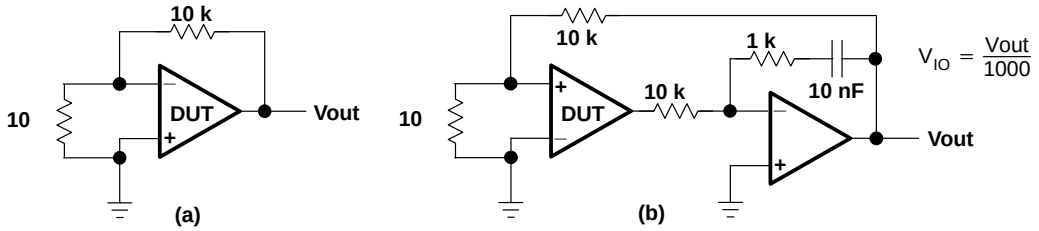

Figure 11–1. Test Circuits for Input Offset Voltage

TI data sheets show two other parameters related to V_{IO}; the average temperature coefficient of input offset voltage, and the input offset voltage long-term drift.

The average temperature coefficient of input offset voltage, αV_{IO}, specifies the expected input offset drift over temperature. Its units are $\mu V/^{\circ}C$. V_{IO} is measured at the temperature extremes of the part, and αV_{IO} is computed as $\Delta V_{IO}/\Delta^{\circ}C$.

Normal aging in semiconductors causes changes in the characteristics of devices. The input offset voltage long-term drift specifies how V_{IO} is expected to change with time. Its units are μV/month.

V_{IO} is normally attributed to the input differential pair in a voltage feedback amplifier. Different processes provide certain advantages. Bipolar input stages tend to have lower offset voltages than CMOS or JFET input stages.

Input offset voltage is of concern anytime that DC accuracy is required of the circuit. One way to null the offset is to use external null inputs on a single op amp package (Figure 11–2). A potentiometer is connected between the null inputs with the adjustable terminal connected to the negative supply through a series resistor. The input offset voltage is nulled by shorting the inputs and adjusting the potentiometer until the output is zero.

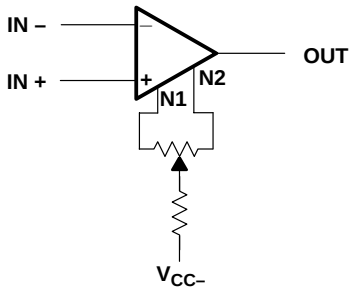

Figure 11–2. Offset Voltage Adjust

11.3.2 Input Current

The input circuitry of all op amps requires a certain amount of bias current for proper operation. The input bias current, I_{IB}, is computed as the average of the two inputs:

$$I_{IB} = \frac{\left(I_N + I_P\right)}{2} \qquad (11\text{–}1)$$

CMOS and JFET inputs offer much lower input current than standard bipolar inputs. Figure 11–3 shows a typical test circuit for measuring input bias currents.

The difference between the bias currents at the inverting and noninverting inputs is called the input offset current, $I_{IO} = I_N – I_P$. Offset current is typically an order of magnitude less than bias current.

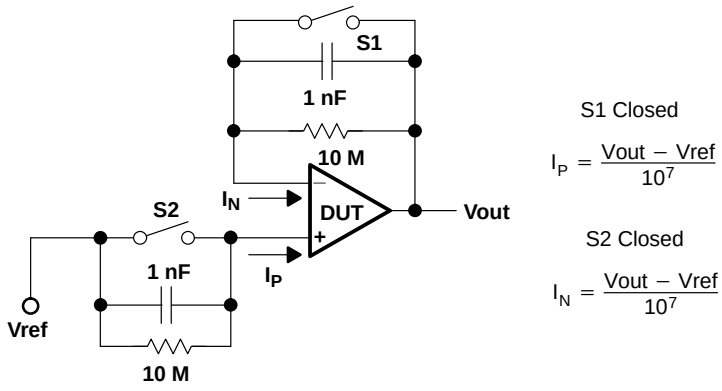

Figure 11–3. Test Circuit – I_{IB}

Input bias current is of concern when the source impedance is high. If the op amp has high input bias current, it will load the source and a lower than expected voltage is seen. The best solution is to use an op amp with either CMOS or JFET input. The source impedance can also be lowered by using a buffer stage to drive the op amp that has high input bias current.

In the case of bipolar inputs, offset current can be nullified by matching the impedance seen at the inputs. In the case of CMOS or JFET inputs, the offset current is usually not an issue and matching the impedance is not necessary.

The average temperature coefficient of input offset current, αI_{IO}, specifies the expected input offset drift over temperature. Its units are $\mu A/°C$. I_{IO} is measured at the temperature extremes of the part, and αI_{IO} is computed as $\Delta I_{IO}/\Delta °C$.

11.3.3 Input Common Mode Voltage Range

The input common voltage is defined as the average voltage at the inverting and noninverting input pins. If the common mode voltage gets too high or too low, the inputs will shut down and proper operation ceases. The common mode input voltage range, V_{ICR}, specifies the range over which normal operation is guaranteed.

Different input structures allow for different input common-mode voltage ranges:

The LM324 and LM358 use bipolar PNP inputs that have their collectors connected to the negative power rail. This allows the common-mode input voltage range to include the negative power rail.

The TL07X and TLE207X type BiFET op amps use P-channel JFET inputs with the sources tied to the positive power rail via a bipolar current source. This allows the common-mode input voltage range to include the positive power rail.

TI LinCMOS op amps use P-channel CMOS inputs with the substrate tied to the positive power rail. This allows the common-mode input voltage range to include the negative power rail.

Rail-to-rail input op amps use complementary N- and P-type devices in the differential inputs. When the common-mode input voltage nears either rail, at least one of the differential inputs is still active, and the common-mode input voltage range includes both power rails.

The trends toward lower, and single supply voltages make V_{ICR} of increasing concern.

Rail-to-rail input is required when a noninverting unity gain amplifier is used and the input signal ranges between both power rails. An example of this is the input of an analog-to digital-converter in a low-voltage, single-supply system.

High-side sensing circuits require operation at the positive input rail.

11.3.4 Differential Input Voltage Range

Differential input voltage range is normally specified as an absolute maximum. Exceeding the differential input voltage range can lead to breakdown and part failure.

Some devices have protection built into them, and the current into the input needs to be limited. Normally, differential input mode voltage limit is not a design issue.

11.3.5 Maximum Output Voltage Swing

The maximum output voltage, $V_{OM\pm}$, is defined as *the maximum positive or negative peak output voltage that can be obtained without wave form clipping, when quiescent DC output voltage is zero*. $V_{OM\pm}$ is limited by the output impedance of the amplifier, the saturation voltage of the output transistors, and the power supply voltages. This is shown pictorially in Figure 11–4.

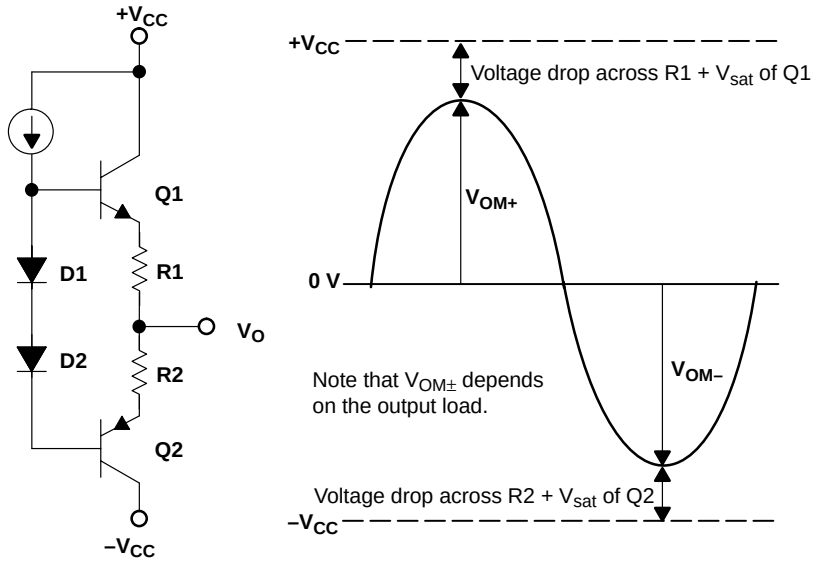

Figure 11–4. V_{OM}

This emitter follower structure cannot drive the output voltage to either rail. Rail-to-rail output op amps use a common emitter (bipolar) or common source (CMOS) output stage. With these structures, the output voltage swing is only limited by the saturation voltage (bipolar) or the on resistance (CMOS) of the output transistors, and the load being driven.

Because newer products are focused on single supply operation, more recent data sheets from Texas Instruments use the terminology V_{OH} and V_{OL} to specify the maximum and minimum output voltage.

Maximum and minimum output voltage is usually a design issue when dynamic range is lost if the op amp cannot drive to the rails. This is the case in single supply systems where the op amp is used to drive the input of an A to D converter, which is configured for full scale input voltage between ground and the positive rail.

11.3.6 Large Signal Differential Voltage Amplification

Large signal differential voltage amplification, A_{VD}, is similar to the open loop gain of the amplifier except open loop is usually measured without any load. This parameter is usually measured with an output load. Figure 11–11 shows a typical graph of A_{VD} vs. frequency.

A_{VD} is a design issue when precise gain is required. The gain equation of a noninverting amplifier:

$$\text{Gain} = \frac{1}{\beta} \times \frac{1}{1 + \frac{1}{A_{VD}\,\beta}} \qquad (11–2)$$

β is a feedback factor, determined by the feedback resistors. The term $\frac{1}{A_{VD}\,\beta}$ in the equation is an error term. As long as A_{VD} is large in comparison with $\frac{1}{\beta}$, it will not greatly affect the gain of the circuit.

11.3.7 Input Parasitic Elements

Both inputs have parasitic impedance associated with them. Figure 11–5 shows a model of the resistance and capacitance between each input terminal and ground and between the two terminals. There is also parasitic inductance, but the effects are negligible at low frequency.

Input impedance is a design issue when the source impedance is high. The input loads the source.

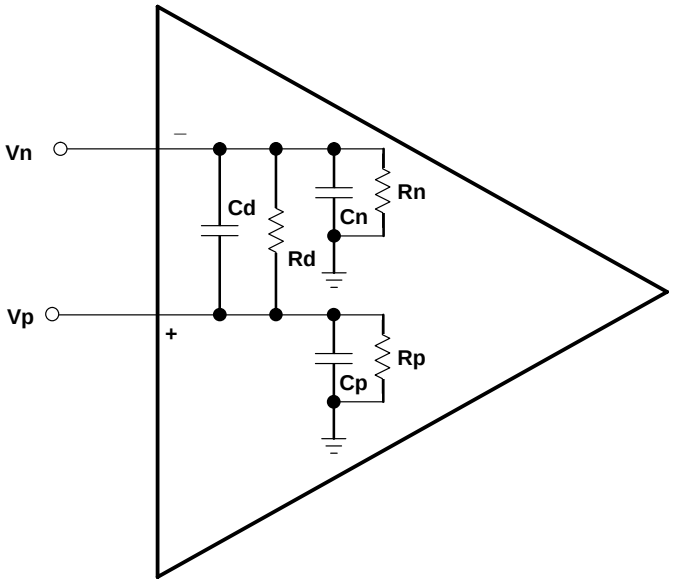

Figure 11–5. Input Parasitic Elements

11.3.7.1 Input Capacitance

Input capacitance, C_i, is measured between the input terminals with either input grounded. C_i is usually a few pF. In Figure 11–5, if $V_{p\ is}$ grounded, then $C_i = C_d \parallel C_n$.

Sometimes common-mode input capacitance, C_{ic} is specified. In Figure 11–5, if V_p is shorted to V_n, then $C_{ic} = C_p \parallel C_n$. C_{ic} is the input capacitance a common mode source would see referenced to ground.

11.3.7.2 Input Resistance

Input resistance, r_i is the resistance between the input terminals with either input grounded. In Figure 11–5, if V_p is grounded, then $r_i = R_d \parallel R_n$. r_i ranges from $10^7\ \Omega$ to $10^{12}\ \Omega$, depending on the type of input.

Sometimes common-mode input resistance, r_{ic}, is specified. In Figure 11–5, if V_p is shorted to V_n, then $r_{ic} = R_p \parallel R_n$. r_{ic} is the input resistance a common mode source would see referenced to ground.

11.3.8 Output Impedance

Different data sheets list the output impedance under two different conditions. Some data sheets list *closed-loop* output impedance while others list *open-loop* output impedance, both designated by Z_o.

Z_o is defined as the small signal impedance between the output terminal and ground. Data sheet values run from 50 Ω to 200 Ω.

Common emitter (bipolar) and common source (CMOS) output stages used in rail-to-rail output op amps have higher output impedance than emitter follower output stages.

Output impedance is a design issue when using rail-to-rail output op amps to drive heavy loads. If the load is mainly resistive, the output impedance will limit how close to the rails the output can go. If the load is capacitive, the extra phase shift will erode phase margin.

Figure 11–6 shows how output impedance affects the output signal assuming Z_o is mostly resistive.

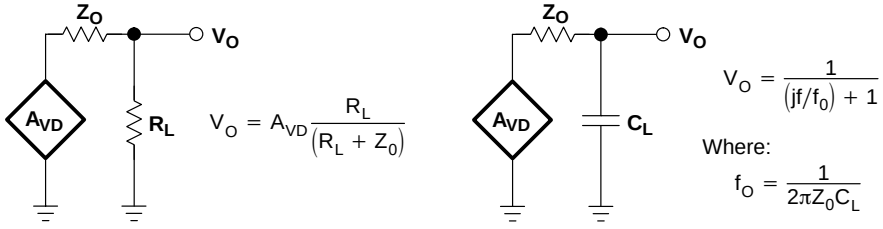

Figure 11–6. Effect of Output Impedance

Some new audio op amps are designed to drive the load of a speaker or headphone directly. They can be an economical method of obtaining very low output impedance.

11.3.9 Common-Mode Rejection Ratio

Common-mode rejection ratio, CMRR, is defined as the ratio of the differential voltage amplification to the common-mode voltage amplification, A_{DIF}/A_{COM}. Ideally this ratio would be infinite with common mode voltages being totally rejected.

The common-mode input voltage affects the bias point of the input differential pair. Because of the inherent mismatches in the input circuitry, changing the bias point changes the offset voltage, which, in turn, changes the output voltage. The real mechanism at work is $\Delta V_{OS}/\Delta V_{COM}$.

In a Texas Instruments data sheet, CMRR = $\Delta V_{COM}/\Delta V_{OS}$, which gives a positive number in dB. CMRR, as published in the data sheet, is a dc parameter. CMRR, when graphed vs. frequency, falls off as the frequency increases.

A common source of common-mode interference voltage is 50-Hz or 60-Hz ac noise. Care must be used to ensure that the CMRR of the op amp is not degraded by other circuit components. High values of resistance make the circuit vulnerable to common mode (and other) noise pick up. It is usually possible to scale resistors down and capacitors up to preserve circuit response.

11.3.10 Supply Voltage Rejection Ratio

Supply voltage rejection ratio, k_{SVR} (AKA power supply rejection ratio, PSRR), is the ratio of power supply voltage change to output voltage change.

The power voltage affects the bias point of the input differential pair. Because of the inherent mismatches in the input circuitry, changing the bias point changes the offset voltage, which, in turn, changes the output voltage.

For a dual supply op amp, $K_{SVR} = \frac{\Delta V_{CC\pm}}{\Delta V_{OS}}$ or $K_{SVR} = \frac{\Delta V_{DD\pm}}{\Delta V_{OS}}$. The term $\Delta V_{CC\pm}$ means that the plus and minus power supplies are changed symmetrically. For a single supply op amp, $K_{SVR} = \frac{\Delta V_{CC}}{\Delta V_{OS}}$ or $K_{SVR} = \frac{\Delta V_{DD}}{\Delta V_{OS}}$.

Also note that the mechanism that produces k_{SVR} is the same as for CMRR. Therefore k_{SVR} as published in the data sheet is a dc parameter like CMRR. When k_{SVR} is graphed vs. frequency, it falls off as the frequency increases.

Switching power supplies produce noise frequencies from 50 kHz to 500 kHz and higher. k_{SVR} is almost zero at these frequencies so that noise on the power supply results in noise on the output of the op amp. Proper bypassing techniques must be used (see Chapter 17) to control high-frequency noise on the power lines.

11.3.11 Supply Current

Supply current, I_{DD}, is the quiescent current draw of the op amp(s) with no load. In a Texas Instruments data sheet, this parameter is usually the total quiescent current draw for the whole package. There are exceptions, however, such as data sheets that cover single and multiple packaged op amps of the same type. In these cases, I_{DD} is the quiescent current draw for each amplifier.

In op amps, power consumption is traded for noise and speed.

11.3.12 Slew Rate at Unity Gain

Slew rate, SR, is the rate of change in the output voltage caused by a step input. Its units are V/μs or V/ms. Figure 11–7 shows slew rate graphically. The primary factor controlling slew rate in most amps is an internal compensation capacitor C_C, which is added to make the op amp unity gain stable. Referring to Figure 11–8, voltage change in the second stage is limited by the charging and discharging of the compensation capacitor C_C. The maximum rate of change is when either side of the differential pair is conducting $2I_E$. Essentially $SR = 2I_E/C_C$. Remember, however, that not all op amps have compensation capacitors. In op amps without internal compensation capacitors, the slew rate is determined by internal op amp parasitic capacitances. Noncompensated op amps have greater bandwidth and slew rate, but the designer must ensure the stability of the circuit by other means.

In op amps, power consumption is traded for noise and speed. In order to increase slew rate, the bias currents within the op amp are increased.

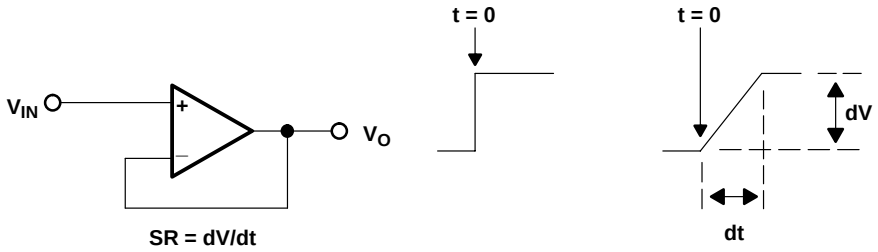

Figure 11–7.Figure 6. Slew Rate

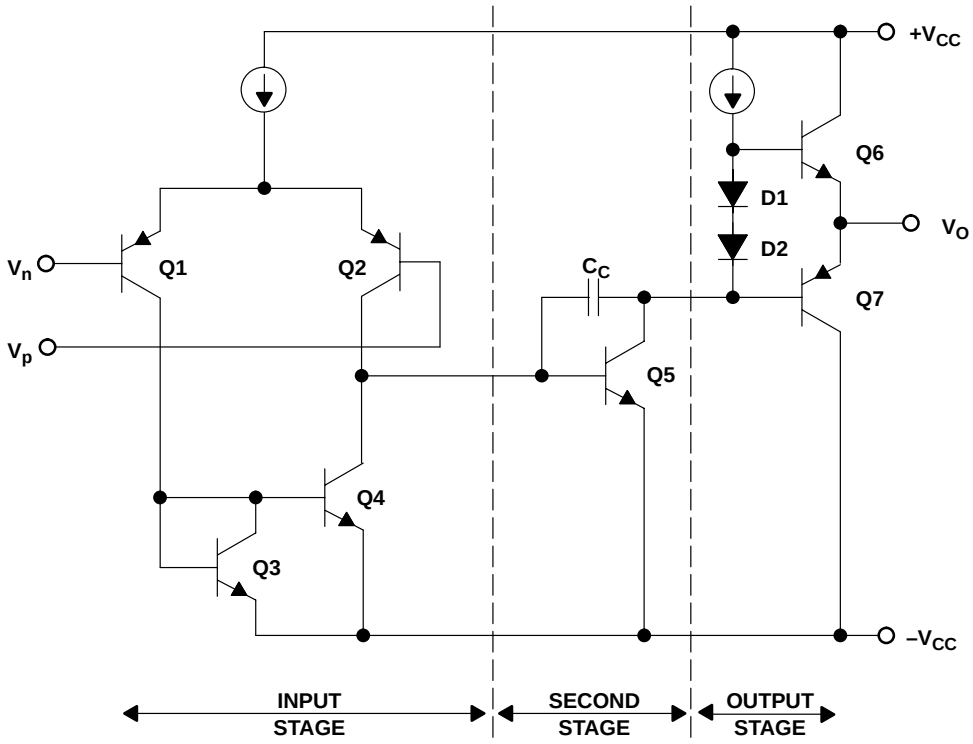

Figure 11–8.Figure 7. Simplified Op Amp Schematic

11.3.13 Equivalent Input Noise

Noise is covered in more detail in Chapter 10.

All op amps have parasitic internal noise sources. Noise is measured at the output of an op amp, and referenced back to the input. Therefore, it is called equivalent input noise.

Equivalent input noise parameters are usually specified as voltage, V_n, (or current, I_n) per root Hertz. For audio frequency op amps, a graph is usually included to show the noise over the audio band.

11.3.13.1 Spot Noise

The spectral density of noise in op amps has a pink and a white noise component. Pink noise is inversely proportional to frequency and is usually only significant at low frequencies. White noise is spectrally flat. Figure 11–9 shows a typical graph of op amp equivalent input noise.

Usually spot noise is specified at two frequencies. The first frequency is usually 10 Hz where the noise exhibits a 1/f spectral density. The second frequency is typically 1 kHz

where the noise is spectrally flat. The units used are normally $\frac{nV_{rms}}{\sqrt{Hz}}$ (or $\frac{pA_{rms}}{\sqrt{Hz}}$ for current noise). In Figure 11–9 the transition between 1/f and white is denoted as the corner frequency, f_{nc}.

11.3.13.2 Broadband Noise

A noise parameter like $V_{N(PP)}$, is the a peak to peak voltage over a specific frequency band, typically 0.1 Hz to 1 Hz, or 0.1 Hz to 10 Hz. The units of measurement are typically nV P–P.

Given the same structure within an op amp, increasing bias currents lowers noise (and increases SR, GBW, and power dissipation).

Also the resistance seen at the input to an op amp adds noise. Balancing the input resistance on the noninverting input to that seen at the inverting input, while helping with offsets due to input bias current, adds noise to the circuit.

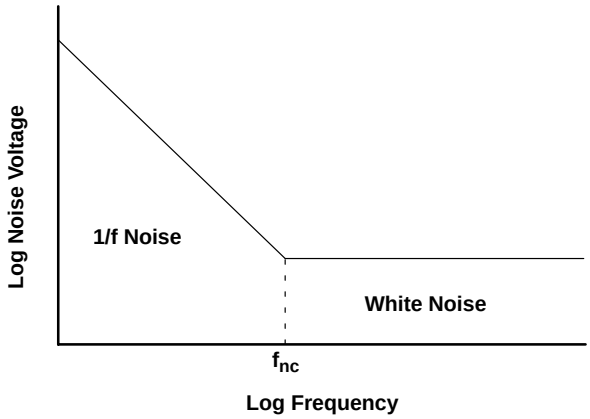

Figure 11–9. Typical Op amp Input Noise Spectrum

11.3.14 Total Harmonic Distortion Plus Noise

Total harmonic distortion plus noise, THD + N, compares the frequency content of the output signal to the frequency content of the input. Ideally, if the input signal is a pure sine wave, the output signal is a pure sine wave. Due to nonlinearity and noise sources within the op amp, the output is never pure.

THD + N is the ratio of all other frequency components to the fundamental and is usually specified as a percentage:

$$\text{THD} + \text{N} = \left[\frac{(\Sigma \text{ Harmonic voltages} + \text{Noise Voltages})}{\text{Fundamental}}\right] \times 100\% \qquad (11\text{–}3)$$

Figure 11–10 shows a hypothetical graph where THD + N = 1%. The fundamental is the same frequency as the input signal. Nonlinear behavior of the op amp results in harmonics

of the fundamental being produced in the output. The noise in the output is mainly due to the input noise of the op amp. All the harmonics and noise added together make up 1% of the fundamental.

Two major reasons for distortion in an op amp are the limit on output voltage swing and slew rate. Typically an op amp must be operated at or below its recommended operating conditions to realize low THD.

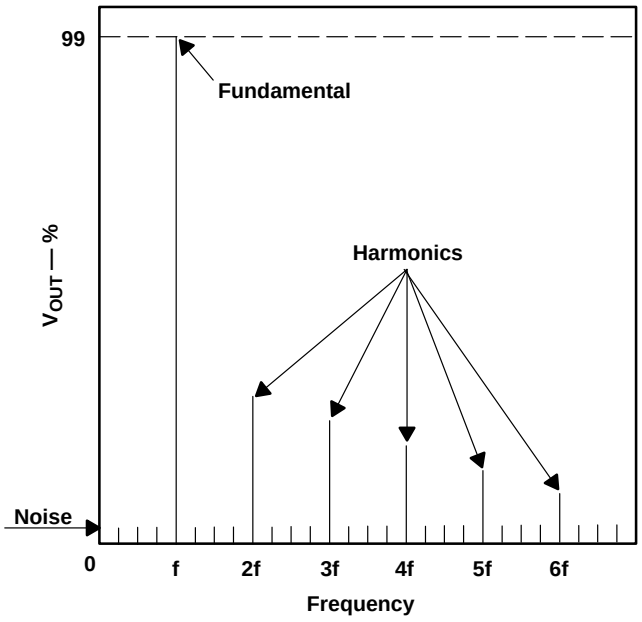

Figure 11–10. Output Spectrum with THD + N = 1%

11.3.15 Unity Gain Bandwidth and Phase Margin

There are five parameters relating to the frequency characteristics of the op amp that are likely to be encountered in Texas Instruments data sheets. These are unity-gain bandwidth (B_1), gain bandwidth product (GBW), phase margin at unity gain (ϕ_m), gain margin (A_m), and maximum output-swing bandwidth (B_{OM}).

Unity-gain bandwidth (B_1) and gain bandwidth product (GBW) are very similar. B_1 specifies the frequency at which A_{VD} of the op amp is 1:

$$B_1 = (f)A_{VD} = 1 \qquad (11–4)$$

GBW specifies the gain-bandwidth product of the op amp in an open loop configuration and the output loaded:

$$GBW = A_{VD} \times f \tag{11–5}$$

GBW is constant for voltage-feedback amplifiers. It does not have much meaning for current-feedback amplifiers because there is not a linear relationship between gain and bandwidth.

Phase margin at unity gain (ϕ_m) is the difference between the amount of phase shift a signal experiences through the op amp at unity gain and 180°:

$$\phi_m = 180^\circ - \phi @ B1 \tag{11–6}$$

Gain margin is the difference between unity gain and the gain at 180° phase shift:

$$\text{Gain margin} = 1 - \text{Gain} @ 180^\circ \text{ phase shift} \tag{11–7}$$

Maximum output-swing bandwidth (B_{OM}) specifies the bandwidth over which the output is above a specified value:

$$B_{OM} = f_{MAX,} \text{ while } V_O > V_{MIN} \tag{11–8}$$

The limiting factor for B_{OM} is slew rate. As the frequency gets higher and higher the output becomes slew rate limited and can not respond quickly enough to maintain the specified output voltage swing.

In order to make the op amp stable, capacitor, C_C, is purposely fabricated on chip in the second stage (Figure 11–8). This type of frequency compensation is termed dominant pole compensation. The idea is to cause the open-loop gain of the op amp to roll off to unity before the output phase shifts by 180°. Remember that Figure 11–8 is very simplified, and there are other frequency shaping elements within a real op amp.

Figure 11–11 shows a typical gain vs. frequency plot for an internally compensated op amp as normally presented in a Texas Instruments data sheet.

As noted earlier, A_{VD} falls off with frequency. A_{VD} (and thus B_1 or GBW) is a design issue when precise gain is required of a specific frequency band.

Phase margin (ϕ_m) and gain margin (A_m) are different ways of specifying the stability of the circuit. Since rail-to-rail output op amps have higher output impedance, a significant phase shift is seen when driving capacitive loads. This extra phase shift erodes the phase margin, and for this reason most CMOS op amps with rail-to-rail outputs have limited ability to drive capacitive loads.

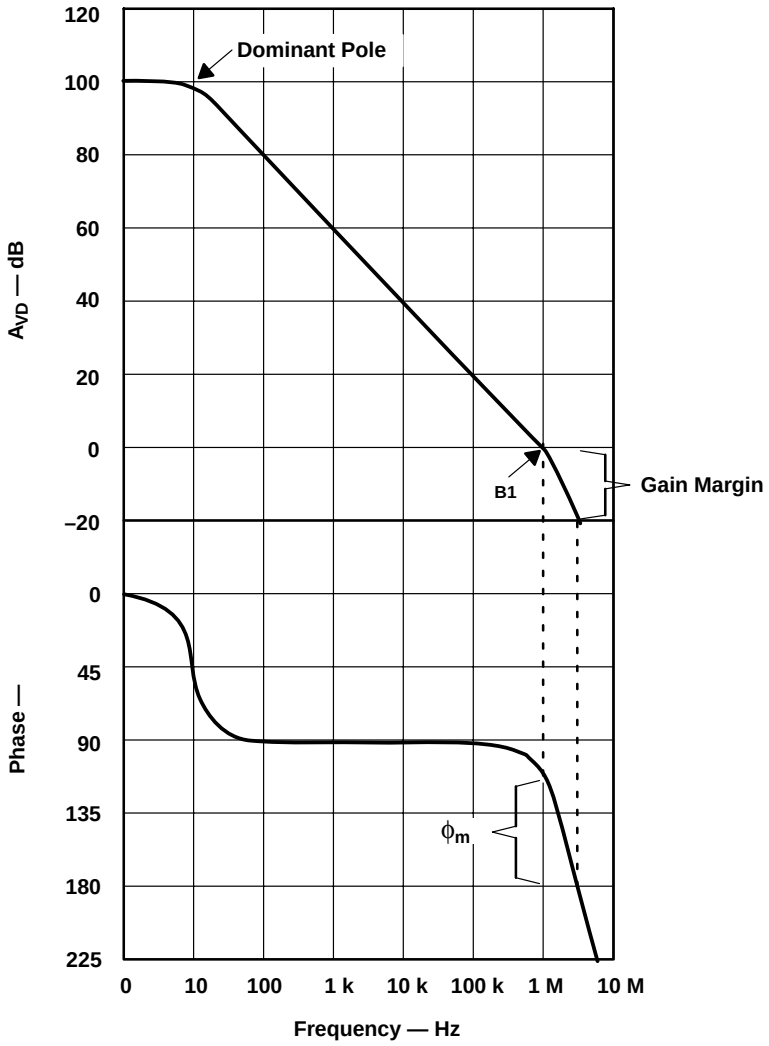

Figure 11–11. Voltage Amplification and Phase Shift vs. Frequency

11.3.16 Settling Time

It takes a finite time for a signal to propagate through the internal circuitry of an op amp. Therefore, it takes a period of time for the output to react to a step change in the input. In addition, the output normally overshoots the target value, experiences damped oscillation, and settles to a final value. Settling time, t_S, is the time required for the output voltage to settle to within a specified percentage of the final value given a step input.

Figure 11–12 shows this graphically:

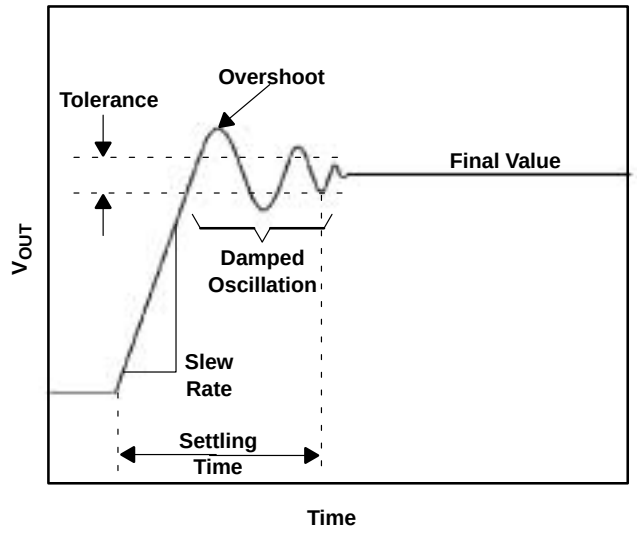

Figure 11–12. Settling Time

Settling time is a design issue in data acquisition circuits when signals are changing rapidly. An example is when using an op amp following a multiplexer to buffer the input to an A to D converter. Step changes can occur at the input to the op amp when the multiplexer changes channels. The output of the op amp must settle to within a certain tolerance before the A to D converter samples the signal.

Instrumentation: Sensors to A/D Converters

12.1 Introduction

The typical transducer measurement system block diagram is shown in Figure 12–1. The transducer is the electronic system's interface with the real world, and it issues data about a variable. The transducer converts the data into an electrical signal adequate for processing by the circuitry that follows the transducer. Bias and excitation circuitry does the care and feeding of the transducer, thus this circuitry provides offset voltages, bias currents, excitation signals, external components, and protection that is required for the transducer to operate properly. The output of the transducer is an electrical signal representing the measured variable.

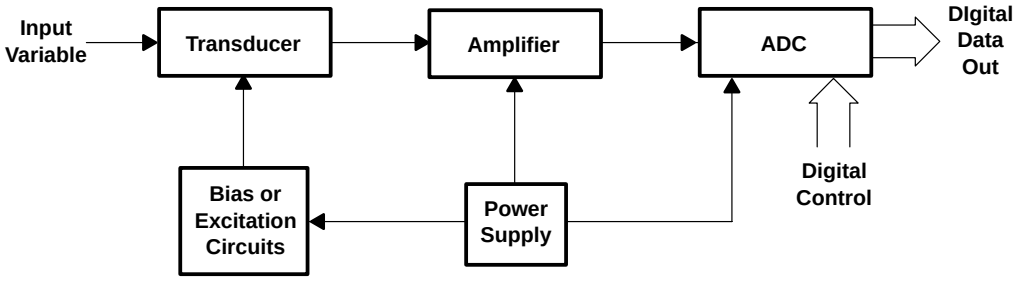

Figure 12–1. Block Diagram of a Transducer Measurement System

The variables that must be measured are determined by the customer's application, and the *measured variable* normally dictates the transducer selection. If the measured variable is temperature, then some sort of temperature sensing transducer must be employed, and the range of temperatures to be measured or the accuracy of the measurement is the primary factor influencing temperature transducer selection. Notice that the electrical output of the transducer is not a major concern at this point in the transducer selection. The transducer's electrical output is always a consideration, although picking the right transducer for the job is the primary goal. The correct transducer for the job can have an Ω/°C change, μV/°C change, or mV/°C change. All transducers have offset voltages or currents, and they can be referenced to ground, either power supply rail, or some other voltage. The selection of the transducer is out of circuit designer's hands; thus, the circuit designer must accept what the application demands.

The ADC selection is based on several system criteria such as resolution, conversion speed, power requirements, physical size, processor compatibility, and interface structure. The ADC must have enough bits to obtain the resolution required by the accuracy specification. The formula for calculating the resolution of an ADC is given in Equation 12–1 where n is the number of significant bits contained in the ADC.

$$\text{RESOLUTION} = 2^n \tag{12–1}$$

Some confusion exists about the word *bits* because the same word is used for binary bits and significant bits. Binary bits are ones and zeros used to calculate binary numbers; for example, a converter with 8 different digital states has 8 significant bits and $2^n = 256$ binary bits (see Figure 12–2). The voltage value of a single bit, called a least significant bit (LSB), is calculated in Equation 12–2.

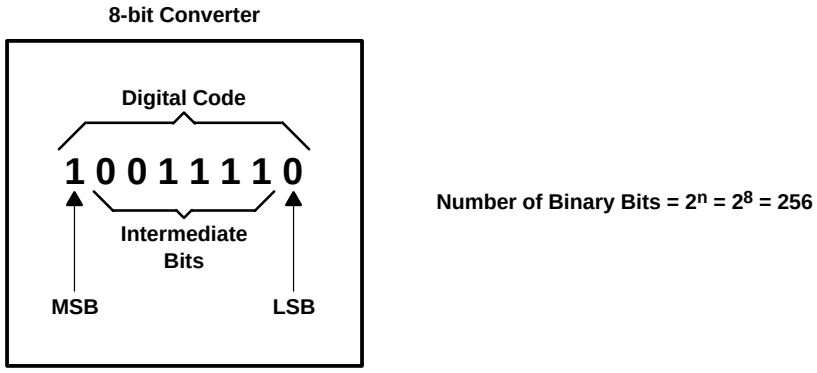

Figure 12–2. Significant Bits versus Binary Bits

$$\text{LSB} = \frac{\text{FSV}}{2^n} \tag{12–2}$$

FSV is the full-scale voltage of the converter in volts; hence, a 12-bit converter FSV = 10 volts has an LSB equal to $10/2^{12} = 2.441406$ mV/bit. In an ADC, an LSB is the maximum voltage change required to for a one-bit output change, and in an ADC an LSB is defined as $\text{LSB} = \text{FSV}/(2^n - 1)$.

Conversion speed is not critical in temperature measurement applications because temperature changes occur at slow rates. Directional control in a rocket traveling at Mach 2 happens much faster than temperature changes, so conversion speed is an important factor in rocket applications. The speed of an ADC is generally thought of as the conversion time plus the time required between conversions, and conversion speed dictates the converter structure. When conversion speed is a primary specification a flash converter is used, and flash converters require low impedance driving circuits. This is an example of a converter imposing a specification requirement, low output impedance, on the driving amplifier.

The system definition specifies the voltages available for design and the maximum available current drain. Some systems have multiple voltages available, and others are limited to a single voltage. The available voltage impacts the converter selection. Size, processor compatibility, and interface structure are three more factors that must be considered when selecting the ADC. The available package that the converter comes in determines what footprint or size that the converter takes on the printed circuit board. Some applications preclude large power-hungry ADCs, so these applications are limited to recursive or $\Sigma\Delta$-type ADCs. The converter must be compatible with the processor to preclude the addition of glue logic; thus, the processor dictates the ADC's structure. This defines the interface structure, sometimes the ADC structure, and the ADC timing.

Notice that the amplifier designer has not been consulted during this decision process, but in actuality, the systems engineers do talk to the amplifier designers if only to pacify them. The selection of the ADC is out of circuit designer's hands; thus, the circuit designer must accept what the application demands.

There are many different transducer/ADC combinations, and each combination has a different requirement. Although they may be natural enemies, any transducer may be coupled with any ADC, thus the amplifier must make the coupling appear to be seamless. There is no reason to expect that the selected transducer's output voltage span matches the selected ADC's input voltage span, so an amplifier stage must match the transducer output voltage span to the ADC input voltage span. The amplifier stage amplifies the transducer output voltage span and shifts its dc level until the transducer output voltage span matches the ADC input voltage span. When the spans are matched, the transducer/ADC combination achieve the ultimate accuracy; any other condition sacrifices accuracy and/or dynamic range.

The transducer output voltage span seldom equals the ADC input voltage span. Transducer data is lost and/or ADC dynamic range is not fully utilized when the spans are unequal, start at different dc voltages, or both. In Figure 12–3 (A), the spans are equal (3 V), but they are offset by 1 V. This situation requires level shifting to move the sensor output voltage up by one volt so the spans match. In Figure 12–3 (B), the spans are unequal (2 V and 4 V), but no offset voltage exists. This situation requires amplification of the sensor output to match the spans. When the spans are unequal (2 V versus 3 V) and offset (1 V), as is the case in Figure 12–3 (C), level shifting and amplification are required to match the spans.

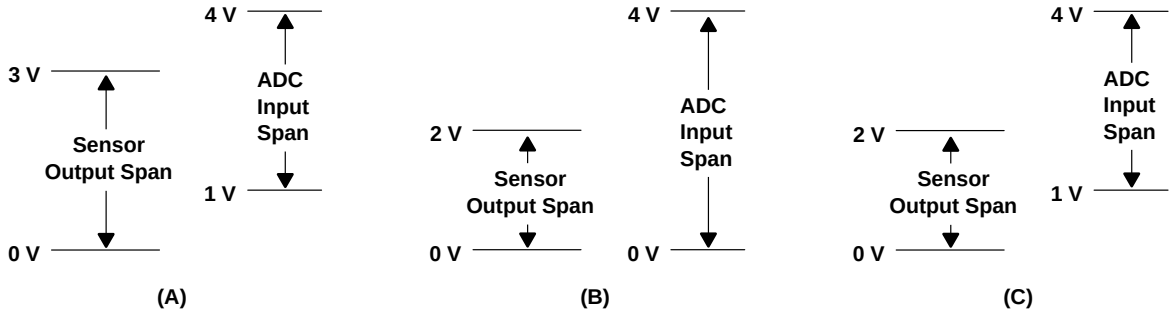

Figure 12–3. Example of Spans That Require Correction

The output span of the transducer must be matched to the input span of the ADC to achieve optimum performance. When the spans are mismatched either the transducer output voltage does not fit into the ADC input span thus losing sensor data, or the transducer output voltage does not fill the ADC input span thus losing ADC accuracy. The latter situation requires an increase in ADC dynamic range (increased cost) because a higher bit converter must be used to achieve the same resolution. The best analog circuit available for matching the spans is the op amp because it level shifts and amplifies the input voltage to make the spans equal. The op amp is so versatile that it shifts the signal's dc level and amplifies the input signal simultaneously.

A similar but different problem exists in the digital to analog converter (DAC) to actuator interface. The DAC output voltage or current span must match the actuator input voltage span to achieve maximum performance. The procedure for matching the DAC output span to the actuator input span can be quite different from the procedure for matching the transducer output span to the ADC input span. Transducer outputs are usually low-level signals, thus care must be taken to preserve their signal to noise ratio. Actuator input signals may require significant power, thus robust op amps are required to drive some actuators.

The system specifications eventually determine the transducer, ADC, and analog circuit specifications. System specifications are seen as absolute specifications; they must be met for the design to function in a satisfactory manner. Component specifications are divided into several categories; absolute maximum ratings (AMR), guaranteed minimum/maximum specifications (V_{MAX} or V_{MIN}), typical specifications (V), and guaranteed but not tested specifications (GNT).

If any of the device parameters are taken beyond the AMR, the device can be destroyed (expect destruction). The manufacturer guard bands the AMR to guarantee safety and quality, and you should guard band the AMRs, too. Typical specifications are the most appealing, but throw them out because they are meaningless in most cases. In the vast majority of cases the typical specifications are not related to meaningful data; rather, they are marketing dreams. Never design with typical specifications unless you are in the habit of designing with meaningless data or have a good reason for believing that typical is close to reality. A violation of this rule is a specification like output voltage swing that de-

pends heavily on test conditions such as the value of the load resistor. When the load resistance is much higher than that specified for the test condition, the output voltage swing is closer to the typical rather than the guaranteed specification. The laws of physics guarantee this truth, but the amount of extra voltage swing that is achieved is hard to calculate.

Guaranteed min/max specifications define the limits of a parameter. The parameter will always exceed the minimum value, and it will never exceed the maximum value. The guaranteed min/max specifications are your design specifications. Guaranteed but not tested (GNT) specifications are usually applied to parameters that are very expensive to test. The manufacturer either tests some other parameter related to the specification or they sample test each lot to insure compliance. GNT specifications are design specifications. There is a fifth specification called guaranteed by design (GBD), and if they are not critical specifications, GBD is a useful design specification.

All specifications have conditions associated with testing. They specify ambient temperature, supply voltage, test signals, test loads, and other conditions, and they define how the measurements are made. Inspect the test conditions carefully; an op amp that specifies a 5-V output swing with a 50-Ω load is much more capable of driving a load than an op amp that specifies a 5-V output swing with a 10-kΩ load. Beware, you assume the risk of a parameter being out of specification when you use devices at conditions other than the test conditions.

An error budget is a logical and orderly method of tabulating errors, and it helps the designer keep track of the errors by error sources. Meeting the system specifications translates into minimizing errors, choosing components with acceptable errors, and canceling or eliminating errors when possible. The error budget is first applied to the ADC and transducer because they are the components that the designer has the least control over. When these two error budgets are combined and subtracted from the system error allowance the result is the error allowance for the amplifier and peripheral circuits. The designer must choose components and design wisely to stay within the error allowance, or the system specifications are not met.

Sometimes the systems specifications can’t be met, and this fact is greeted with moans, name calling, and finger pointing. The error budgets are the design engineer’s only defense against subjective accusations. The error budgets document the design trail, and they show where changes need to be made to do the best job possible. It is very hard to maintain an error budget because errors must be converted to equivalent units (volts, bits, or amps), and the impact of the error term may not be calculable at that point in the design. When this situation occurs, tabulate the error terms in a table and calculate their effect later in the design process.

This chapter teaches the designer how to characterize the transducer and ADC, how to determine amplifier and design specifications through the use of error budgets, and how to complete circuit design. The equations developed in this chapter are not nearly as important as the design philosophy.

12.2 Transducer Types

This is not a treatise on transducers, but an appreciation for the many different types of transducers gives a feel for the extent and complexity of the transducer characterization problem (following section). The variety of electrical output that transducers offer loosely groups transducers. Various types of transducer outputs are resistive, optical, ac-excited, junction voltage, and magnetic, and each of these outputs must be converted to an electrical signal that can be amplified to fit the input span of an ADC. There are excellent references[1] that deal with transducer characterization, but the transducer manufacturer should be your first source of reference material.

The transducer manufacturer publishes data similar to that contained in an IC data sheet, and they take the same liberties with typical specifications that the IC manufacturers do. Sort through the data to determine the meaning of the various specifications, and then pay special attention to the test conditions that prevailed when the data was gathered. Look for application notes that show transducer excitation, bias, or interface circuits. Search several manufacturers for similar information because nobody manages to cover every aspect of a design

Some transducers such as strain gages, thermistors, RTDs, and potentiometers sense a change in resistance (ΔR). The ΔR sensing devices are used in at least three circuit configurations; the voltage divider, current excited, and Wheatstone bridge circuits shown in Figures 12–4, 12–5, and 12–6. The transducer resistance is R_T, and the change in transducer resistance caused by a change in the measured variable is ΔR.

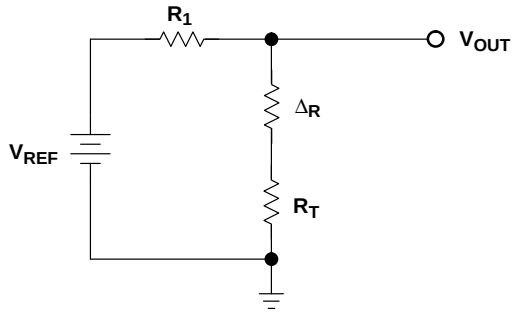

Figure 12–4. Voltage Divider Circuit for a Resistive Transducer

The voltage divider circuit uses a stable reference voltage to convert the transducer resistance into voltage, and its output voltage is given in Equation 12–3.

$$V_{OUT} = V_{REF} \frac{\Delta R + R_T}{\Delta R + R_T + R_1} \qquad (12–3)$$

If R_1 is comparable in value with R_T, the circuit has very low sensitivity because the circuit must measure a small change in resistance in the presence of a large resistance. When

the bias resistor, R_1, is selected as a large value, V_{REF} and R_1 act as a current source, and the transducer resistance can be neglected in the calculations thus yielding Equation 12–4. When $R_1 >> (R_T + \Delta R)$ Equation 12–3 reduces to Equation 12–4.

$$V_{OUT} = \frac{V_{REF}}{R_1}\left(\Delta R + R_T\right) \qquad (12–4)$$

Equation 12–5 is the equivalent of Equation 12–4, and it is obtained by exciting the transducer with a bias current as shown in Figure 12–5. The bias current can be made very accurate by employing op amps in a current source configuration as shown in Figure 12–6, thus the approximation $R_1 >> (R_T + \Delta R)$ need not enter the calculations.

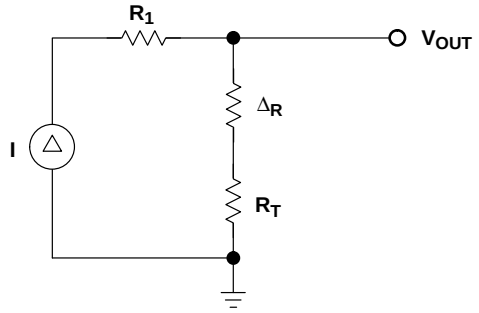

Figure 12–5. Current Source Excitation for a Resistive Transducer

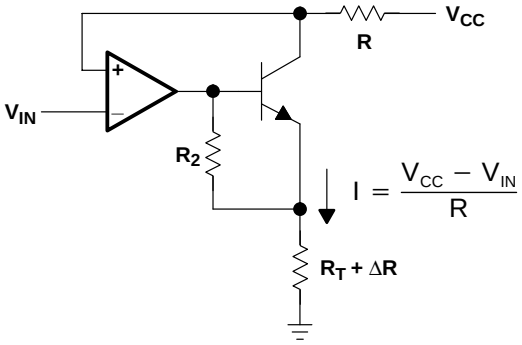

Figure 12–6. Precision Current Source

$$V_{OUT} = I\left(\Delta R + R_T\right) \qquad (12–5)$$

The Wheatstone bridge shown in Figure 12–7 is a precision device used to measure small changes in resistance. One leg of the bridge is made up of a voltage divider consisting of equal stable resistors (R_1 and R_2) and the reference voltage. When R_X and ΔR equal zero, R_{TX} is selected equal to R_T. As the transducer resistance changes ΔR assumes

some value, and R_X is switched until the bridge output voltage nulls to zero. At this point the value of ΔR is read from the R_X dial. Bridge circuits are used to convert resistive transducer values to dial readings, but there are methods of using transducers in bridge circuits that yield a voltage change proportional to the resistance change. The bridge circuit has a high output impedance, thus op amps configured in an instrumentation configuration (both inputs are equal high resistances) must be used to amplify the output voltage from bridge circuits.

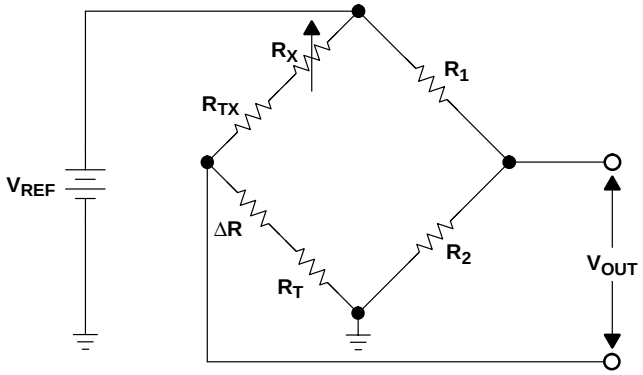

Figure 12–7. Wheatstone Bridge Circuit

The three most popular optical transducers are the photoconductive cell, the photodiode and the photovoltaic cell. The photoconductive cell acts like a light sensitive resistor, thus one of the circuits shown in Figures 12–4, 12–5, or 12–7 that convert resistance changes to voltage is used in photoconductive cell applications. The photodiode is a very fast diode with a small output current, and the circuit shown in Figure 12–8 is used to convert current to voltage. The photodiode is reversed biased with a constant voltage, so the photodiode terminating voltage stays constant thus maintaining linearity. The photodiode amplifier output voltage equation is Equation 12–6.

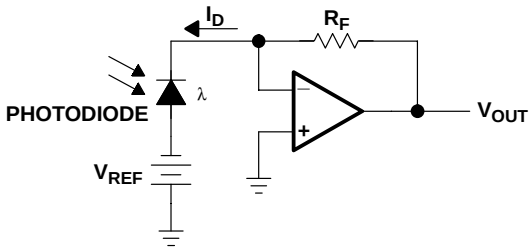

Figure 12–8. Photodiode Amplifier

$$V_{OUT} = I_D R_F \quad (12–6)$$

The phototransistor has a junction that is light sensitive, and the junction has a transparent cover so that it can sense ambient light. The collector-base junction of the transistor is reverse biased, and normal transistor action takes place with the ambient light induced base current taking place of the normal base current (see Figure 12–9).

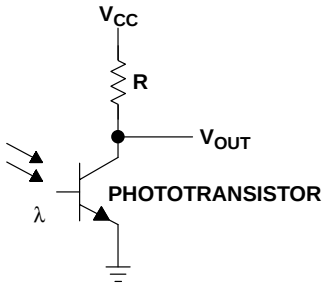

Figure 12–9. Phototransistor Amplifier

The photovoltaic or solar cell circuit is shown in Figure 12–10. The circuit zero-biases the cell for minimum leakage current, and the cell's output current is a linear function of the area exposed to light. When the photovoltaic cell is properly masked and evenly flooded with light, it operates as a linear distance transducer (see Figure 12–10 and Equation 12–6).

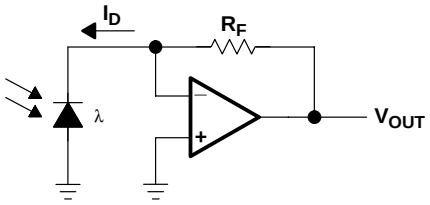

Figure 12–10. Photovoltaic Cell Amplifier

AC-excited transducers are usually used to make motion and/or distance sensors. In one type of ac-excited transducer, a stationary winding is excited with an ac current, and another winding is moved past the stationary winding inducing a voltage in the second winding. In a well-designed transducer, the induced voltage is proportional to distance, hence the output voltage is proportional to distance. Another ac-excited transducer uses two plates; one plate is excited with an ac current, and the other plate is ground. An object coming near the excited plate changes the capacitance between the plates, and the result is an output voltage change.

Resolvers and synchros are position transducers that indicate position as a function of the phase angle between the exciting signal and the output signal. Resolvers and synchros normally are multiple-winding devices excited from two or more sources. They indicate position very accurately, but their special circuitry requirements, cost, and weight limit them to a few applications such as airfoil control surfaces and gyros.

AC-excited transducers require a rectifier circuit to make the output voltage unipolar prior to integration. Coarse transducers use a diode or diode bridge to rectify the output voltage, but diodes are not adequate for precision applications because their forward voltage drop is temperature sensitive and poorly regulated. The diode problems are overcome through the use of feedback in the active full wave rectifier circuit shown in Figure 12–11. An integrating capacitor, C, is added to the circuit so the output voltage is a dc voltage proportional to the average voltage value of the input voltage.

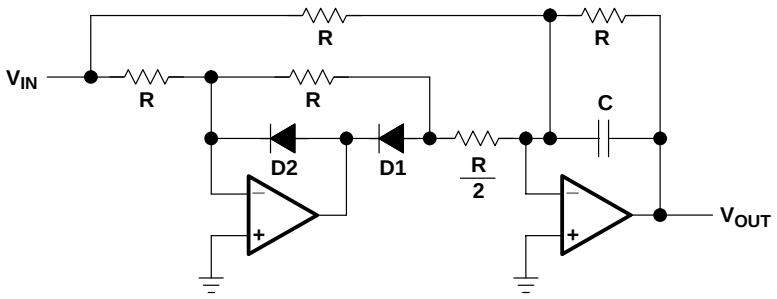

Figure 12–11. Active Full-Wave Rectifier and Filter

Semiconductor or wire junctions (thermocouples) are often used as temperature transducers because there is a linear relationship between temperature and output voltage over a restricted temperature range. Thermocouples have small voltages varying from μV/°C to mV/°C, and they normally are configured with thermistors and zeroing resistors in the output circuit. Thermocouples have small output voltages and high output resistance, thus a special op amp called an instrumentation amplifier is required for thermocouple amplification. An instrumentation amplifier has very high and equal input impedances, thus they don't load the input signal source.

Semiconductor junctions have a nominal temperature coefficient (TC) of –2 mV/°C. The TC is linear, but it varies from diode to diode because of manufacturing techniques, semiconductor materials, and bias currents. In a well-controlled application where thermal mass is insignificant, semiconductor junctions make excellent temperature transducers. The junction effect is so stable and linear that commercial temperature transducers have become available in a single IC.

Magnetic fields can be sensed by the Hall effect, and special semiconductors called Hall-effect sensors have been developed to sense magnetic fields. Current is passed through

the semiconductor in a direction perpendicular to the magnetic field. A pair of voltage pick off leads is placed perpendicular to the direction of current flow, and the output voltage is proportional to the magnetic field strength. The manufacturing process for Hall effect transducers is a standard semiconductor manufacturing process, so Hall effect transducers are offered for sale as transistors or ICs.

12.3 Design Procedure

A step-by-step design procedure that results in the proper op amp selection and circuit design is given below. This design procedure works best when the op amp has almost ideal performance, thus the ideal op amp equations are applicable. When nonideal op amps are used, parameters like input current affect the design, and they must be accounted for in the design process. The latest generation of rail-to-rail op amps makes the ideal op amp assumption more valid than it ever was.

No design procedure can anticipate all possible situations, and depending on the op amp selected, procedure modifications may have to be made to account for op amp bias current, input offset voltage, or other parameters. This design procedure assumes that system requirements have determined the transducer and ADC selection and that changing these selections adversely impacts the project.

1) Review the system specifications to obtain specifications for noise, power, current drain, frequency response, accuracy, and other variables that might affect the design.

2) Characterize the reference voltage including initial tolerances and drift.

3) Characterize the transducer to determine its salient parameters including output voltage swing, output impedance, dc offset voltage, output voltage drift, and power requirements. These parameters determine the op amp's required input voltage range (V_{IN1} to V_{IN2}), and input impedance requirements. The offset voltage and voltage drift are tabulated as errors. At this point it is assumed that the selected op amp's input voltage span is greater than the transducer's output voltage excursion. Design peripheral circuits if required.

4) Scrutinize the ADC's specification sheet to determine it's required input voltage range because this range eventually sets the op amp's output voltage swing requirement (V_{OUT1} to V_{OUT2}). Determine the ADC's input resistance, input capacitance, resolution, accuracy, full-scale range, and allowable input circuit charge time. Calculate the LSB value.

5) Create an error budget (in bits) for the transducer and ADC. Use the transducer/ADC error budget to determine the value and range of the critical op amp parameters. Select an op amp, and justify the selection by creating an error budget for the op amp circuit.

6) Scan the transducer and ADC specifications, and make a set of analog interface amplifier (AIA) specifications

7) Complete the AIA circuit design.

8) Build the circuit, and test it.

12.4 Review of the System Specifications

The power supply has only one voltage available, and that voltage is 5V ± 5% = 5 V ± 250 mV. The power supply is connected with the negative terminal at ground and the positive terminal at V_{CC}. This is not a portable application, thus the allowed current drain, 50 mA, is adequate for the job. No noise specifications are given, but the proposed power, ground, and signal traces are being done on high-quality circuit board material with planes and good size copper. A system of this quality should experience no more than 50 mV of noise on the logic power lines and 10 mV of noise on the analog power lines.

This is a temperature measuring system that requires updates every 10 seconds. Clearly, ADC conversion speed or input charging rate is not cause for consideration. The low conversion speed translates into lower logic speed, and slow logic means less noise generated. The temperature transducer is located at the end of a three-foot long cable, so expect some noise picked up by the cable to be introduced into the circuit. Fortunately, the long time between ADC conversions enable extensive filtering to reduce the cable noise.

The system accuracy required is 11 bits. The application measures several parameters so it is multiplexed, and a TLV2544 12 bits resolution ADC has been selected. The temperature transducer is a diode, and the temperature span to be measured is –25°C to 100°C. The ambient temperature of the electronics package is held between 15°C to 35°C.

12.5 Reference Voltage Characterization

A reference voltage is required to bias the transducer and act as a reference voltage for the analog interface amplifier (AIA). Selecting a reference with a total accuracy better than the accuracy specification (11 bits) does not guarantee meeting the system accuracy specification because other error sources exist in the design. Resistor tolerances, amplifier tolerances, and transducer tolerances all contribute to the inaccuracy, and the reference can’t diminish these errors. The quandary here is a choice between an expensive reference and expensive accurate components, or an adjustment to null out initial errors. This quandary boils down to which is the lesser of two evils; expensive components or the expense of an adjustment.

System engineering has decided that they want the adjustment, so the reference does not have to have 11-bit accuracy. A TL431A voltage reference is chosen for the design. The output voltage specification at 25°C and 10-mA bias current is 2495 mV ± 25 mV. This

reference has a temperature drift of 25 mV over 70°C, and this translates to 7.14 mV drift over a 20°C temperature range. There is another drift caused by the cathode voltage change, and this drift is 2.7 mV/V. The supply voltage regulation is 0.5 V, but much of this tolerance is consumed by the initial tolerance and wiring scheme, so the less than 0.1 V is due to regulator drift. The total drift is 7.14 mV + 0.27 mV = 7.41 mV. This yields a total drift of 0.3% maximum. The amplifier usually uses a fraction of the reference voltage, so the final AIA will not drift the full 0.3%.

12.6 Transducer Characterization

The temperature transducer is a special silicon diode that is characterized for temperature measurement work. When this diode is forward biased at 2.0 mA ± 0.1 mA its forward voltage drop is 0.55 V ± 50 mV, and its temperature coefficient is –2 mV/°C. The wide acceptable variation in bias current makes this an easy device to work with. The circuit for the bias calculations is shown in Figure 12–12.

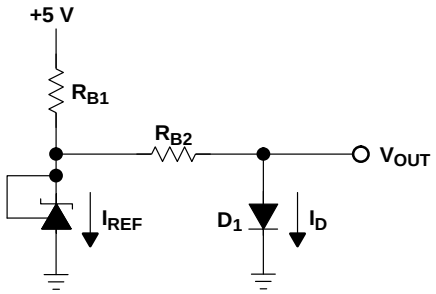

Figure 12–12. Reference and Transducer Bias Circuit

The current through R_{B1} is calculated in Equation 12–7. Remember, the reference must be biased at 10 mA, and the transducer must be biased at 2 mA.

$$I = I_{REF} + I_D = 10 + 2 = 12 \text{ mA} \quad (12\text{–}7)$$

The value of R_{B1} is calculated in Equation 12–8, and the value of R_{B2} is calculated in Equation 12–9.

$$R_{B1} = \frac{V_{+5} - V_{ref}}{I} = \frac{5 - 2.495}{12} = 208\ \Omega \quad (12\text{–}8)$$

$$R_{B2} = \frac{V_{ref}}{I_D} = \frac{2.495}{2} = 1247\ \Omega \quad (12\text{–}9)$$

Both resistors are selected from the list of 1% decade values, thus R_{B1} = 210 Ω, 1%, and R_{B2} = 1240 Ω, 1%. The resistor values have been established, so it is time to calculate

the worst case excursions of I_D (Equations 12–10 and 12–11). The resistors are assumed to have a 2% tolerance in these calculations. The extra 1% allows for temperature changes, vibration, and life. Three percent tolerances would have been used if the electronics' ambient temperature range were larger.

$$I_{D(MIN)} = \frac{V_{REF(MIN)}}{R_{B2(MAX)}} = \frac{2.47 - 0.025 - 0.007}{1.02\ (1.24)} = 1.93\ mA \quad (12–10)$$

$$I_{D(MAX)} = \frac{V_{REF(MAX)}}{R_{B2(MIN)}} = \frac{2.52 - 0.025 - 0.007}{0.98\ (1.24)} = 2.10\ mA \quad (12–11)$$

The bias current extremes do not exceed the transducer bias current requirements, so the transducer will meet the specifications advertised. The converter is 12 bits and the full-scale voltage is assumed to be 5 V, so the value of an LSB is calculated in Equation 12–12. The nominal transducer output voltage is 550 mV at an ambient temperature of 25°C. At –25°C, the transducer output voltage is 550 mV+ (–2 mV/°C)(–50°C) = 650 mV. At 125°C, the transducer output voltage is 550 mV + (–2 mV°C)(75°C) = 400 mV. This data is tabulated in Table 12–1.

$$LSB = \frac{FSV}{2^N} = \frac{5}{2^{12}} = 1.22\ mV \quad (12–12)$$

Table 12–1. Transducer Output Voltage

TRANSDUCER TEMPERATURE	TRANSDUCER OUTPUT VOLTAGE	ANALOG INTERFACE AMPLIFIER INPUT VOLTAGE
–25°C	650 mV	V_{IN1} = 650 mV
25°C	550 mV	550 mV
100°C	400 mV	V_{IN2} = 400 mV

The steady state (V_{TOS}) offset voltage is ± 50 mV, thus transducer output voltage (V_{TOV}) ranges from 350 mV to 700 mV. The offset voltage is stripped out by the adjustments in the AIA, so it is not of any concern here. V_{TOS} spans 100 mV, thus it is a 100 mV/1.22 mV/bit = 82 bit error unless it is adjusted out.

The output impedance of the transducer is equivalent to the resistance of a forward biased diode (Equation 12–13).

$$R_D = \frac{26}{I} = \frac{26}{2} = 13\ \Omega \quad (12–13)$$

At this stage of the design there are two parameters that influence the accuracy of the measurement, and they are the temperature coefficient of the transducer and the output

impedance of the transducer. The temperature transducer has been biased correctly, thus its temperature coefficient should be the advertised value of –2 mV/°C. The output impedance of the transducer forms a voltage divider with the input resistance of the AIA, but this error can't be calculated until the AIA is selected. The final transducer error contribution is that portion of the V_{TOS} that can't be adjusted out, and this error is determined during the AIA design.

12.7 ADC Characterization

This particular ADC was selected because it has a multiplexer and it enables different modes of operation. The temperature measurement is done in the single-shot mode because this mode allows the user to set the charge time at the input to the converter. During charging, the ADC's input resistance is low, but after the ADC input is charged the input resistance rises to 20 kΩ. This high input resistance does not load the AIA output circuit, thus the AIA achieves full rail-to-rail output voltage swing.

The internal reference is used in this application, and the reference sets the input voltage span required to obtain full accuracy for the ADC. Using the internal reference, the input voltage span is 0 V to 4 V. The offset voltage (V_{ADCOS}) is ± 150 mV, and the voltage drift is 40 PPM/°C. The voltage drift over the full temperature range is 40 PPM/°C(20°C) = 800 PPM. There are 244 PPM/LSB in a 12-bit converter, so the drift voltage error is 800/244 ≈ 4 bits error.

The ADC output is full scale (all bits 1) when the input voltage is 4 V, and it is zero (all bits 0) when the input voltage is 0 V. This data is tabulated in Table 12–2. Because the full scale output voltage has changed to 4 volts the LSB is calculated to be $4/(2^{12})$ = 976.6 μV/bit.

Table 12–2. ADC Input Voltage

ADC INPUT VOLTAGE	DIGITAL OUTPUT	ANALOG INTERFACE AMPLIFIER OUTPUT VOLTAGE
0 V	000000000000	V_{OUT1} = 0 V
4 V	111111111111	V_{OUT2} = 4 V

12.8 Op Amp Selection

It is time to select the op amp, and the easiest way to do this is to list the known specifications or requirements, list a candidate op amp's specifications, and calculated the projected error that the candidate op amp yields.

Table 12–3. Op Amp Selection

DESIGN SPECIFICATION	ESTIMATED VALUE	CANDIDATE OP AMP: TLV247X
R_{IN}	10^6 (13) Ω	10^{12} Ω
V_{TOV}	350 mV to 700 mV	–0.2 V to 5.2 V
R_{OUT}		1.8 Ω
V_{INADC}	0 V to 4 V	0.15 V to 4.85 V
V_{OS}	——	2.2 mV
I_B	——	100 pA
V_N	——	$\frac{28\ nV}{\sqrt{Hz}}$
I_N	——	$\frac{0.39\ pA}{\sqrt{Hz}}$
Analog noise	——	10 mV
k_{SVR}	——	63 dB

There should be almost no error from R_{IN} because the transducer output impedance is very low. The high side of the op amp's output voltage swing (4.85 V) is much higher than the ADC input voltage (4 V). The low side of the op amp's output voltage swing (0.185 V) is less than the ADC input voltage swing (0 V). The ADC input circuit is 20 kΩ and that doesn't load the op amp output stage, so the op amp output voltage swing is very close to the ADC input voltage range. R_{OUT} should present no problems acting as a voltage divider with the ADC input resistance. V_{OS} and I_{IB} create offset voltages that add to the reference offset voltage, and they have to be adjusted out as a group. The system noise overshadows the op amp noise, thus the op amp noise is accepted unless later calculation prove otherwise.

12.9 Amplifier Circuit Design

Enough information exists for the AIA to be designed. The TLV247X op amp is selected because it meets all the system requirements. The first step in the design is to determine the AIA input and output voltages, and this has already been done. These voltages are taken from Tables 12–1 and 12–2, and repeated here as Table 12–4.

Table 12–4. AIA Input and Output Voltages

INPUT VOLTAGE	OUTPUT VOLTAGES	
V_{IN1} = 650 mV	V_{OUT1} = 0 V	1st pair of data points
V_{IN2} = 400 mV	V_{OUT2} = 4 V	2nd pair of data points

The equation of an op amp is the equation of a straight line as given in Equation 12–14.

$$Y = mX + b \tag{12–14}$$

Two pairs of data points shown in Table 12–4 are substituted in Equation 12–14 making Equations 12–15 and 12–16.

$$4 = 0.4m + b \tag{12–15}$$

$$0 = 0.65m + b \tag{12–16}$$

Equation 12–15 is solved and substituted into Equation 12–16 to obtain Equation 12–17.

$$4 = 0.4\left(\frac{-b}{0.65}\right) + b \tag{12–17}$$

Solving Equation 12–17 yields b = 10.4, and solving Equation 12–15 yields m = –16. Substituting these values back into Equation 12–14 yields Equation 12–18, and Equation 12–18 (the final equation for the AIA) is put in electronic terminology.

$$V_{OUT} = -16V_{IN} + 10.4 \tag{12–18}$$

The circuit that yields the transfer function developed in Equation 12–18 is shown in Figure 12–13.

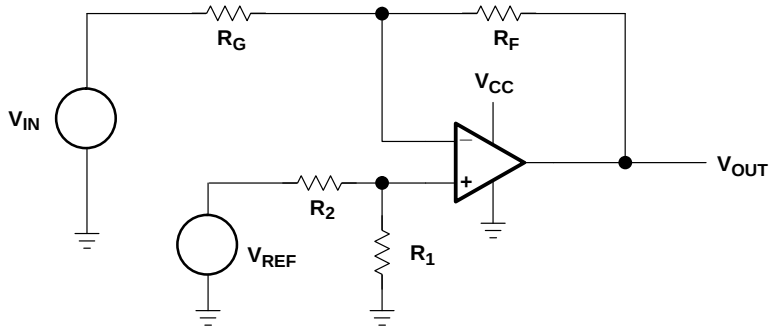

Figure 12–13. AIA Circuit

The equations for the AIA circuit are given below.

$$V_{OUT} = -V_{IN}\left(\frac{R_F}{R_G}\right) + V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \tag{12–19}$$

$$|m| = \frac{R_F}{R_G} \tag{12–20}$$

$$b = V_{REF}\left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F + R_G}{R_G}\right) \tag{12–21}$$

Equation 12–18 gives the value for m as 16, and using Equation 12–20 yields $R_F = 16R_G$. Select R_F = 383 kΩ and R_G = 23.7 kΩ because they are standard 1% resistor values, and

this yields m = 16.16. The resistors R1 and R2 are calculated with the aid of Equations 12–22 and 12–23.

$$\frac{R_1}{R_1 + R_2} = \frac{b}{V_{REF}}\left(\frac{R_G}{R_F + R_G}\right) = \frac{10.4}{2.495}\left(\frac{23.7}{23.7 + 383}\right) = 0.2424 \qquad (12–22)$$

$$R_1 = \frac{0.2424}{0.7576} R_2 = 0.32 R_2 \qquad (12–23)$$

The parallel combination of R_1 and R_2 should equal the parallel combination of R_F and R_G so that the input voltage offset caused by the op amp input current is cancelled. Select R_2 = 105 kΩ and R_1 = 33.2 kΩ because they are standard 1% values, and then b = 10.3. The value of the parallel combination of R_1, R_2 ($R_1||R_2$ = 25.22 kΩ) almost matches the value of the parallel combination of R_F, R_G ($R_F||R_G$ = 22.3kΩ), and this is an adequate match for input current cancellation. The downsides of selecting large resistor values for R_F are current noise amplification, increased resistor noise, smaller bandwidth because of stray capacitance, and increased offset voltage due to input current. Bandwidth clearly is not a factor in this design. The op amp input current is 100 pA, so it won't cause much offset with a 383-kΩ feedback resistor (38.3 μV). The noise current and voltage are calculated later when the error budget is made.

The gain, m, and the intercept, b, are not accurate because the exact resistor values were not available in the 1%-resistor selection chart. This is a normal situation, and in less demanding designs the small error either does not matter or is corrected someplace else in the signal chain. That error is critical in this design, so it must eliminated. There are several nondrift type errors that have accumulated up to this point, and now is the time to correct all the nondrift errors with the addition of adjustments. Two adjustments are used; one adjustment controls the gain, m, and the other controls the intercept, b. The value of the adjustable resistor must be large enough to deliver an adequate adjustment range, but any value larger than that decreases the adjustment resolution.

The data that determines the adjustment range required is tabulated in Table 12–5. Drift and gain errors are calculated in volts, but drift errors are calculated in bits because they are not eliminated by adjustments. Remember, a LSB for this system is 4/4096 = 976.6 μV/bit.

Table 12–5. Offset and Gain Error Budget

ERROR PARAMETER	INTERCEPT	GAIN	DRIFT
V_{REF}	±25 mV		
V_{REF} drift			7.41 mV ≈ 8 LSB
Transducer offset		± 50 mV	
Transducer R_{OUT}			13 Ω ≈ 0 LSB
ADC reference		± 150 mV	1 LSB
Total unadjusted ADC error			2 LSB
Gain error		1.6 LSB	
ADC drift			4 LSB
V_{OS} op amp	2.2 mV		
I_B op amp	100 pA		
V_N op amp			$\frac{28\ nV}{\sqrt{Hz}}$ ≈ 1 LSB
I_N op amp			$\frac{139\ pA}{\sqrt{Hz}}$ ≈ 0 LSB
V_{NPS} PS noise			10 mV ≈ 2 LSB
R_{OUT} op amp			1.8 Ω ≈ 0 LSB
$V_{OUT\ LOW}$ op amp			70 mV ≈ 72 LSB
Total error			18 LSB

The adjustment for the intercept, b, depends on R_1, R_2, and V_{REF}. This adjustment has to account for the reference offset, the op amp input voltage offset, the op amp input current, and the resistor tolerances. The offset voltage inherent in the reference is given as ± 25 mV. The op amp input offset voltage is 2.2 mV; usually op amp offset voltage calculations include multiplying this offset by the closed loop gain, but this isn't done because the offset voltage is adjusted out in the input circuit. The op amp input current is converted to a common-mode voltage by the parallel combination of the reference resistors, so it is neglected in this calculation.

The worst case reference input voltage for the op amp, $V_{REF(MIN)}$, is calculated in Equation 12–24, where the resistor tolerances are assumed to be 3%, and the reference voltage error is 50 mV.

$$V_{REF(MIN)} = \left(V_{REF} - 50\ mV\right)\frac{0.97R_1}{0.97R_1 + 1.03R_2}$$
$$= (2.495 - 0.05)\frac{0.97(33.2)}{0.97(33.2) + 1.03(105)} = 0.566\ V \quad (12–24)$$

The nominal reference voltage at the op amp input is 0.6 V, so the reference voltage has to have about 40 mV adjustment around the nominal, or a total adjustment range of 80 mV. The nominal current through the voltage divider is $I_{DIVIDER}$ = (2.495/(105 + 33.2) kΩ = 0.018 mA. A 4444-kΩ resistor drops 80 mV, thus the adjustable resistor (a potentiometer) must be greater than 4444 kΩ. Select the adjustable resistor, R_{1A}, equal to 5 kΩ because this is an available potentiometer value, and the offset adjustment is ± 45 mV. Half of the potentiometer value is subtracted from R_1 to yield R_{1B}, and this subtraction centers the adjustment about the nominal value of 0.6V. R_{1B} = 33.2 kΩ – 2.5 kΩ = 30.7 kΩ. Select R_{1B} as 30.9 kΩ.

The adjustment for the gain employs R_F and R_G to insure that the gain can always be set at the value required to insure that the transducer output swing fills the ADC input range. The gain equation (Equation 12–18) is algebraically manipulated, worst case values are substituted for m and b, and it is presented as Equation 12–25.

$$G = \frac{V_{OUT} - 10.4}{-V_{IN}} = \frac{3.85 - 10.4}{-0.35} = 18.71 \quad (12–25)$$

Equation 12–26 is Equation 12–27 with 3% resistor tolerances.

$$0.97R_F = 18.71\left(1.03R_G\right) \quad (12–26)$$

Doing the arithmetic in Equation 12–26 yields R_F = 19.86 R_G. Thus, on the high side the gain must go from 16 to 19.86, or it must increase by 3.86. Assuming that the low side gain variation is equal, and rounding off to 4 sets the gain variation from 12 to 20. When R_G = 23.7 kΩ R_F varies from 284.4 kΩ to 474 kΩ. R_F is divided into a potentiometer R_{FA} = 200 kΩ and R_{FB} = 280 kΩ, thus the nominal gain can be varied from 11.8 to 20.2.

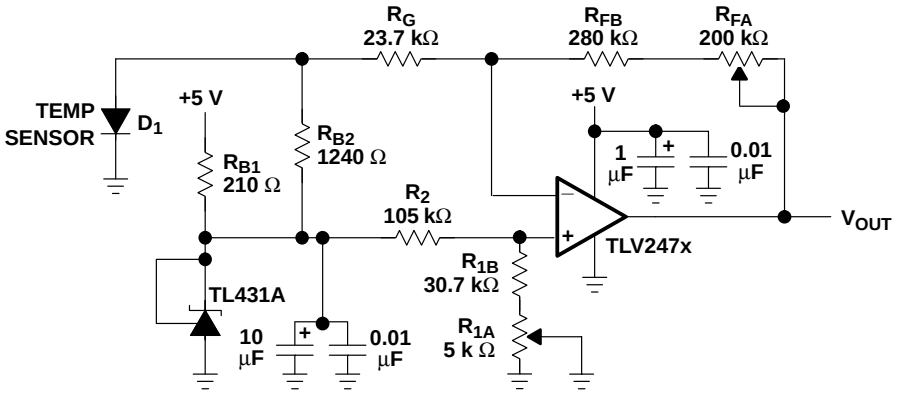

Figure 12–14. Final Analog Interface Circuit

There is no easy method of setting two interacting adjustments because when the gain is changed the offset voltage changes. They quickest method of adjustment is to connect the transducer to the circuit, adjust the offset, and then adjust the gain. It takes several series of adjustments to get to the point where the both parameters are set correctly.

The impedance and noise errors are calculated prior to completing the error budget. The op amp input impedance works against the transducer output impedance to act like a voltage divider. The value of the voltage divider is calculated in Equation 12–27, and as Equation 12–27 indicates, the output resistance of the transducer is negligible compared to the input resistance of the op amp. This is not always the case!

$$V_D = V_T \frac{R_{IN}}{r_c + R_{IN}} = V_T \frac{10^6}{13 + 10^6} \approx V_T \qquad (12\text{–}27)$$

The ADC input impedance works against the op amp output impedance to act like a voltage divider. The value of the voltage divider is calculated in Equation 12–28. The voltage divider action introduces about a 0.009% error into the system, and this is within 13-bit accuracy, so it can be neglected.

$$V_{IN} = V_{OUT} \frac{20(10^3)}{1.8 + 20(10^3)} = \frac{20}{20.0018} = 0.99991\ V_{OUT} \qquad (12\text{–}28)$$

The noise specification is given in nV/(Hz$^{0.5}$), and this must be converted to volts. There are involved formulas for the conversion, but the simplest thing to do is assume the noise is wide band. If the numbers add up to a significant error, detail calculations have to be made. The voltage noise is multiplied by the closed loop gain, thus $V_{NWB} = V_N\ (G_{MAX})$ = 28 nV(20) = 560 nV = 0.56 μV. The current noise is multiplied by the parallel combination of R_F and R_G, thus I_{NWB} $I_N(R_F||R_G)$ = 139 pA(22.5 kΩ) = 3.137 nV. The system noise is 10 mV, and this noise comes in through the inputs and the power supply. The power sup-

ply contribution is reduced by the power supply rejection ratio, and it is 10 mV/63 dB = 10 mV/1412 = 7.08 nV. This calculation assumes that high-frequency noise is not a problem, but if this is not true, CMRR must be reduced per the data sheet CMRR versus frequency curves.

Some of the system noise propagates through the inputs and is rejected by the common-mode rejection of the op amp. The op amp is not configured as a differential amplifier, so a portion of the closed loop gain will multiply some of the system noise.

The ac gain of the AIA is given in Equation 12–29.

$$V_{OUT} = \alpha V_{SN} \left(\frac{R_1}{R_1 + R_2}\right)\left(\frac{R_F}{R_F + R_G}\right) - \alpha V_{SN} \frac{R_F}{R_G} \qquad (12\text{–}29)$$

$$= \alpha V_{SN} (4.12 - 16) = 11.8\, \alpha V_{SN}$$

All of the system noise does not get in on the inputs, rather most of the system noise is found on the power supply. The fraction of the system noise that gets into the ground system and onto the op amp inputs is very small. This fraction, α, is normally about 0.01 because the power supplies are heavily decoupled to localize the noise. Considering this, the system noise is 1.18 mV, or less than 2 LSBs.

The op amp output voltage range does not include 0 volts, and the ADC output voltage low value is 0 volts, so this introduces another error. The guaranteed op amp low voltage is 185 mV at a load current of 2.5 mA. The output current in this design is 185 mV/20 kΩ = 9.25 μA. This output current approximates a no load condition, hence the nominal low voltage typical specification of 70 mV is used. This leads to a 72 LSB error, by far the biggest error.

Referring to Table 12–5, notice that the total error is 90 LSB. Losing 90 LSBs out of 4096 total LSBs is approximately 11.97 bits accurate, so the 11-bit specification is met. The final circuit is shown in Figure 12–14.

Notice that large decoupling capacitors have been added to the power supply and reference voltage. The decoupling capacitors localize IC noise, prevent interaction between circuits, and help keep noise from propagating. Two decoupling capacitors are used, a large electrolytic for medium and low frequencies, and a ceramic for high frequencies. Although this portion of the design is low frequency, the op amp has a good frequency response, and the decoupling capacitors prevent local oscillations through the power lines. If cable noise is a problem, an integrating capacitor can be put in parallel with R_F to form a low-pass filter.

12.10 Test

The final circuit is ready to build and test. The testing must include every possible combination of transducer input and ADC output to determine that the AIA functions in all manufacturing situations. The span of the adjustments, op amp output voltage range, and ADC input range must be checked for conformance to the design criteria. After the design has been tested for the specification limits it should be tested for user abuse. What happens when the power supply is ramped up, turned on instantly, or something between these two limits? What happens when the inputs are subjected to over voltage, or when the polarity is reversed? These are a few ideas to guide your testing.

12.11 Summary

The systems engineers select the transducer and ADC, and their selection criterion is foreordained by the application requirements. The AIA design engineer must accept the selected transducer and ADC, and it is the AIA designer's job to make these parts play together with adequate accuracy. The AIA design often includes the design of peripheral circuits like transducer excitation circuits, and references.

The design procedure starts with an analysis of the transducer and ADC. The analysis is followed by a characterization of the transducer and reference. At this point enough information is available to make an error budget and select candidate op amps. The op amp is selected in the next step in the procedure, and the circuit design follows.

The output voltage span of the transducer and corresponding input voltage span of the ADC are coupled as two pairs of data points that form the equation of a straight line. The data point pairs are substituted into simultaneous equations, and the equations are solved to determine the slope and intercept of a straight line (an op amp solution). The op amp circuit configuration is selected based on the sign of the slope and the intercept. Finally, the passive components used in the op amp circuit are calculated with the aid of the op amp circuit design equations.

The final circuit must be tested for conformance to the system specifications, but the prudent engineer tests beyond these specifications to determine the AIA's true limits.

Chapter 13

Wireless Communication: Signal Conditioning for IF Sampling

Perry Miller and Richard Cesari

13.1 Introduction

High-speed operational amplifiers (op amps) are used extensively in wireless communication systems. These amplifiers typically operate at intermediate frequencies (IF) ≤ 500 MHz and most frequently operate below 25 MHz. Applications for high-speed op amps include filtering circuits in radio receivers, IF amplifiers, mixer circuits, and bandpass amplifiers.

13.2 Wireless Systems

This chapter focuses on the requirements for the op amp and a number of techniques used in wireless communication systems to interface high-speed op amps to analog-to-digital converters (ADCs) and digital-to-analog converters (DACs). This section provides several examples of different op amp usage.

Figure 13–1 shows an example of a dual-IF receiver. In this application, several stages with different IF frequencies are used to get the desired performance. The receiver converts the received radio frequency (RF) input from the antenna to a baseband signal. This type of system requires the ability to receive and operate over a wide range of signal strength. The inherent system noise level determines the lower operating limit and is a critical factor in the overall performance of the receiver. The receiver performance is measured in terms of receiver sensitivity, which is defined as the ratio between the power of the wanted baseband signal at the output of the ADC and the total power of all unwanted signals (include random noise, aliasing, distortion, and phase noise contributed by the local oscillator) introduced by the different circuit elements in the receiver. A low-sensitivity receiver can cause signal saturation in the ADC input.

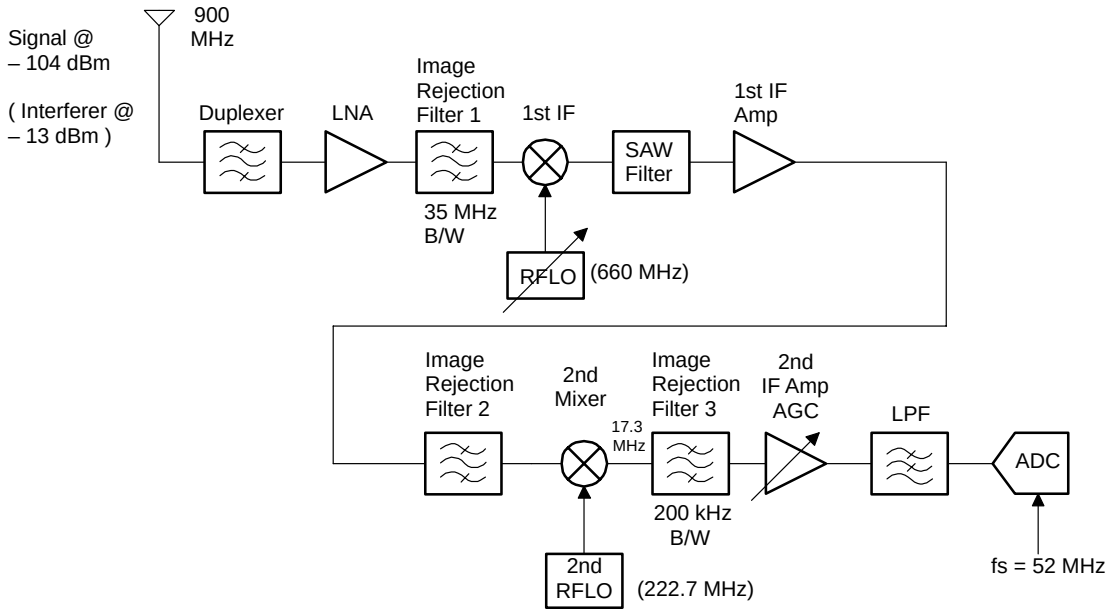

Figure 13–1. A Typical GSM Cellular Base Station Receiver Block Diagram

The receiver contains two mixer stages reminiscent of a classic superhetrodyne receiver with good selectivity. The process of hetrodyning involves the translation of one frequency to another by the use of a mixer and local oscillator (LO) offset at the proper frequency to convert the RF signal to the desired IF. The LO signal is at a much higher level than the RF signal. In Figure 13–1, the 900 MHz RF signal is picked up by the antenna and amplified by a low-noise amplifier (LNA). After being sufficiently amplified by the LNA to overcome the noise level, the RF signal passes through a bandpass filter (BPF) used to provide image rejection and sufficient selectivity prior to the first stage mixing.

High selectivity prevents adjacent channel energy from getting into the input of the ADC and decreasing the receiver dynamic range. A strong signal in an adjacent channel causes intermodulation products in the receiver that can result in loss of the received signal. The band-pass filter is implemented with a surface acoustic wave (SAW) filter. The SAW filter provides very sharp edges to the passband, with minimum ripple and phase distortion.

The first stage mixer down-converts the band-limited RF signal with the LO signal, producing a number of new frequencies in the spectrum, including the sum frequency component, the difference frequency component, and spurious responses. The first stage IF filter provides sufficient filtering after the mixing circuit. It selects the difference frequency component while rejecting the sum frequency component and undesirable spurious responses. Passing the difference frequency component on to the next stage of the receiver makes it much easier to provide the gain and filtering needed for proper receiver function-

ality. Image rejection also places a constraint on the choice of the IF (10 MHz – 20 MHz). The spurious responses are the result of power supply harmonics and intermodulation products created during the mixing of the RF signal and the LO signal. If not substantially suppressed, spurious responses often corrupt the IF signal and cause it to be accepted as a valid IF signal by the IF amplifier.

The first stage IF amplifier minimizes the effects of the first stage filter loss on the noise figure and amplifies the signal to a suitable level for the second stage mixer. The output from the second stage mixer is applied to the second stage IF amplifier, automatic gain control (AGC) amplifier, and the subsequent low-pass filter, producing a 1-V full-scale input to the ADC. The ADC samples and digitizes this baseband analog input. The AGC amplifier ensures that if the received signal amplitude goes up rapidly, the ADC is not saturated. At the other extreme, if there is a fast power ramp down, the AGC prevents the signal quality from passing below an acceptable level. High-speed current-feedback operational amplifiers (CFA) are typically used to filter and amplify the IF signals because this type of operational amplifier has good slew rate, wide bandwidth, large dynamic range, and a low noise figure.

In this type of receiver, the ADC is a key component requiring sampling rates ≥ 40 MSPS with 12 bits to 14 bits of resolution and is usually a pipeline architecture device. The output of the ADC is highly dependent on the ADC's sampling frequency, nonlinearities in the ADC and the analog input signal, and the converter maximum frequency.

Table 13–1 tabulates the contribution of each stage depicted in Figure 13–1 to the system level budget for a typical GSM receiver. GSM is the global system for mobile communications. It is one of the most popular digital cellular formats in the world.

Figure 13–2 shows a more flexible implementation for the receiver using a digital signal processor (DSP). Using a DSP allows a single receiver to access several different wireless systems through changes in software configuration.

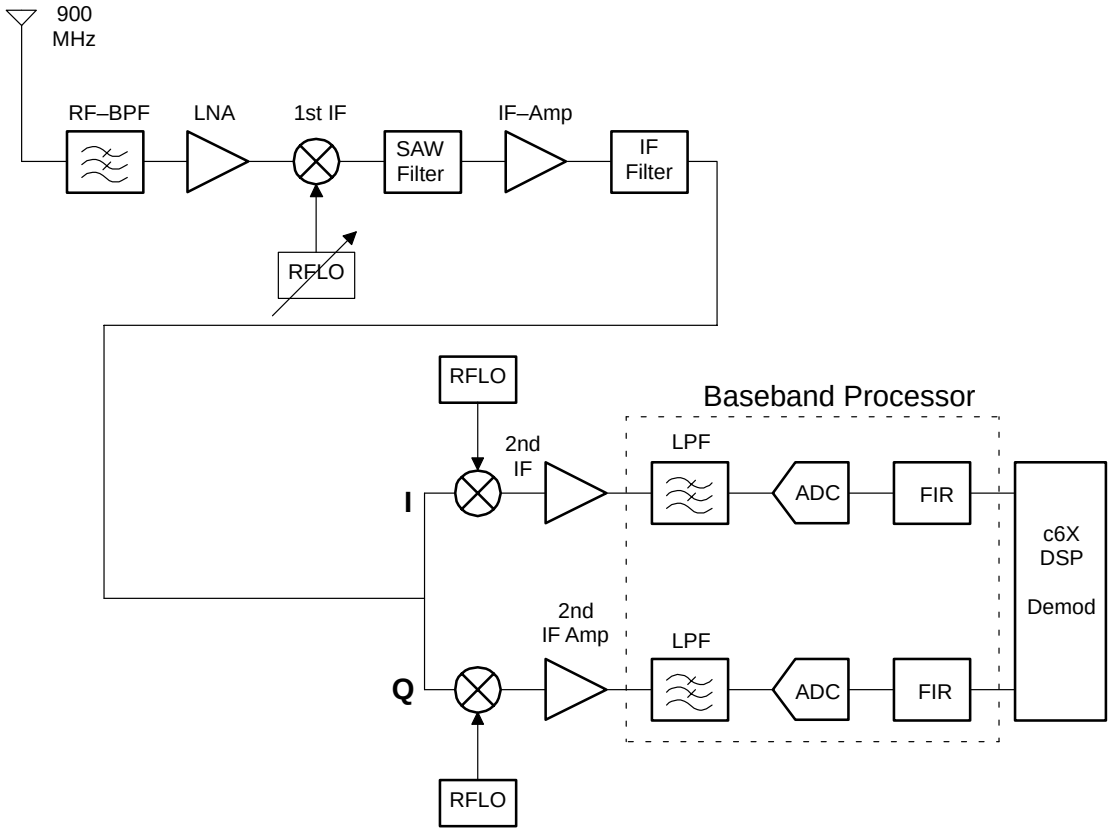

Figure 13–2. An Implementation of a Software-Configurable Dual-IF Receiver

Figure 13–3 shows a basic W-CDMA transmit chain. A voiceband CODEC (coder–decoder), op amps, and a DSP are used to digitize and band-limit the audio signal. The digitized signal is then compressed to the appropriate data rate either in hardware or by a software program implemented on the DSP. Redundancy (error correction), encryption, and the appropriate form of modulation (QPSK for W–CDMA or GMSK for GSM) are added to the compressed digitized signal. This signal goes via an interpolating filter to the communication DAC as shown in Figure 13–4. Eight times interpolation[1],[2] is shown in Figure 13–4, but other multiple-of-2 interpolations are possible and quite often used. Assuming that the modulated bit stream is a 3.84 MSPS W–CDMA signal, for 8x interpolation, the sampling clock frequency would need to be 30.72 MHz. The DAC converts the modulated bit stream to analog, and the conversion is usually performed by a pair of DACs: one for I channel and one for Q channel — see Figure 13–3. The reconstruction filter, at the output

of the DAC, is usually a high-order Bessel or elliptic filter used to low-pass filter the analog output from the DAC.

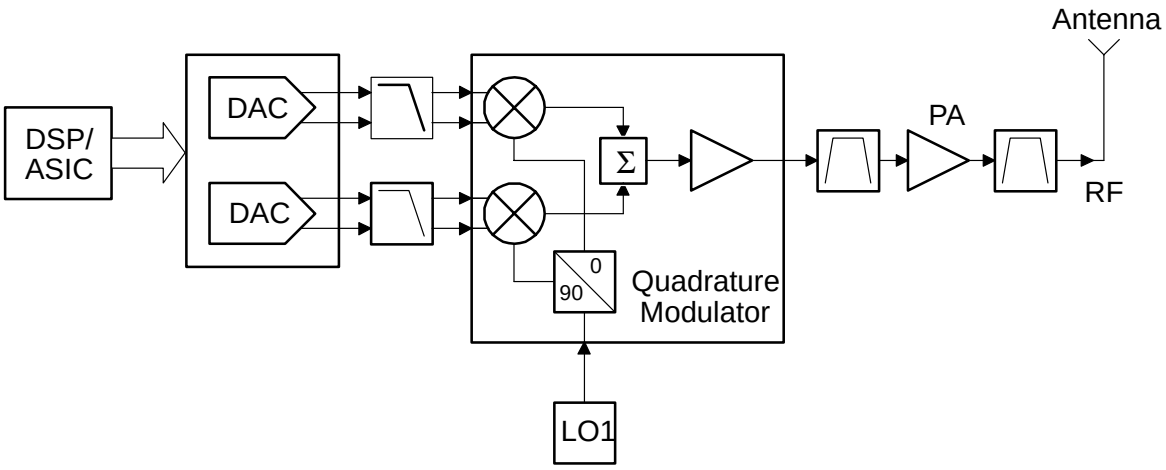

Figure 13–3. Basic W-CDMA Cellular Base Station Transmitter Block

The modulator block converts the baseband I and Q signal to the appropriate carrier frequency, typically 864 MHz. The up-converted 864 MHz signal is amplified to a suitable level by the power amplifier (PA) and sent out via the antenna over the air or to a nearby wireless base station.

The RF power amplifier is a large-signal device with power gain and efficiency on the order of 50% for GSM and about 30% for code division multiple access (CDMA), an access method in which multiple users are permitted simultaneously on the same frequency.

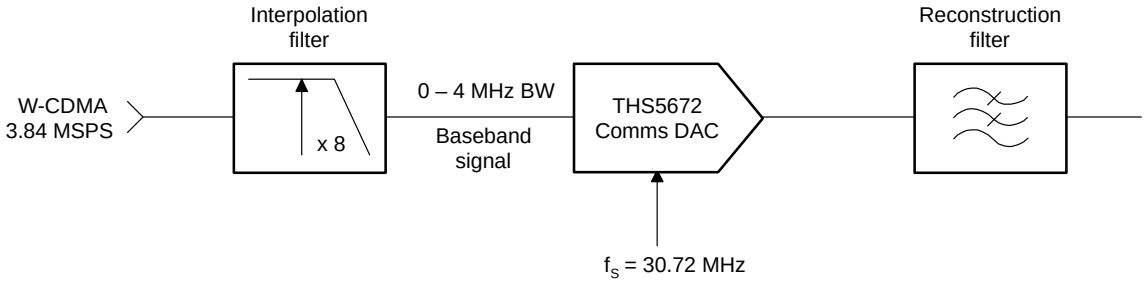

Figure 13–4. Communication DAC with Interpolation and Reconstruction Filters

13.3 Selection of ADCs/DACs

In communication applications, the dc nonlinearity specifications that describe the converter's static performance are less important than the dynamic performance of the ADC. The receiver (overall system) specifications depend very much on the ADC dynamic performance parameters: effective number of bits (ENOB), SFDR (spurious free dynamic range), THD (total harmonic distortion), and SNR (signal-to-noise ratio). Good dynamic performance and fast sampling rate are required for accurate conversion of the baseband analog signal at RF or IF frequencies. The SFDR specification describes the converter's in-band harmonic characterization and it represents the converter's dynamic range. SFDR is slew rate and converter input frequency dependent.

The output from an ADC is highly dependent on the converter sampling frequency and the maximum frequency of the analog input signal. A low-pass or band-pass anti-aliasing filter placed immediately before the ADC band-limits the analog input. Band-limiting ensures that the original input signal can be reconstructed exactly from the ADC's output samples when a sampling frequency (f_S) of twice the information bandwidth of the analog input signal is used (Nyquist sampling). Undesirable signals, above f_S/2, of a sufficient level, can create spectrum overlap and add distortion to the desired baseband signal. This must not be allowed to dominate the distortion caused by ADC nonlinearities. Sampling at the Nyquist rate places stringent requirements on the anti-aliasing filter — usually a steep transition 10^{th} or higher order filter is needed.

Oversampling techniques (sampling rate greater than the Nyquist rate) can be employed to drastically reduced the steepness of the anti-aliasing filter rolloff and simplify the filter design. However, whenever oversampling is used, a faster ADC is required to digitize the input signal. Very fast ADCs can be costly and they consume a fair amount of power (≥ 1000 mW). In a system application, such as a wireless base station, where large numbers of ADCs are used, the individual device power consumption must be kept to the bare minimum (≤ 400 mW). High-resolution ADCs, with slower sampling rates, offer potential cost savings, lower power consumption, and good performance, and are often used in some applications. In this case, undersampling or bandpass sampling techniques (the analog signal digitization by the ADC exceeds half the sampling frequency (f_S) of the ADC, but the signal information bandwidth is ≤ f_S/2) are employed.

Operating the ADC in a bandpass sampling application requires knowledge of the converter's dynamic performance for frequencies above f_S/2. In general, as the input signal frequency to the converter increases, ENOB, SNR, SFDR, and harmonic performance degrades.

The fact that the analog input to the ADC cannot be represented exactly with a limited number of discrete amplitude levels introduces quantization error into the output digital samples. This error is given by the rms quantization error voltage $e^2_{qns} = \frac{1}{12} q_s^2$.

The mean squared quantization noise power is is $P_{qn} = \frac{q_s^2}{12R}$ where q_s is the quantization step size and R is the ADC input resistance, typically 600 Ω to 1000 Ω.

Communication ADCs similar to the THS1052 and THS1265 typically have a full scale range (FSR) of 1 Vp–p to 2 Vp–p. Generally, wireless systems are based on a 50-Ω input/output termination, therefore, the ADC input is made to look like 50 Ω. Based on this assumption, the quantization noise power for a 12-bit, 65 MSPS ADC (THS1265) is –73.04 dBm.

For a noise-limited receiver, the receiver noise power can be computed as the thermal noise power in the given receiver bandwidth plus the receiver noise figure NF[3].

For 200 kHz BW (GSM channel), temperature 25°C, and 4 dB to 6 dB NF, the receiver noise power is –115 dBm. Therefore, to boost the receiver noise to the quantization noise power level requires a gain of 42 dB.

In Figure 13–1, the GSM–900 signal is at –104 dBm (GSM–900 spec for smallest possible signal at which the raw bit-error rate must meet or exceed 1%) and, therefore, the signal-to-noise ratio (SNR) at baseband or at the converter and due to the thermal noise component is given by $SNR_{thermal} = \frac{E_b}{N_0}$ = –104 dBm +115 dBm = 9 dB.

In order for the raw BER to be 1% in a GSM system, testing and standard curves [4] indicate, that a baseband SNR (derived from the sum of both thermal noise and ADC noise) of 9 dB is needed for this performance node.

The process gain G_p is defined as:

$$G_p = \frac{f_s}{BW} = \frac{52 \times 10^6}{200 \times 10^3} = 2.6 \times 10^2 = 24.15 \text{ dB} \qquad (13–1)$$

where GSM channel BW = 200 kHz and f_s = 52 MHz (the ADC sampling frequency).

The converter noise at baseband should be much better than the radio noise (= thermal noise + process gain). Furthermore, the thermal noise alone brings the system only to the reference bit-error rate (BER).

Therefore the converter noise (at baseband) = SNR_{adc} + process gain G_p.

The ADC SNR_{adc} should be 20 dB to 40 dB above the $SNR_{thermal}$ of the thermal noise component (+9 dBm). In this example, ADC SNR_{adc} is selected to be 37 dB better than the $SNR_{thermal}$ of the thermal noise component (9 dB).

In other words, if the converter SNR_{adc} is desired to be 37 dB better than the thermal noise component ($SNR_{thermal}$), the baseband converter is chosen to be 9 + 37 dB = 46 dB.

The total noise (N_{sum}) = thermal noise (N_t) + converter noise (N_{conv}).

Therefore, the noise-to-signal ratio is:

$$\frac{N_{sum}}{S_{GSM}} = \frac{N_t}{S_{GSM}} + \frac{N_{conv}}{S_{GSM}} = \frac{1}{10^{0.9}} + \frac{1}{10^{4.6}} \quad (13\text{–}2)$$

The signal-to-noise ratio $\frac{S_{GSM}}{N_{sum}}$ = 7.942 (linear), which is 8.999 dB.

This shows that the converter noise degenerates the baseband SNR due to thermal noise alone, by only 0.0001 dB (9.000 dBm – 8.999 dB) when the signal is at reference sensitivity level.

At f_s = 52 MSPS, the converter SNR_{adc} required to fit the GSM–900 signal is (46 – 24.15) dB = 22 dB.

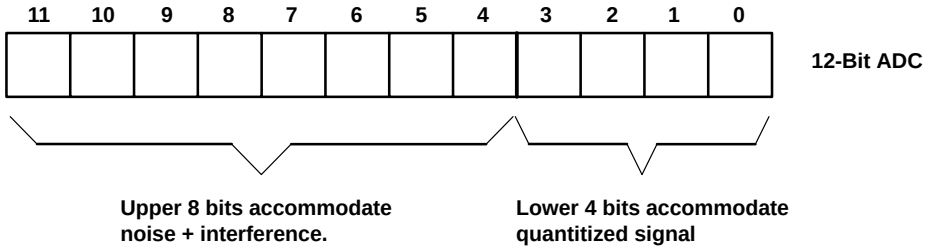
The effective number of bits (ENOB) required for fitting the GSM–900 signal is

$$ENOB = \frac{SNR - 1.76}{6.02} \quad (13\text{–}3)$$

and thus 4 bits are needed for the GSM–900 signal.

Assuming that filter #3 attenuates the interferer by 50 dB, the interferer drops from –13 dBm to –53 dBm, or 40 dB above the GSM signal. The requirements for the number of bits needed to accommodate the interferer is $\frac{40\ dB}{6\ dB/bit}$ = 6.3 bits.

Approximately 6 bits are needed to accommodate the interferer, plus 2 bits of head room for constructive interference, for a total of 8 bits. The ADC requirements are 4 bits for the GSM signal plus 8 bits for the interferer for a total of 12 bits:



It follows from the above analysis that the GSM signal is 8 bits down, or 8 bits x 6 dB/bit = 48 dB down from the 1 V FSR of the ADC. The full-scale input power to an ADC having a 50-Ω termination can be calculated as:

$$\frac{V^2}{R} = \frac{(1)^2}{50} = 2 \times 10^{-2} = 13\ dBm\ (full\ scale\ or\ FSR) \quad (13\text{–}4)$$

Therefore, the 4 bits for the GSM signal gives 13 dBm – (8 bits x 6 dB/bit) = –35 dBm, the smallest possible ADC input signal power with the interferer that will meet the GSM speci-

fication. Without the interferer present, the signal level is chosen to be about 20 dB below the ADC full scale, or –8 dBm, to accommodate constructive interference and to accommodate any large ADC input signal that may arise from short-term errant gain due to gain settling in the AGC. Thus, with the smallest possible signal specified by the GSM–900 spec, the signal is amplified from –104 dBm to –8dBm without the interferer, and to –35 dBm with the interferer.

For a practical receiver, as shown in Figure 13–1, an AGC is necessary to assure that the LSB represents a uniform noise input while the peak power does not exceed the ADC's FSR.

The receiver block shown in Figure 13–1 uses a high-speed, fairly wide bandwidth (100 MHz to 550 MHz) communication ADC to convert the baseband signal to a high-speed parallel bit stream for processing in a DSP. For an ADC to accurately produce a digital version of the baseband analog input, the device must have very good resolution and dynamic performance.

The signal path shown in Figure 13–1 needs 95 dB of gain in order to bring the –104 dBm GSM signal up to –9 dBm (equivalent to about 0.112 Vp–p across 50 Ω), with allowances for losses in the filters, and mixers. Usually this gain is split evenly between the RF and baseband, but baseband gain is less expensive and consumes less power. The LNA provides 18 dB, which, after filtering and cable losses, yields about 16 dB, while the mixer provides –7 dB of conversion gain/loss.

Modern communication DACs are, effectively, an array of matched current sources optimized for frequency domain performance. To handle both strong and weak signals, communication DACs require large dynamic range. The dynamic specifications of most interest are SFDR, SNR, THD, IMD (two-tone intermodulation distortion), ACPR (adjacent channel power rejection), and settling time.

Besides these, there are a number of dc parameters, such as integral nonlinearity (INL) and differential nonlinearity (DNL), that are considered important because of their influence on the SFDR parameter. DNL errors occur only at certain points in the converter's transfer function. INL and DNL errors appear as spurious components in the output spectrum and can degrade the signal-to-noise ratio of the DAC.

Typical SFDR figures for 12-bit DACs and 14-bit DACs, with a 5-MHz single tone input at 50 MSPS, range from 75 dB to 80 dB. In order to prevent adjacent communication channels from interfering with each other, the DAC must exhibit a good SFDR specification. Communication DACs normally have differential outputs, and the current-mode architecture is used to give the DAC a higher update rate.

13.4 Factors Influencing the Choice of Op Amps

IF amplifiers and filters can be built from discrete components, though most modern applications use integrated circuits. High-speed wideband op amps are employed as buffer amplifiers in the LO circuit, at the front end of ADCs, at the output of the DAC, in the external voltage reference circuits for ADCs and DACs, and in the AGC amplifier and anti-aliasing stage. Op amps operating at IF frequencies, such as the AGC amplifier in Figure 13–1, must attain a large gain control range. How well the amplifier handles large and small signals is a measure of its dynamic range. The current-feedback op amp can be used everywhere except for the anti-aliasing filter and in the reconstruction filter stage. The op amp must have a level gain response from almost dc to at least 500 MHz, after which a gentle rolloff is acceptable. Also, the phase response is important to avoid dispersing the signal — this requires a linear phase response.

Several factors influence the choice of the current-feedback op amp (CFA) and voltage-feedback amplifier (VFA) for use in wireless communication systems:

- The ADC/DAC resolution
- ADC/DAC dynamic specification
- Operating frequencies
- Type of signal
- Supply voltages and
- Cost

In both the receiver and transmit circuits, shown in Figures 13–1 and 13–3, the SFDR and IMD are the key ADC/DAC parameters that have the most influence on op amp selection. A minimum requirement is that the op amp's SFDR or THD parameter, measured at the frequency of operation, should be 5 dB to 10 dB better than the converter's SFDR. For a perfect 12-bit ADC, the SFDR is 72 dB, thus the op amp in front of the ADC should exhibit a SFDR (or THD) of 77 dB to 82 dB.

When an op amp is used as a buffer amplifier, it must faithfully reproduce the input to a very high degree of accuracy. This requires that the amplifier be designed and optimized for settling time. Fast settling time is mandatory when driving the analog input of an ADC because the op amp output must settle to within 1 LSB of its final value (within a time period set by the sampling rate) before the ADC can accurately digitize the analog input. The amplifier settling time determines the maximum data transfer rate for a given accuracy. For example, to settle within 1 LSB of full scale range implies that the settling accuracy of the ADC is ± ½ LSB. Hence, a 12-bit ADC will require the op amp to settle to $\frac{1}{2 \times 2^{12}} = 1.22 \times 10^{-4}$ of final value, or 0.0122% of final value. An LSB = 244 μV for a 12-bit ADC with 1 V full-scale range. Values for the settling time and other important op amp parameters as they relate to the receiver and transmit blocks are listed in Table 13–2.

The op amp dynamic parameters in Table 13–2 represent the range of values to achieve low noise, good SFDR, high slew rate, good bandwidth, etc.

Table 13–2. High-Speed Op Amp Requirements

PARAMETER	VALUE
Noise voltage	2.7 nV/$\sqrt{\text{Hz}}$ to 8 nV/$\sqrt{\text{Hz}}$
Noise current	1 pA/$\sqrt{\text{Hz}}$ to 30 pA/$\sqrt{\text{Hz}}$
THD	70 dBc to 95 dBc
Slew rate	260 V/μV to 3500 V/μV
Small signal bandwidth	200 MHz to 600 MHz
Large signal bandwidth	≥ 100 MHz
Common-mode input voltage	3 V
Supply voltage	± 5 V
Settling time	8 ns to 20 ns
Output current	40 mA to 100 mA
Output impedance	≤ 20 Ω
PSRR	– 60 dB
CMRR	–70 dB
Input offset voltage	10 mV (typical)

Op amps operating from ± 5-V supplies typically have 6 V to 8 V of common-mode range. Single-supply op amps often handle much smaller voltage ranges, and in some communication applications, could exhibit limited linear operation over a wide signal swing. With the exception of rail-to-rail op amps, most op amps can swing to within 1 V to 1.5 V of the positive rail. Typically signal-to-noise ratio, slew rate, and bandwidth suffer for devices operating from low supply voltages.

When selecting current-feedback op amps, the gain-bandwidth plots are essential. They are needed because with current feedback ordinary loop-gain-proportional bandwidth relationships do not hold.

13.5 Anti-Aliasing Filters

Spurious effects in the receiver channel (Figure 13–1) appear as high frequency noise in the baseband signal present at the ADC. The spurious signals (> f_S/ 2) must be blocked from getting to the ADC (sampling at Nyquist rate, f_S) where they will cause aliasing errors in the ADC output.

A suitable anti-aliasing low-pass analog filter placed immediately before the ADC can block all frequency components capable of causing aliasing from reaching the ADC. The

anti-aliasing filter cutoff frequency ($f_{c)}$ is set to the highest baseband signal frequency of interest (f_{max}) so that $f_c = f_{max}$. Sampling theorem requires that the ADC minimum Nyquist rate sampling frequency $fs = 2f_{max}$. This ensures that the original base band or IF signal can be reconstructed exactly from the ADC's digital outputs. It is important to know that only an anti-aliasing filter having a *brickwall*-type response could fully satisfy the exacting requirements imposed by the sampling theorem. The rolloff of real filters increases more gradually from cutoff to the stop band, and therefore, in practice, the ADC sampling frequency is usually slightly higher than $2f_{max}$.

The anti-aliasing filter must reduce the out-of-band aliasing producing signals to less than 1 LSB of the ADC resolution, without introducing additional distortion of the baseband or IF signal in-band components and without predominating distortion due to the ADC nonlinearities. The spectrum overlap (aliasing) requirements are determined by:

- Highest frequency of interest
- Sampling rate
- ADC resolution

The highest signal frequency of interest sets the filter cutoff frequency. For example, suppose the input signal is to be sampled to 12-bit accuracy with a sampling frequency of 52 MHz. If the IF signal is 17 MHz an 18 MHz filter –3dB cutoff frequency could be chosen. All frequencies above the Nyquist frequency should be attenuated to $\leq$ ½ LSB, but generally only frequencies above the ADC's limit of resolution will be a problem; i.e., f_{alias} = (52 – 17) MHz = 35 MHz. The frequency rolloff is 18 MHz to 35 MHz (about 1 octave) and the required attenuation is 72 dB (12-bit ADC). A very high-order filter is required to accomplish this task. Practical ant-aliasing filters are limited to fifth-order or sixth-order type because of amplifier bandwidth, phase margin, layout parasitics, supply voltage, and component tolerances. Keep in mind that as the rolloff sharpens, the passband ripple and phase distortion increase.

For communication applications, linear phase characteristic and gain accuracy (low passband ripple) are important. And normally, Chebychev or elliptic (Cauer) filter types are used for the anti-aliasing filter.

For good transient response or to preserve a high degree of phase coherence in complex signals, the filter must be of linear-phase type (Bessel-type filter).

The THS4011 or THS4021 voltage-feedback op amp is a good choice for implementing anti-aliasing filter in this example.

The quality of the capacitors and resistors used to implement the design is critical for performance anti-aliasing filter.

13.6 Communication D/A Converter Reconstruction Filter

Modern communication DACs are, effectively, an array of matched current sources optimized for frequency domain performance. The most important dynamic specifications are SFDR, SNR, THD, IMD, ACPR and settling time. The dc parameters INL and DNL are considered important because of their influence on the SFDR parameter. Typical SFDR figures for 12-bit to 14-bit DACs, with a 5-MHz single-tone input at 50 MSPS, ranges from 75 dB to 80 dB. In order to prevent adjacent communication channels from interfering with each other, the DAC must exhibit a good SFDR specification.

Communication DACs normally have differential outputs and current-mode architecture is used to give the DAC a higher update rate.

Figure 13–4 shows an interpolating filter block before the DAC and the reconstruction analog filter at the output of the DAC. The interpolating filter is a digital filter whose system clock frequency is an integer multiple of the filter input data stream and is employed to reduce the DAC's in-band aliased images. This eases the job of the reconstruction filter at the output of the DAC. The filter is used to smooth the input data — the output waveform frequency is the same as the input to the interpolating filter. Figure 13–5 shows the interpolation filter output. The system clock frequency of the DAC and the interpolating filter are running at the same rate; therefore, the frequency spectrum of the DAC output signal, repeated at integer multiples of the sampling rate, becomes increasingly separated as the sampling rate is increased. The further apart the repeated DAC output spectrum, then the less steep the attenuation characteristic of the anti-aliasing needs to be. Consequently, a simpler anti-aliasing filter with a less steep rolloff from pass band to stop band can be used without any increase in distortion due to aliasing. In Figure 13–4, the system clock is 30.772 MHz (3.84 MSPS x 8). Figure 13–6 shows the attenuation characteristics needed for the reconstruction anti-aliasing filter.

The aliasing frequency is f_{alias} = (28.7 – 2) = 26.7 MHz, and the required attenuation is 84 dB (14-bit DAC). A third-order anti-aliasing low-pass elliptic or Bessel filter could be used to meet the attenuation requirements. Either type of high-order filter gives a relatively flat response up to just below ½ the sampling frequency, followed by a sharp cutoff. But this arrangement provides no correction for the sinc function (Sinx)/x falloff in amplitude naturally produced by the sample and hold function in the DAC.

The tradeoff in building a simpler reconstruction filter is that a faster DAC is required to convert the input digital data stream to analog signal.

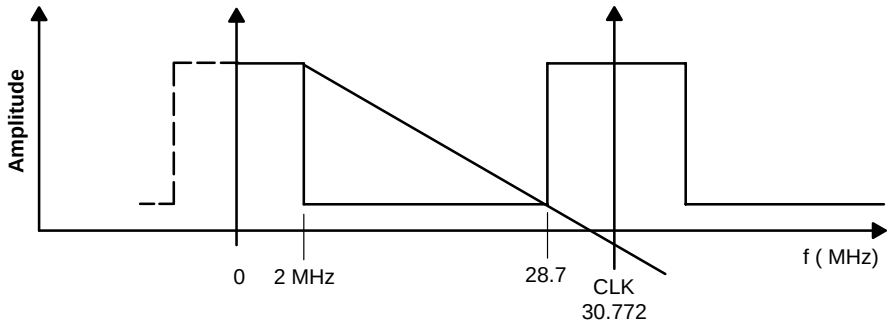

Figure 13–6. Reconstruction Filter Characteristics

Figure 13–7 shows a first-order reconstruction (low-pass) filter consisting of a high-speed differential amplifier configured for unity gain. The DAC outputs are terminated into 50 Ω. In Figure 13–7, the value for the filter capacitor is given by the expression:

$$C_{fb} = \frac{3.1827 \times 10^{-4}}{\frac{f_{clk}}{2}} \tag{13–5}$$

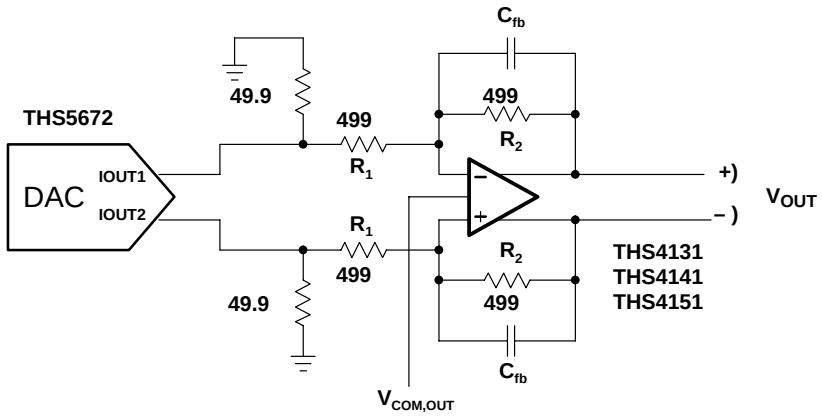

Figure 13–7. A Single-Pole Reconstruction Filter

13.7 External V_{ref} Circuits for ADCs/DACs

Figure 13–8 shows an op amp voltage follower circuit that is often used to interface the external precision voltage reference supplying the ADC/DAC external reference voltage (see for example, Miller and Moore, [5], [6],1999, 2000 for a more detailed discussion on voltage reference circuits used in ADC an DAC systems). V_{in} is the output from a precision voltage reference, such as the Thaler Corp. VRE3050. The low-pass filter (formed by C_1R_1) filters noise from the reference and op amp buffer. The –3 dB corner frequency of the filter is $1/2\pi C_1R_1$and the transfer function for this circuit can be written as

$$\frac{V_o}{V_{in}} = \frac{\left(1 + sC_2R_2\right)}{\left(s^2 + \frac{sC_2R_2}{C_1C_2R_1R_2} + \frac{1}{C_1C_2R_1R_2}\right) C_1C_2R_1R_2} \tag{13–6}$$

which has a zero at $s = C_2R_2$.

With the approximation $C_2R_2 = 2C_1R_1$, the denominator polynomial is solved for complex poles p_1 and p_2 of the response, which results in:

$$P_1 = -\frac{1}{2C_1R_1} + j\frac{1}{2C_1R_1} \quad (13\text{–}7)$$

$$P_2 = -\frac{1}{2C_1R_1} - j\frac{1}{2C_1R_1} \quad (13\text{–}8)$$

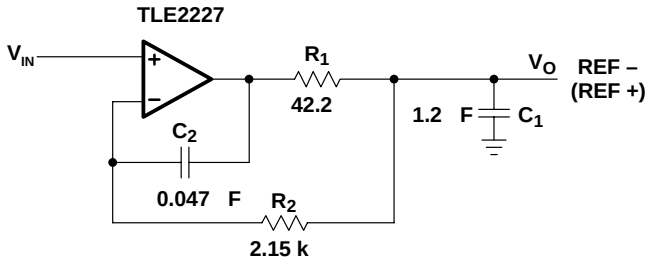

Figure 13–8. Voltage Reference Filter Circuit

The zero in the numerator of the transfer function improves the relative stability of the circuit. Resistor R_2 should be kept fairly low, since a small amount of bias current flows through it and causes dc error and noise. Resistor R_1 value ranges from 10 Ω to 50 Ω. Resistor R_1 is in the feedback loop, so any small leakage current that is due to capacitor C_1 flows through R1and the voltage dropped across R_1 is divided by the loop gain. For all practical purposes, the voltage across C_2 is 0 V and hence give rise to negligible leakage current.

A design example for a 3-kHz bandwidth filter is illustrated:

Choose C1 = 1.2 μF and R1 = 42.2 Ω.

Having determined the value for C1 and R1, the capacitor C2 value is estimated to be approximately 4% to 5% of C1 value (C2 = 0.047 μF) and resistor R2 is calculated using the approximation $C_2R_2 = 2C_1R_1$ (R2 = 2.15 kΩ).

The calculated –3-dB bandwidth for the circuit is 3.1 kHz and this value agrees with the circuit's frequency response plot shown in Figure 13–9. This circuit topology is good for driving large capacitive loads.

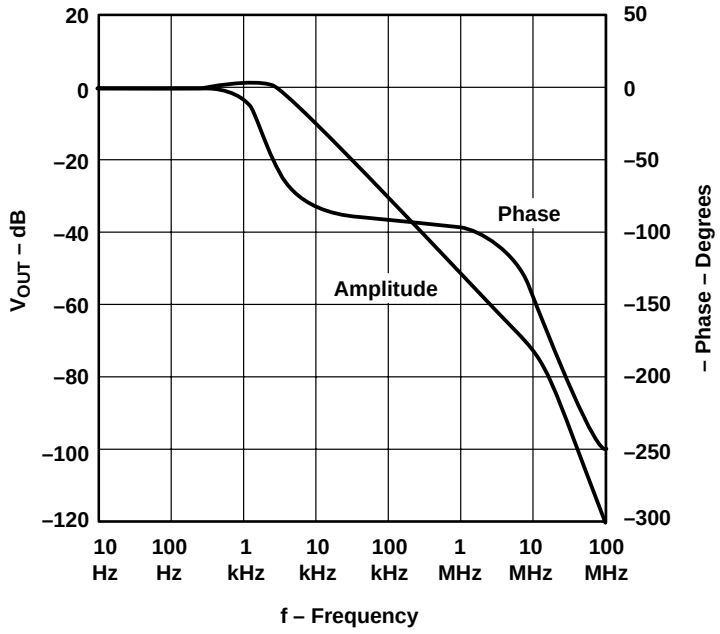

Figure 13–9. Voltage Follower Frequency Response Plot

Figure 13–10 shows an external reference circuit that provides a wide adjustment range of the ADC full-scale range. Resistors R281 and R282 play two roles in this circuit:

- Form part of the low-pass filter used to rolloff noise
- Isolate the ADC's reference input load capacitance from the buffer op amp output

Potentiometer R247 sets the external common-mode voltage (V_{ocm}) for the differential amplifier in Figure 13–11.

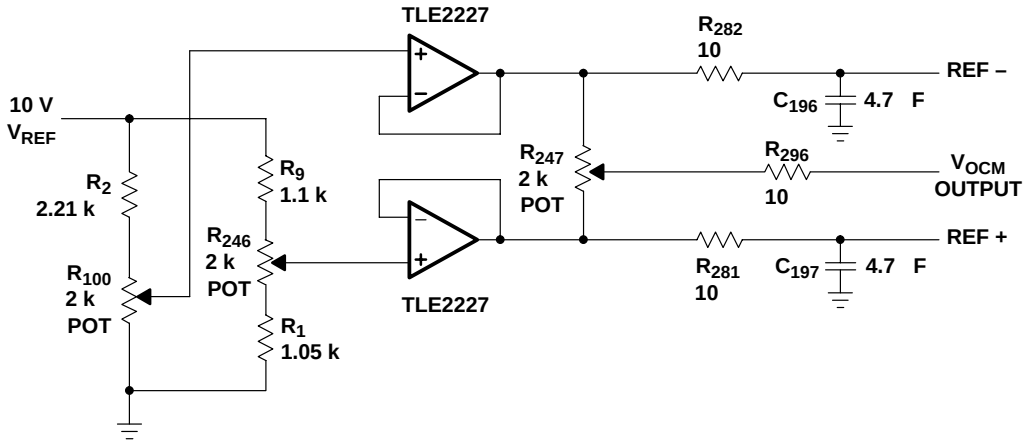

Figure 13–10. External Voltage Reference Circuit for ADC/DAC.

13.8 High-Speed Analog Input Drive Circuits

Communication ADCs, for the most part, have differential inputs and require differential input signals to properly drive the device. Drive circuits are implemented with either RF transformers or high-speed differential amplifiers with large bandwidth, fast settling time, low output impedance, good output drive capabilities, and a slew rate of the order of 1500 V/μS. The differential amplifier is usually configured for a gain of 1 or 2 and is used primarily for buffering and converting the single-ended incoming analog signal to differential outputs. Unwanted common-mode signals, such as hum, noise, dc, and harmonic voltages are generally attenuated or cancelled out. Gain is restricted to wanted differential signals, which are often 1 V to 2 V.

The analog input drive circuit, as shown in Figure 13–11, employs a complementary bipolar (BiCom) THS4141 device. BiCom offers fast speed, linear operation over a wide frequency range, and wide power-supply voltage range, but draws slightly more current than a BiCMOS device. The circuit closed-loop response is shown in Figure 13–12, where the –3-dB bandwidth is 120 MHz measured at the output of the amplifier. The analog input V_{in} is ac-coupled to the THS4141 and the dc voltage V_{ocm} is the applied input common-mode voltage. The combination R47– C57 and R26 – C34 are selected to meet the desired frequency rolloff. If the input signal frequency is above 5 MHz, higher-order low-pass filtering techniques (third-order or greater) are employed to reduce the op amp's inherent second harmonic distortion component.

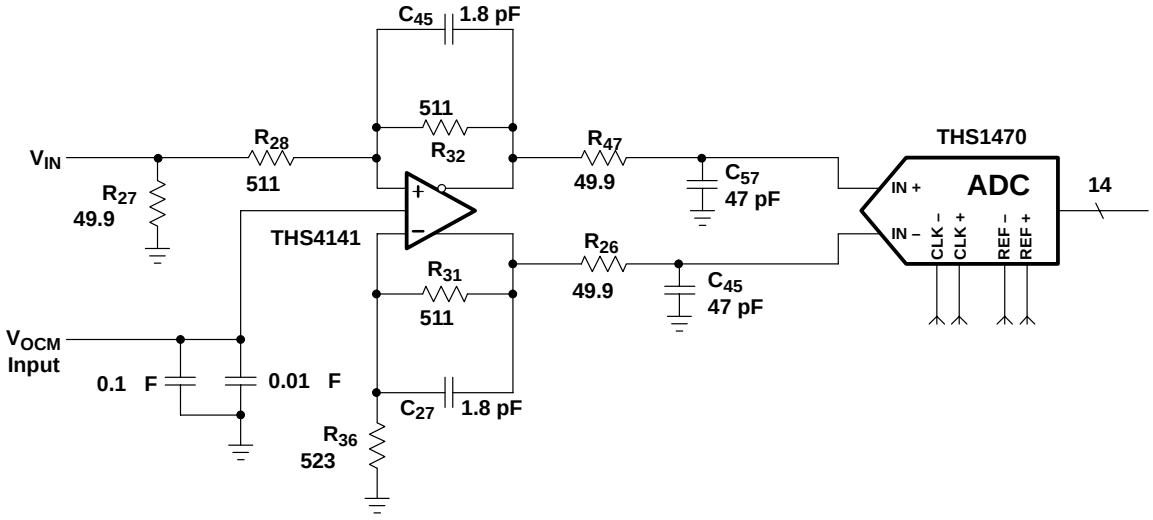

Figure 13–11. Single-Ended to Differential Output Drive Circuit

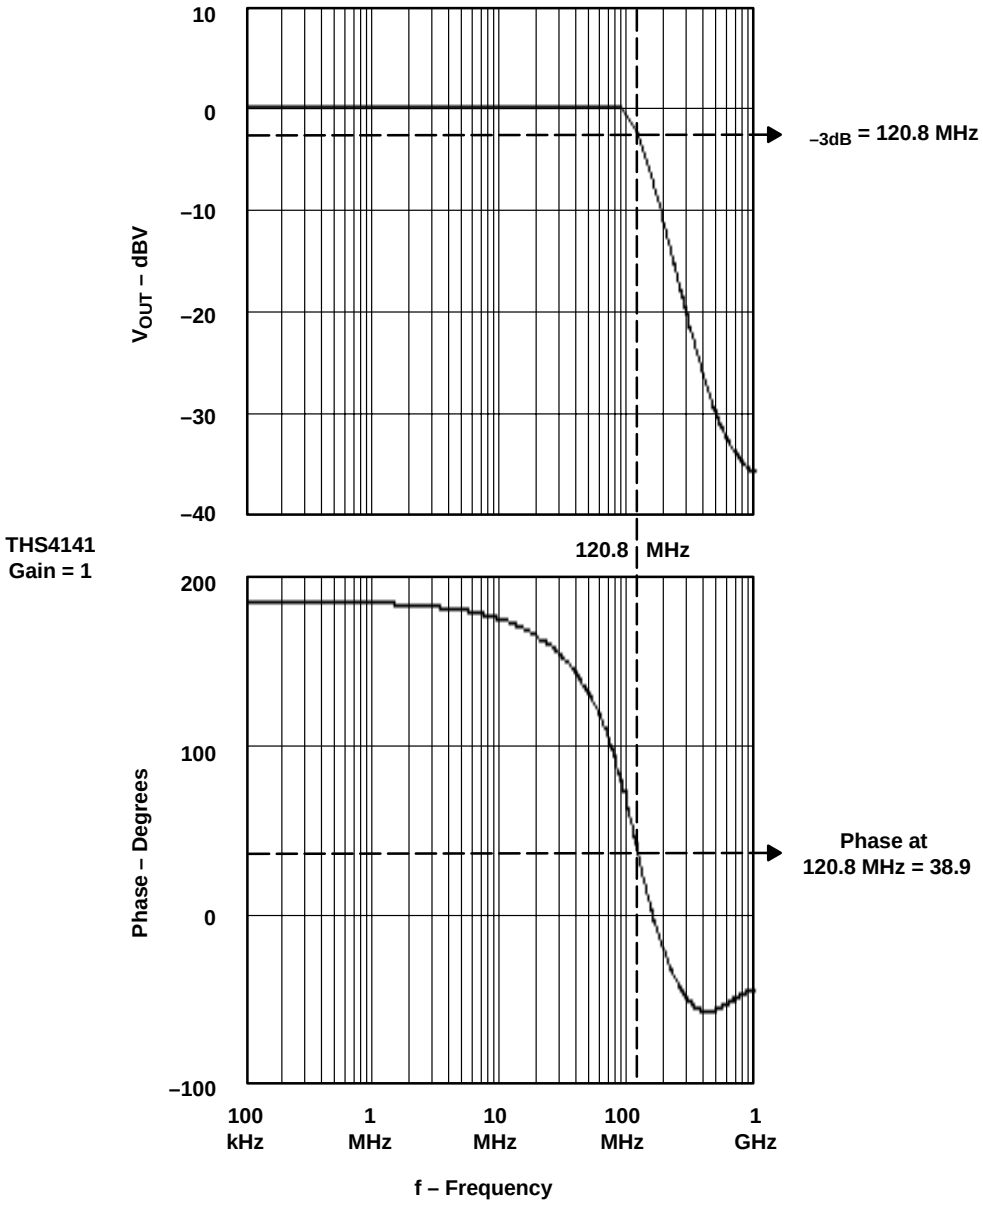

Figure 13–12. Differential Amplifier Closed-Loop Response

Figure 13–13 shows a design example of an ac-coupled, single-ended analog input drive circuit. This circuit uses a THS3201 current-feedback op amp and operates up to 975 MHz. The amplifier is configured as a noninverting amplifier with a gain of 2, where gain is 1 + R4/R3. In a current-feedback amplifier, the feedback resistor sets the amplifier

bandwidth and the frequency response shape as well as defining the gain of the circuit. R4 and R3 cannot be arbitrary values.

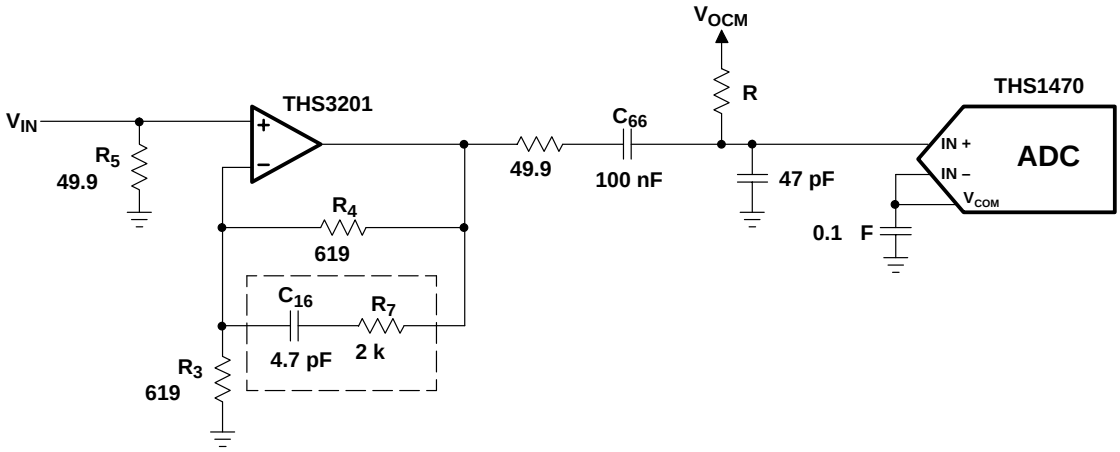

Figure 13–13. ADC Single-Ended Input Drive Circuit

The frequency response plots for a gain of 2, with R3 = R4 = 619 Ω, are shown in Figures 13–13 and 13–14. R4 affects the amplifier bandwidth and frequency response peaking. R3 has no effect on bandwidth and frequency peaking; it only affects the gain. The –3-dB bandwidth is 520 MHz. Increasing the resistance of R4 decreases the bandwidth. Conversely, lowering R4 resistance increases the bandwidth at the expense of increased peaking in the ac response.

The phase plot in Figure 13–14 exhibits a fairly linear phase shift (a flat group delay response) and hence the amplifier output should show excellent signal reproduction.

Unlike a voltage-feedback amplifier, the power supply voltage affects the bandwidth of a current-feedback amplifier. For example, lowering the supply voltage of the THS3201 from ± 5 V to ± 2.5 V reduces the bandwidth from 925 MHz to 350 MHz.

Chapter 14

Interfacing D/A Converters to Loads

Bruce Carter

14.1 Introduction

A digital to analog converter, or D/A, is a component that takes a digital word and converts it to a corresponding analog voltage. It has the opposite function of an A/D converter. The D/A is only capable of producing a quantized representation of an analog voltage, not an infinite range of output voltages.

The application will almost always dictate the selection of the D/A converter, leaving the designer the task of interfacing that converter with the output load.

A D/A converter interfaces with a buffer op amp. Most D/A converters are manufactured with a process that is incompatible with op amps. Therefore, the op amp cannot be manufactured on the same IC. It must be external, and its characteristics are an integral part of the conversion process. In most cases, the data sheet will make a recommendation for the selection of a buffer op amp. Follow the recommendation, unless there is a compelling reason not to do so. Performance can be improved only if you know exactly what op amp specifications need to be optimized.

Signal conditioning — low pass filtering, DC offsets, and power stages — should all be placed after the recommended op amp buffer. Do not attempt to combine these functions with the buffer unless you are an experienced designer with a good grasp of all of the implications.

14.2 Load Characteristics

There are two main types of loads that a D/A may have to drive — ac and dc. Each has different characteristics, and will require different interface circuitry.

14.2.1 DC Loads

These include linear actuators such as those used on positioning tables, motors, programmable power supplies, outdoor displays, and lighting systems. Large load currents

and/or high voltages characterize some of these loads. DC accuracy is important, because it is related to a series of desired mechanical positions or intensities in the load device.

14.2.2 AC Loads

These include linear actuators such as those used on positioning tables, motors, programmable power supplies, outdoor displays, and lighting systems. Large load currents and/or high voltages characterize some of these loads. DC accuracy is important, because it is related to a series of desired mechanical positions or intensities in the load device.

14.3 Understanding the D/A Converter and its Specifications

It is important to understand the D/A converter and its specifications before discussing interfaces.

14.3.1 Types of D/A Converters — Understanding the Tradeoffs

D/A converters are available in several types, the most common of which is the resistor ladder type. There are several variations on the resistor ladder technique, with the R/2R configuration being the most common.

14.3.2 The Resistor Ladder D/A Converter

In this type of converter, a precision voltage reference is divided into 2^{N-1} parts in an internal voltage divider, where N is the number of bits specified for the converter. One switch at a time turns on, corresponding to the correct dc level (Figure 14–1).

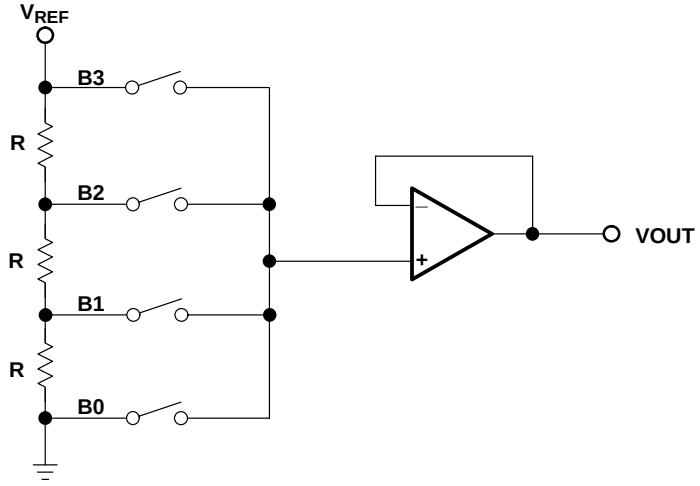

Figure 14–1. Resistor Ladder D/A Converter

Unfortunately, the number of resistors and switches doubles for each additional bit of resolution. This means that an 8-bit D/A converter would have 255 resistors and 256 switches, and a 16-bit D/A converter would have 65535 resistors and 65536 switches. For this reason, this architecture is almost never used for higher resolution D/A converters.

14.3.3 The Weighted Resistor D/A Converter

This type of converter is very similar to the Resistor Ladder D/A converter. In this case, however, each resistor in the string is given a value proportional to the binary value of the bit it represents. Currents are then summed from each active bit to achieve the output (Figure 14–2).

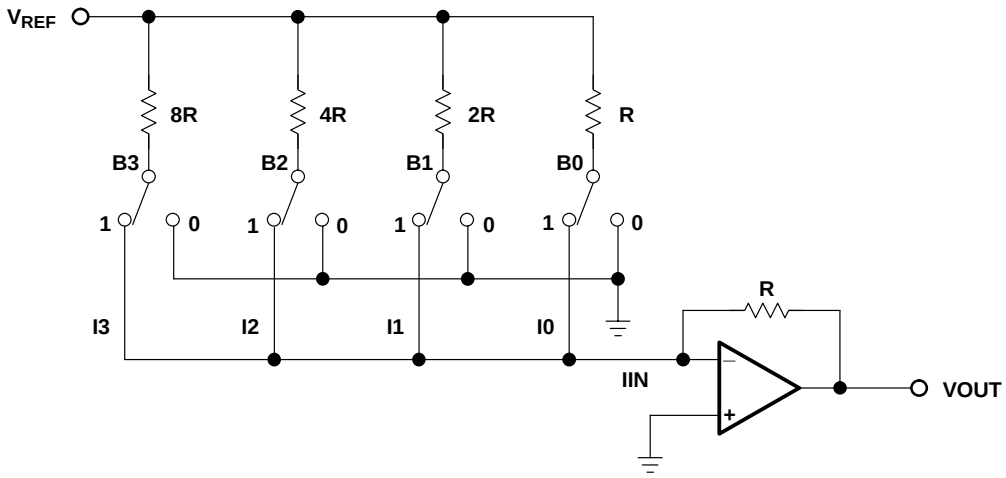

Figure 14–2. Binary Weighted D/A Converter

The number of resistors and switches reduced to one per bit, but the range of the resistors is extremely wide for high-resolution converters, making it hard to fabricate all of them on the IC. The resistor used for B3 is the limiting factor for power dissipation from V_{REF} to ground.

This converter architecture is often used to make logarithmic converters. In this case, the R, 2R, 4R, 8R … resistors are replaced with logarithmically-weighted resistors.

This type of converter, and the R/2R converter described in the next paragraph, use a feedback resistor fabricated on the D/A IC itself. This feedback resistor is not an optional convenience for the designer — it is crucial to the accuracy of the D/A. It is fabricated on the same silicon as the resistor ladder. Therefore, it experiences the same thermal drift as the resistor ladder. The gain of the buffer amplifier is fixed, with a full-scale output voltage limited to V_{REF}. If a different full-scale D/A output voltage is needed, change V_{REF}.

If the full scale V_{OUT} must exceed the maximum rating of the D/A reference voltage, use a gain stage after the buffer op amp (see Paragraph 14.7.2).

The op amp must be selected carefully, because it will be operated in much less than unity gain mode for some combinations of bits. This is probably one of the main reasons why this architecture is not popular, as well as the requirement for a wide range of resistor values for high precision converters.

14.3.4 The R/2R D/A Converter

An R/R2 network can be used to make a D/A converter (Figure 14–3).

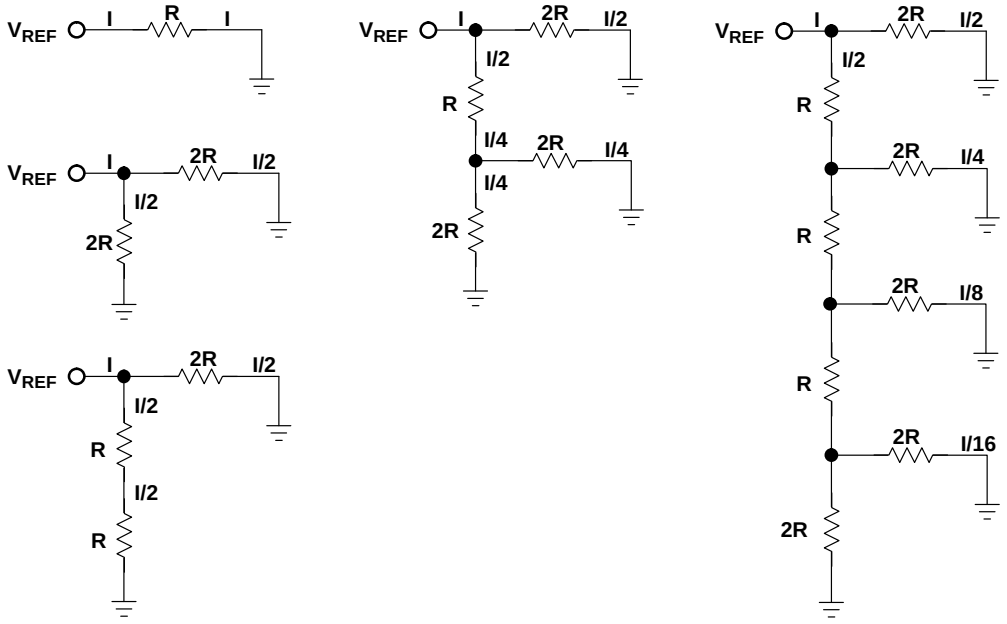

Figure 14–3. R/2R Resistor Array

For a given reference voltage V_{REF}, a current I flows through resistor R. If two resistors, each the same value (2R) are connected from V_{REF} to ground, a current I/2 flows through each leg of the circuit. But the same current will flow if one leg is made up of two resistors, each with the value of R. If two resistors in parallel whose value is 2R replace the bottom resistor, the parallel combination is still R. I/4 flows through both legs, adding to I/2. Extending the network for 4 bits as shown on the right, the total current on the bottom leg is I/4 plus I/8 plus I/16 plus I/16 in the resistor to ground. Kirchoff's current law is satisfied, and convenient tap points have been established to construct a D/A converter (Figure 14–4):

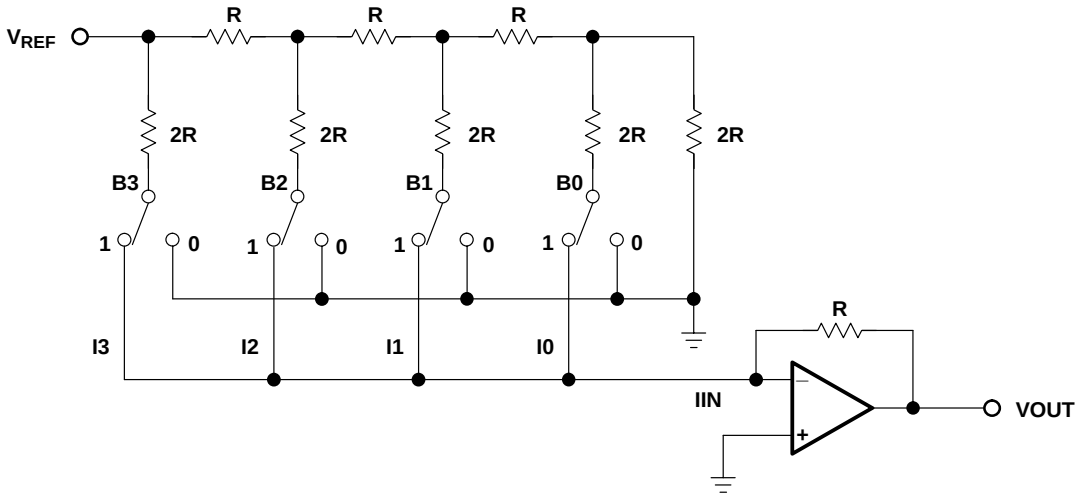

Figure 14–4. R/2R D/A Converter

This converter architecture has advantages over the types previously mentioned. The number of resistors has doubled from the number required for the current-summing type, but there are only two values. Usually, the 2R resistors are composed of two resistors in series, each with a value of R. The feedback resistor for the buffer amplifier is again fabricated on the converter itself for maximum accuracy. Although the op amp is still not operated in unity gain mode for all combinations of bits, it is much closer to unity gain with this architecture.

The important op amp parameters for all resistor ladder D/As are:

- Input offset voltage — the lower the better. It adds to the converter offset error.
- Input bias current — the lower the better. The product of the bias current and the feedback resistance creates an output offset error.
- Output voltage swing — it must meet or preferably exceed the zero to full-scale swing from the D/A.
- Settling time and slew rate — must be fast enough to allow the op amp to settle before the next digital bit combination is presented to the D/A input register.

14.3.5 The Sigma Delta D/A Converter

The sigma delta D/A converter takes advantage of the speed of advanced IC processes to do a conversion as a series of approximations summed together. A phase-locked loop-derived (PLL) sample clock operates at many times the overall conversion frequency — in the case shown in Figure 14–5, it is 128×. The PLL is used to drive an interpolation filter, a digital modulator, and a 1-bit D/A converter. The conversion is done by using the density

ratio of the voltage out of the 1-bit D/A as the analog signal. As the pattern of 1s and 0s is presented to the 1-bit converter, their time average at the sample frequency recreates the analog waveform.

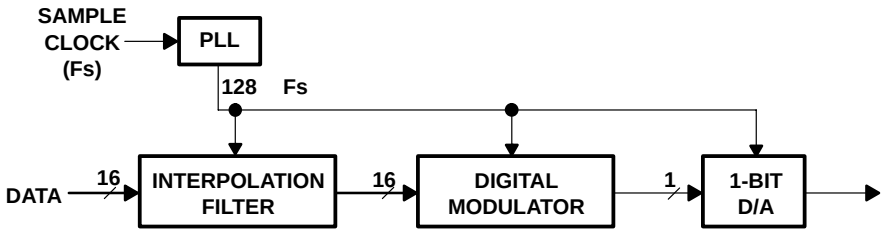

Figure 14–5. Sigma Delta D/A Converter

Sigma delta converters are popular for audio frequencies, particularly CD players. The primary limiting factor is the sample clock. CD players operate at a sample rate of 44.1 kHz, which means that according to Nyquist sampling theory, the maximum audio frequency that can be reproduced is 22.05 kHz. If an audio frequency of 23.05 kHz is present in the recorded material, it will alias back into the audio output at 1 kHz — producing an annoying whistle. This places a tremendous constraint on the low-pass filter following the D/A in a CD player. It must reject all audio frequencies above 22.05 kHz while passing those up to 20 kHz, the commonly accepted upper limit of human hearing. While this can be done in conventional filter topologies, they are extremely complex (9 or more poles). Inevitably, phase shift and amplitude rolloff or ripple will start far below 20 kHz. The original CD players often sounded a bit “harsh” or “dull” because of this.

The solution was to overclock the sample clock. To keep things simple, designers made it a binary multiple of the original sampling frequency. Today, 8× or even higher oversampling is standard in CD players. Little do the audio enthusiasts know that the primary reason why this was done was to substantially reduce the cost of the CD player! A faster sample clock is very cheap. Nine-pole audio filters are not. At 8× oversampling, the CD player only needs to achieve maximum rolloff at 352.8 kHz — a very easy requirement. Instead of the filter having to roll off in a mere 2 kHz of bandwidth, now it has 332 kHz of bandwidth to accomplish the rolloff. The sound of an oversampled CD player really is better, but it comes at the cost of increased radiated RFI, coming from the sample clock.

Sigma delta converters introduce a great deal of noise onto the power rails, because the internal digital circuitry is continually switching to the power supply rails at the sample clock frequency F_S.

14.4 D/A Converter Error Budget

The system designer must do an error budget to know how many bits are actually needed to meet the system requirements — how much “graininess” or what step size is acceptable in the output signal.

14.4.1 Accuracy versus Resolution

It is important for the designer to understand the difference between converter accuracy and converter resolution. The number of bits determines resolution of a converter. Insufficient resolution is not error — it is a design characteristic of the D/A. If a given converter's resolution is insufficient, use a converter with better resolution (more bits).

Accuracy is the error in the analog output from the theoretical value for a given digital input. Errors are described in the next paragraph. A very common method of compensating for D/A error is to use a converter that has one or two bits more resolution than the application requires. With the cost of converters coming down, and more advanced models being introduced every day, this may be cost effective.

14.4.2 DC Application Error Budget

DC applications will depend on the value of dc voltage coming out of the converter. THD and signal-to-noise will not be important because the frequency coming out of the converter is almost dc.

The resolution of a converter is ±1/2 LSB, where an LSB is defined as:

$$1\ \text{LSB} = \frac{V_{FS}}{2^N - 1} \qquad (14\text{–}1)$$

Where:

V_{FS} Full-scale output voltage
N Number of converter bits

The number of bits in a dc system determines the dc step size that corresponds to a bit. Table 14–1 shows the number of bits, and the corresponding voltage step size for three popular voltages:

Table 14–1. DC Step Size for D/A converters

BITS	STATES	3 V	5 V	10 V
4	16	0.1875	0.3125	0.625
8	256	0.011719	0.019531	0.039063
10	1024	0.00293	0.004883	0.009766
12	4096	0.000732	0.001221	0.002441
14	16384	0.000183	0.000305	0.00061
16	65536	4.58 E–05	7.63 E–05	0.000153
18	262144	1.14 E–05	1.91 E–05	3.81 E–05
20	1048576	2.86 E–06	4.77 E–06	9.54 E–06
22	4194304	7.15 E–07	1.19 E–06	2.38 E–06
24	16777216	1.79 E–07	2.98 E–07	5.96 E–07

The bit step size can get critical, especially for portable equipment. There is a requirement to operate off of low voltage, to minimize the number of batteries. The buffer amplifier, if it includes gain, will use large resistor values, lowering its noise immunity. Fortunately, the vast majority of dc applications are not portable; they are in an industrial environment.

For example: A converter is used to position a drill on a table used to drill PCB holes. The positions of the holes are specified as 0.001 inches, ±0.0003 inches. The actuators are centered on the table at zero volts, with full negative position of –12 inches occurring at –5 V, and full positive position of +12 inches occurring at +5 V. There are two actuators, one for vertical, and one for horizontal.

This example has several aspects. The first is that the positioning voltage has to swing both positive and negative. In the real world, it may be necessary to add (or subtract in this case) a fixed offset to the D/A output. The output voltage has to swing over a 10-V range, which may mean that the output of the D/A has to be amplified. The actuators themselves probably operate off of higher current than the D/A is designed to provide. Section 14.7 covers some methods for meeting these requirements.

Assume, for now, that the D/A has the necessary offset and gain. A ±12 inch position is 24 inches total, which corresponds to ±5 V from the D/A circuitry. The 24-inch range must be divided into equal 0.0003-inch steps to meet the resolution requirement, which is 80,000 steps. From Table 14–1, an 18-bit D/A converter is required. The actual system will be able to position with a step size of 0.0000916 inches. Two independent conversion systems are needed, one for horizontal and one for vertical.

14.4.3 AC Application Error Budget

The error budget for an ac application will most likely be specified as total harmonic distortion, dynamic range, or signal-to-noise ratio. Assuming no internal noise, and no noise in the buffer op amp circuitry, the inverse of the dynamic range is the signal-to-noise ratio of the converter D/A. Of course, noise is always present, and is measured with all input data set to zero. Noise will make the S/N ratio decrease.

The number of converter bits, however, is the overwhelming factor determining these parameters. Technically, they are not “errors”, because the design of the converter sets them. If the designer cannot live with these design limits, the only choice is to specify a converter with better resolution (more bits).

14.4.3.1 Total Harmonic Distortion

The total harmonic distortion of an ideal D/A converter is the quantization noise due to the converter resolution. The number of bits of the converter determines the lowest possible total harmonic distortion. The greater the number of bits, the lower the amplitude of the harmonics, as shown in Figure 14–6.

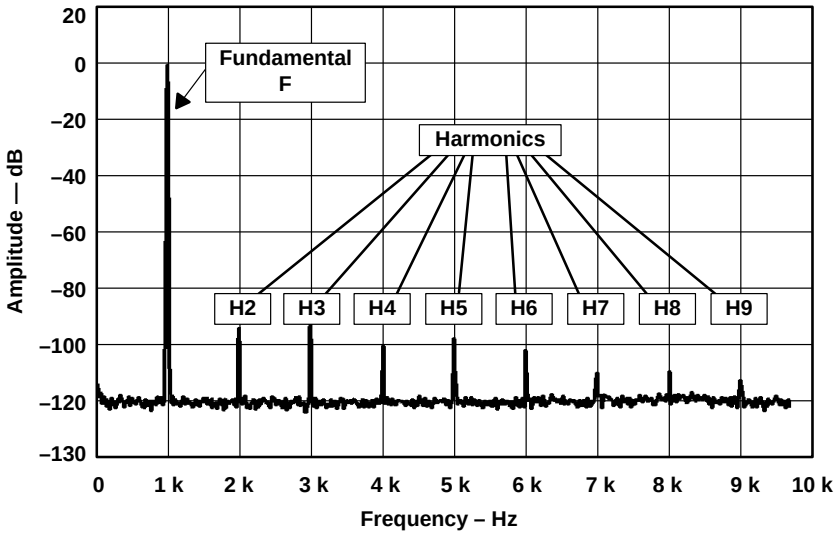

Figure 14–6. Total Harmonic Distortion

Assuming ideal D/A conversion, there is a direct relationship between the number of bits and the THD caused by the resolution:

$$\text{THD}(\%) = \frac{1}{2^N} \times 100 \qquad (14\text{–}2)$$

Where N is the number of converter bits. Of course, this is the limit for ideal conversion.

14.4.3.2 Dynamic Range

There is also a direct relationship between the number of bits (n) and the maximum dynamic range of the D/A (Equation 14–2 and Table 14–2):

$$\text{Dynamic Range} = 6.02 \times n + 1.76 \qquad (14\text{–}3)$$

Notice that there is approximately a 6-dB improvement in dynamic range per bit. This is an easy way to figure out what improvement can be realized by increasing the number of bits from one value to another.

Table 14–2. Converter Bits, THD, and Dynamic Range

BITS	STATES	THD	Dynamic Range
4	16	6.25%	25.8
8	256	0.390625%	49.9
10	1024	0.097656%	62.0
12	4096	0.024414%	74.0
14	16384	0.006104%	86.0
16	65536	0.001526%	98.1
18	262144	0.000381%	110.1
20	1048576	0.000095%	122.2
22	4194304	0.000024%	134.2
24	16777216	0.000006%	146.2

For example, if the designers of a CD player want to have a 90-dB signal-to-noise ratio, they would pick a 16-bit converter from Table 14–2. The THD is 0.0015% minimum.

14.4.4 RF Application Error Budget

RF applications are a high-frequency subset of ac applications. RF applications may be concerned with the position and relative amplitude of various harmonics. Minimizing one harmonic at the expense of another may be acceptable if the overall RF spectrum is within specified limits.

14.5 D/A Converter Errors and Parameters

The D/A errors described in this section will add to the errors caused by the resolution of the converter.

This section is divided into dc and ac sections, but many of the dc errors masquerade as ac errors. A given D/A may or may not include either dc or ac error specifications. This should give the designer a clue that the device is optimized for dc or ac applications. Like any component, D/A converters are designed with tradeoffs. It is possible to misapply a converter meant for high-frequency ac operation in a dc application, etc.

14.5.1 DC Errors and Parameters

The following paragraphs describe D/A dc errors and parameters.

14.5.1.1 Offset Error

The analog output voltage range for the complete range of input bits may be shifted linearly from the ideal 0 to full-scale value (Figure 14–7). The offset error is the $\pm\Delta$ V from 0 V that results when a digital code is entered that is supposed to produce 0.

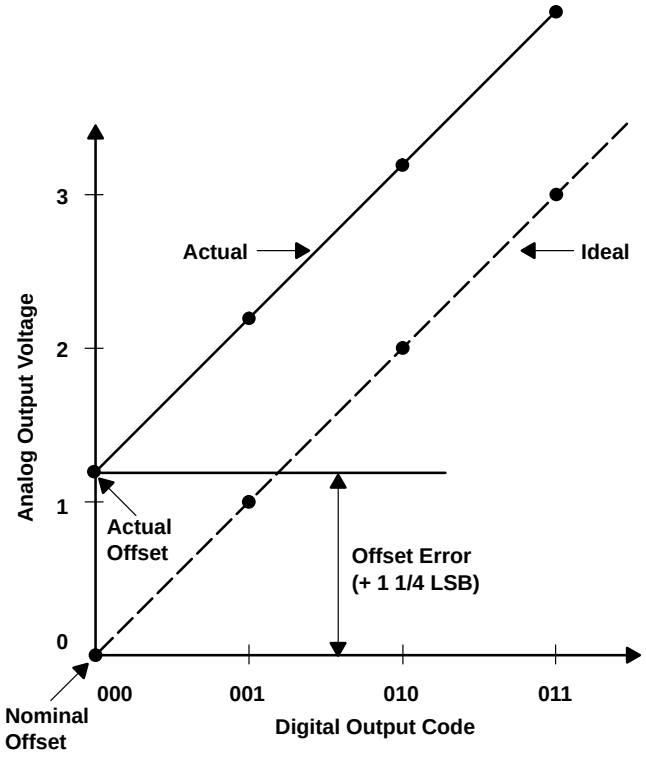

Figure 14–7. D/A Offset Error

Related to the offset error is the offset error temperature coefficient, which is the change in offset over temperature. This is usually specified in ppm/°C.

Offset error is critical in dc applications. For this reason, a buffer op amp must be selected that does not contribute to the problem — its own offset voltages should be much less than that of the converter. In ac applications, the offset error is not important and can be ignored. The buffer op amp can be selected for low THD, high slew rate, or whatever other parameters are important for the application.

14.5.1.2 Gain Error

The gain of the D/A converter may greater than or less than the gain needed to produce the desired full-scale analog voltage (Figure 14–8). The gain error is the difference in slope between the ideal D/A output gain and the actual gain.

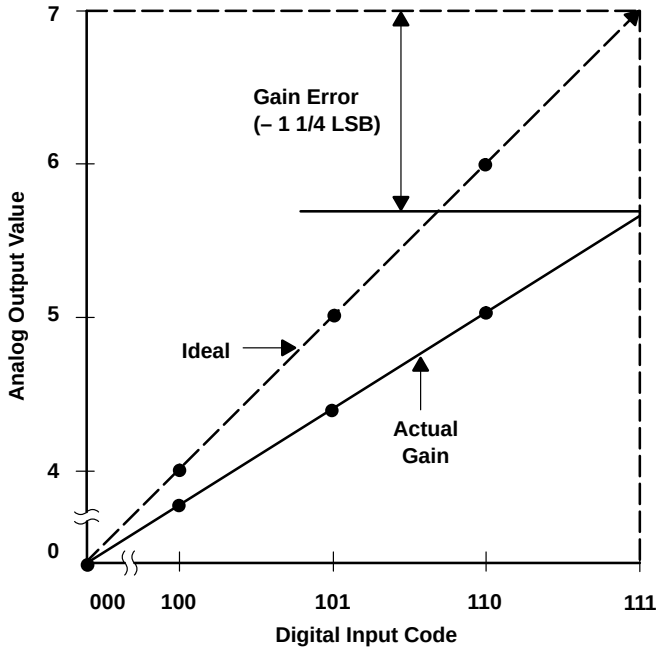

Figure 14–8. D/A Gain Error

Related to the gain error is the gain error temperature coefficient, which is the change in gain over temperature.

Gain error can be critical in both ac and dc applications. For example:

- An RF predriver must not cause the output stage to exceed FCC license requirements.
- A mechanical positioner must not stop short of or go past its intended position.

The op amp buffer should be operated with the internal feedback resistor. If possible, full-scale amplitude adjustments should be made to V_{REF}. This way, tolerances and thermal drift in external resistors do not contribute to the gain error.

14.5.1.3 Differential Nonlinearity Error

When the increase in output voltage (ΔV) is not the same for every combination of bits, the converter has a differential nonlinearity error (DNL). If the DNL exceeds 1 LSB, the converter is nonmonotonic. This can cause a problem for some servo control loops. A nonmonotonic D/A would appear in Figure 14–9 as a momentary dip in the analog output characteristic.

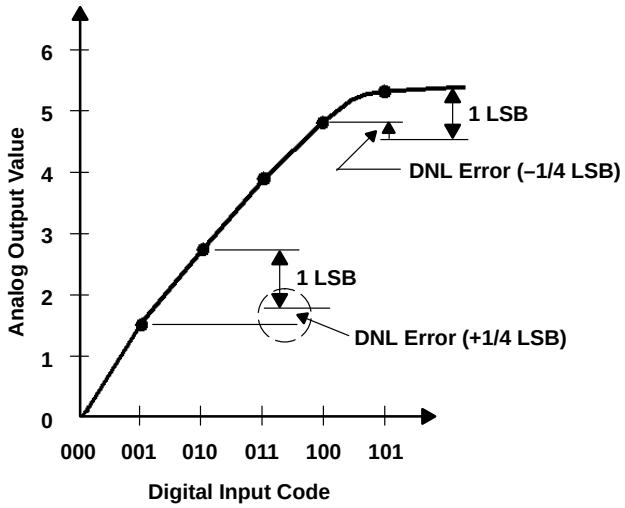

Figure 14–9. Differential Nonlinearity Error

14.5.1.4 Integral Nonlinearity Error

The integral nonlinearity error is similar to the differential nonlinearity error, except it is a first-order effect that stretches across the entire range from 0 to full scale output voltage (Figure 14–10).

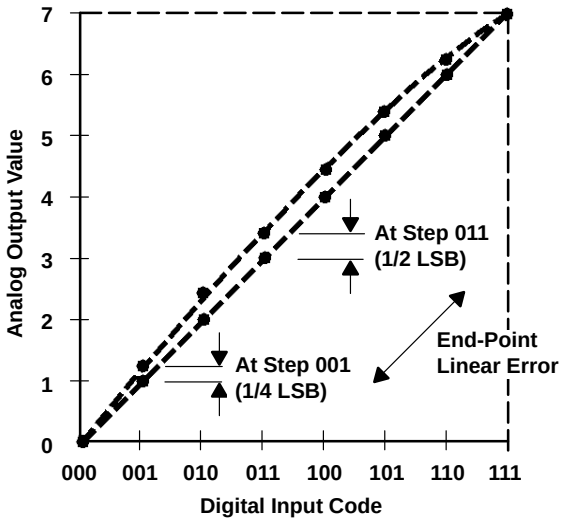

Figure 14–10. Integral Nonlinearity Error

Both the INL and DNL errors affect ac applications as distortion and spectral harmonics (spurs). In dc applications, they will result in an error in the dc output voltage. The mechanical steps of a positioning table, for instance, may not be exact increments.

14.5.1.5 Power Supply Rejection Ratio

The power supply rejection ratio is sometimes called the *power supply sensitivity*. It is the ability of the converter to reject ripple and noise on its power inputs. DC applications may not be adversely affected. Poor power supply rejection can cause spurs and harmonic distortion in ac applications, as external frequency components leak into the output and modulate with it. The designer must decouple the D/A and buffer op amp carefully to combat these problems.

14.5.2 AC Application Errors and Parameters

The following paragraphs describe D/A ac errors and parameters.

14.5.2.1 THD+N

There will always be some noise that is generated internally in the converter and buffer amp. A useful specification for audio and communication system designers is the THD+N (total harmonic distortion plus noise). The distortion plus noise (THD+N) is the ratio of the sum of the harmonic distortion and noise to the rms power of the input signal. As was the case with op amp parameters (Chapter 11), the noise sources add according to the root-mean-square law. The distortion and noise are measured separately and then added together to form the ratio. The noise voltage relates to the measured bandwidth.

14.5.2.2 SINAD

The signal-to-noise and distortion (SINAD) is the ratio of the input signal to the sum of the harmonic distortion and noise. The distortion and noise are measured separately and than added together to form the ratio. The SINAD is the reciprocal to the THD+N. The SINAD and THD+N are a good indication of the overall dynamic performance of the ADC, because all components of noise and distortion are included.

14.5.2.3 ENOB

The SINAD is used to determine the *effective number of bits* (ENOB) of accuracy the converter displays at that frequency. For example, a nominal 8-bit resolution D/A may be specified as having 45-dB SNR at a particular input frequency. The number of effective bits is defined as

$$\text{ENOB} = \frac{\text{SNR}_{\text{REAL}} - 1.76}{6.02} = 7.2 \text{ bits} \qquad (14\text{–}4)$$

The actual performance of the device is therefore less than its nominal resolution at this frequency.

14.5.2.4 Spurious Free Dynamic Range

Spurious free dynamic range is the difference in dB between the maximum signal component and the largest distortion component (Figure 114–11):

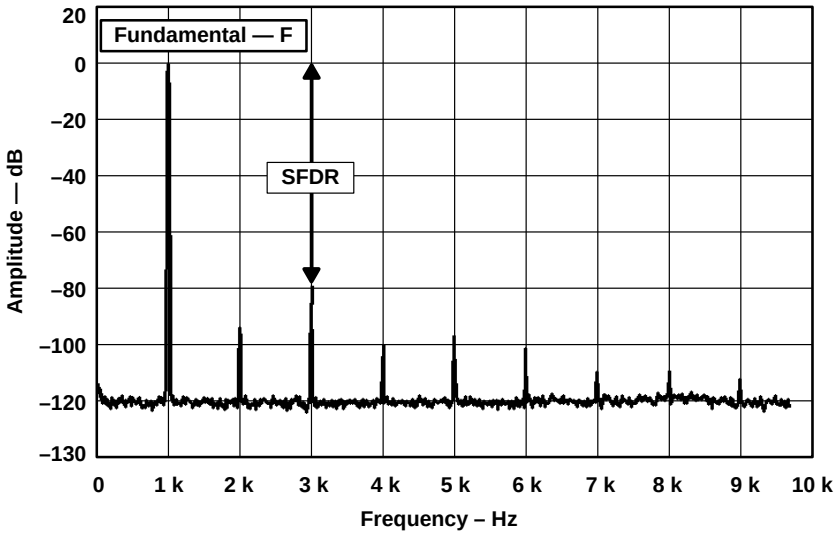

Figure 14–11. Spurious Free Dynamic Range

It is an important specification in RF applications, where FCC regulations specify the magnitude of spurs.

Improper decoupling may cause spurs. A notch filter can be used to eliminate a spur, but many RF applications are RF agile — changing the frequency of the spur as well. The notch must catch all spur frequencies, or it is useless.

14.5.2.5 Intermodulation Distortion

The differential and integral nonlinearity errors described previously appear in a high-frequency ac application as intermodulation distortion (Figure 14–12).

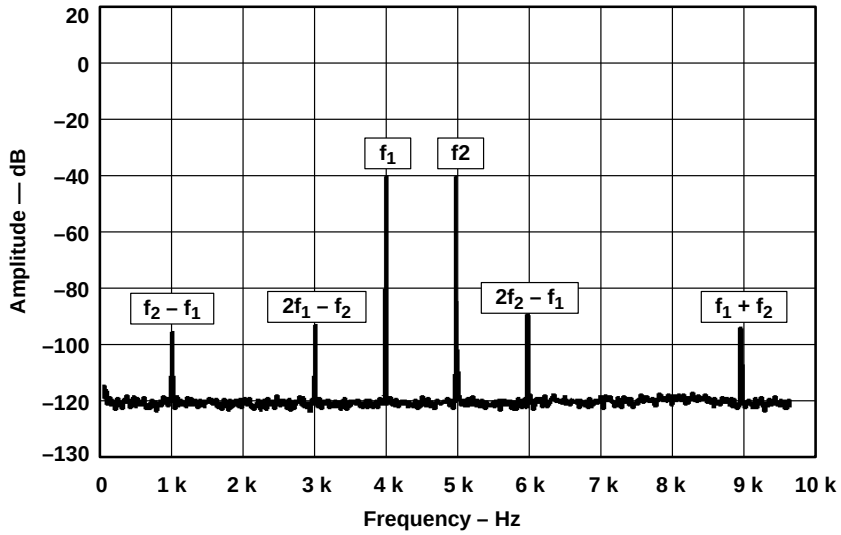

Figure 14–12. Intermodulation Distortion

The best method of combating intermodulation distortion is to make the buffer amplifier system as linear as possible (beware of rail-to-rail op amps that may not be linear near the voltage rails). Try to limit current through the internal feedback resistor in the DAC. See Paragraph 14.7.1 on increasing the voltage rail for suggestions about reducing internal feedback resistor power dissipation.

14.5.2.6 Settling Time

The settling time of a D/A converter is the time between the switching of the digital inputs of the converter and the time when the output reaches its final value and remains within a specified error band (Figure 14–13). Settling time is the reciprocal of the maximum D/A conversion rate.

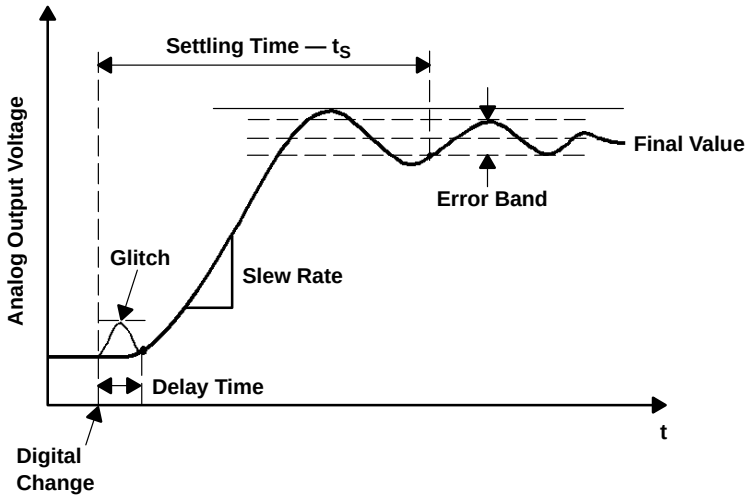

Figure 14–13. D/A Settling Time

When an output buffer op amp is used with a D/A, it becomes a part of the settling time/ conversion rate calculations.

Related to the settling time is a glitch response that occurs when the digital code changes state. Even though this effect is transitory in nature, it can result in noise or harmonics when used in fast AC applications. The best way of reducing the glitch is to properly decouple the D/A and op amp buffer (see Chapter 17). In extreme cases, a deglitching circuit may be needed (Figure 14–14).

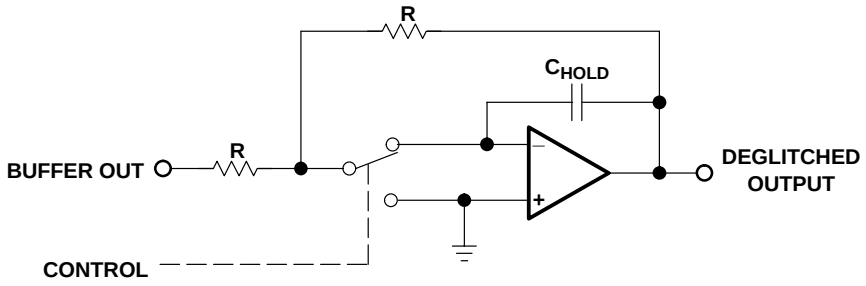

Figure 14–14. D/A Deglitch Circuit

This technique relies on the software designer to balance the timing of the control signal so it activates the hold function right before the D/A input code changes, then releases the hold right after the code has changed. The selection of C_{HOLD} is critical — it must hold the buffer output without droop and without compromising system bandwidth.

14.6 Compensating For DAC Capacitance

D/A converters are constructed of either bipolar or CMOS technology, with CMOS being the more common. CMOS transistors, however, have a lot of capacitance. This capacitance will add in D/A converters, depending on the number of resistors switched on or off. Capacitance at an inverting op amp input is a good way to cause it to oscillate, especially since some buffer amplifiers will be operated at less than unity gain. The converter capacitance C_O must be compensated for externally (Figure 14–15).

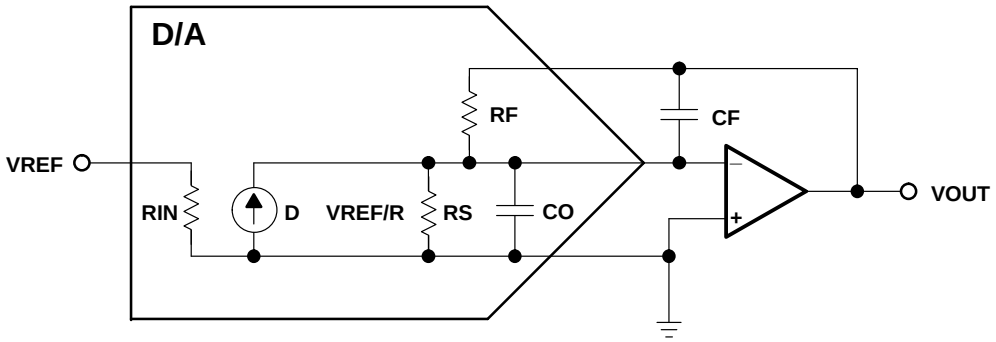

Figure 14–15. Compensating for CMOS DAC Output Capacitance

The normal technique for compensating the buffer amplifier for output capacitance is to add a feedback capacitor C_F. C_F is calculated by the following:

$$C_F = 2 \times \sqrt{\frac{C_O}{2\pi R_F} \times \frac{1}{G_{BW}}} \qquad (14–5)$$

Where:

C_O	the output capacitance from the D/A data sheet
R_F	the feedback resistance from the D/A data sheet
G_{BW}	the small signal unity gain bandwidth product of the output amplifier

Unfortunately, the feedback capacitors C_F and the internal D/A capacitance C_O will both limit the conversion speed of the D/A. If faster conversion is needed, a D/A with a lower output capacitance, and therefore a lower feedback compensation capacitor will be needed. The overall settling time with the external capacitance is:

$$T_S \approx \sqrt{\frac{R_F\left(C_O + C_F\right)}{2G_{BW}}} \qquad (14\text{–}6)$$

Where:

C_O	the D/A internal capacitance
R_F	the feedback resistor
C_F	the compensation capacitance
G_{BW}	the small signal unity gain bandwidth product of the output amplifier

14.7 Increasing Op Amp Buffer Amplifier Current and Voltage

Process limitations of op amps limit the power that can be dissipated at the output. Unfortunately, there are applications that will require the DAC to interface to loads that dissipate considerable power. These include actuators, position solenoids, stepper motors, loudspeakers, vibration tables, positioning tables — the possibilities are endless.

While several “power op amps” are available that can drive heavy loads, they usually compromise several other specifications to achieve the high power operation. Input voltage offset, input current, and input capacitance can be decades higher than the designer is accustomed to, and make these power op amps unsuitable for direct interface with a DAC as a replacement for the buffer op amp.

The power booster stage can be designed discretely, or a prepackaged amplifier of some sort, depending on what is needed for the application. Sometimes high current is required for driving loads such as actuators and stepper motors. Audio applications can require a lot of wattage to drive loudspeakers. This implies a higher voltage rail than op amps commonly operate at. This and other high voltage applications can operate off of, and generate lethal voltages. The designer needs to be extremely careful not to create an unsafe product, or be electrocuted while developing it.

The power stage is most often included in the feedback loop of the op amp circuit, so that the closed loop can compensate for power stage errors. This is not always possible if the voltage swing of the output exceeds that of the op amp voltage rails. In these cases, a voltage divided version of the output should be used.

There are three broad categories of booster, the current booster, the voltage booster, and boosters that do both. All of them work on the same principle: anything that is put inside the feedback loop of the op amp will be compensated for — the output voltage will swing to whatever voltage it needs to make the voltage at the buffer op amp inputs equal.

14.7.1 Current Boosters

These usually use some variation of the class-B push-pull amplifier topology (Figure 14–16).

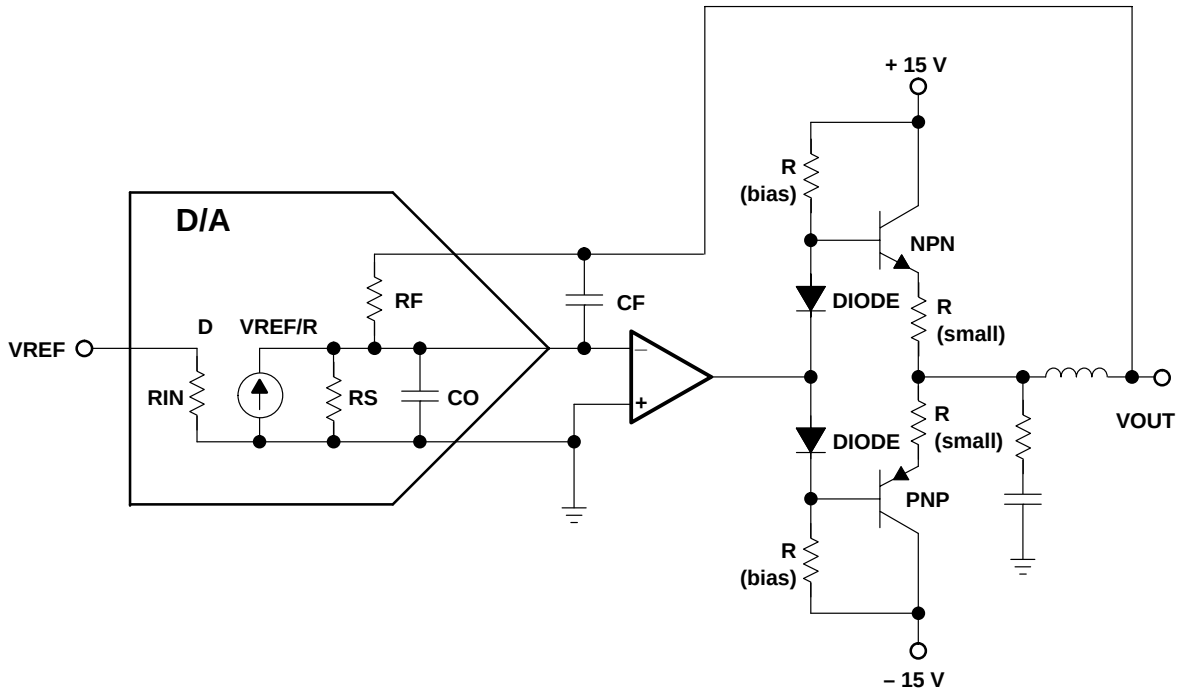

Figure 14–16. D/A Output Current Booster

The circuit in Figure 14–16 has been employed for decades — many resources are available that can be used to design exact component values. It boosts current because the output impedance of the op amp has been bypassed, and used as the driver for the base of the NPN and PNP power transistors. The two diodes compensate for the VBE drop in the transistors, whose bases are biased by two resistors off of the supplies. The output of the booster stage is fed back to the feedback resistor in the D/A to complete the feedback loop. The output impedance of the stage is only limited by the characteristics of the output transistors and small emitter resistors. Modern power transistors have such high frequency response that this circuit may oscillate. The RC snubber network and a small inductor in series with the load can be used to damp the oscillation — or be omitted if oscillation is not a problem. Beware of varying transistor betas, however.

14.7.2 Voltage Boosters

If even more current is needed, or the output voltage swing must be more than ±15 V, the booster stage can be operated at voltages higher than the buffer amplifier potentials. A designer might be tempted to try the circuit of Figure 14–17.

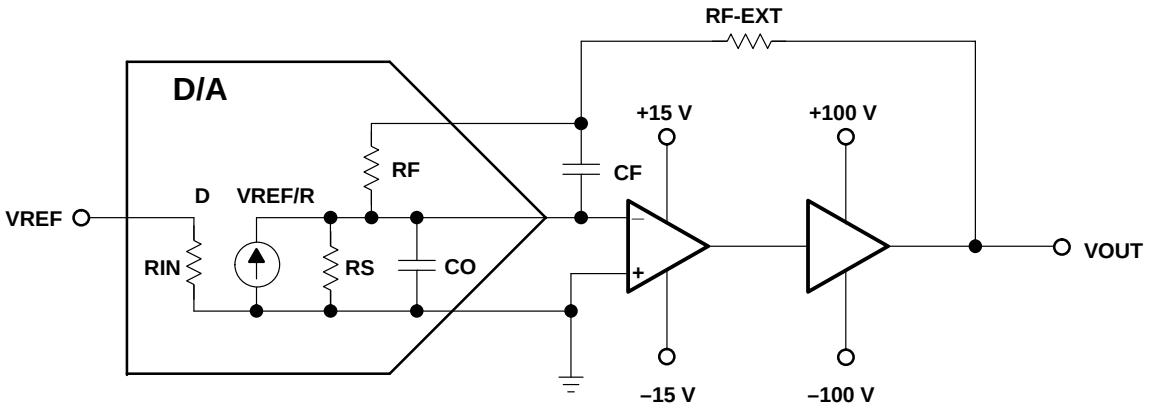

Figure 14–17. Incorrect Method of Increasing Voltage Swing of D/A Converters

Any time there are higher voltage rails on the output section, there are potential hazards. The circuit above illustrates a common misapplication.

- The whole reason for using the booster amp is to allow the V_{OUT} to swing to a ±100-V rail. If this circuit was operated in the unity gain mode (external $R_F = 0$), the VOUT will only swing ±15 V, maximum. There would be no need for the ±100-V rail. That voltage rail is there to allow voltage gain.
- If the circuit is operated with a gain (external R larger than 0), the external R_F adds to the internal R_F to create the gain:

$$\text{Gain} = \frac{R_{F-EXT} + R_{F-INT}}{R_S} \qquad (14\text{–}7)$$

The problem with this is that the wattage of the resistors increases as the external voltage rail increases. The designer has control over the wattage of the external R_F, but has no control whatsoever over internal R_F or R_S. Because these resistors are fabricated on the IC, their wattage is limited. Even if the wattage rating of the internal resistors is meticulously observed, they may have undesirable thermal coefficients if allowed to dissipate that wattage. Resistor self-heating will change the resistance according to its rated temperature coefficient (maximum). The external resistor is sure to have a different thermal coefficient from the internal resistors, causing a gain error. The designer may never have encountered the effects of resistor self-heating before, because through-hole and surface-mount devices have enough bulk to minimize the effect of self-heating. At the geometries present on IC D/As, resistor self-heating is a much more pronounced effect. It will produce a nonlinearity error in the D/A output.

This effect is most pronounced in high-resolution converters, where the geometry is the smallest. The designer, therefore, must limit the current in the feedback resistor if at all possible. Figure 14–18 shows a method of achieving gain control while keeping the high current path out of the internal feedback resistor:

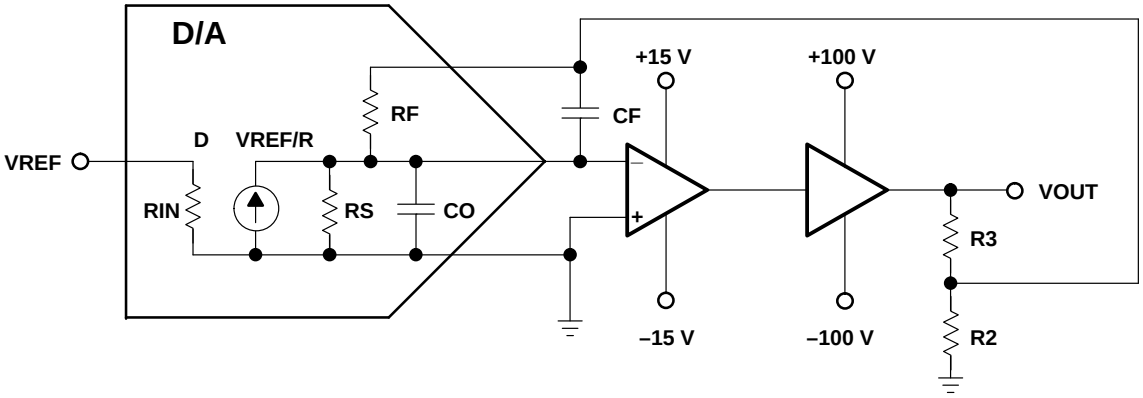

Figure 14–18. Correct Method of Increasing Voltage Range

In Figure 14–18:

- R3 and R2 are selected to ensure that the feedback voltage to the D/A internal R_F can never exceed the D/A rated limits.
- R3 and R2, of course, have to be the correct power rating. R2, in particular, has to be carefully selected. If it burns out, the feedback loop will present hazardous voltages to the D/A. R3, which drops the bulk of the voltage, will have to dissipate considerable wattage.

If the combination of voltage swing and power ratings cannot be balanced to achieve a working design, the only choice left to the designer will be to break the feedback loop and live with the loss of accuracy. For ac applications, this may be acceptable.

14.7.3 Power Boosters

The two types of boosters above can, of course, be combined to produce more power. In audio applications, for example, a ±15-V power supply limits the output power to 112.5 W, absolute maximum, into an 8-Ω load. In order to increase the power, the voltage rails must also be increased, with all of the cautions of the previous paragraph observed.

14.7.4 Single-Supply Operation and DC Offsets

A D/A power circuit is not the right place to try to apply single-supply design techniques. In audio applications, a single-supply design would force a large coupling capacitor, which would distort and limit low frequency response. In dc applications, a dc offset will continually drive a load — which will have to dissipate the excess voltage through its internal resistance as heat.

Nevertheless, there may be applications that require a dc offset. The designer is fortunate in that there is already a precision reference available in the circuit. The reference drives

the resistor network in the D/A, and may be external or internal to it. In most cases, an internal reference is brought out to a pin on the device. It is important for the designer not to excessively load the reference, as that would directly affect D/A accuracy (Figure 14–19).

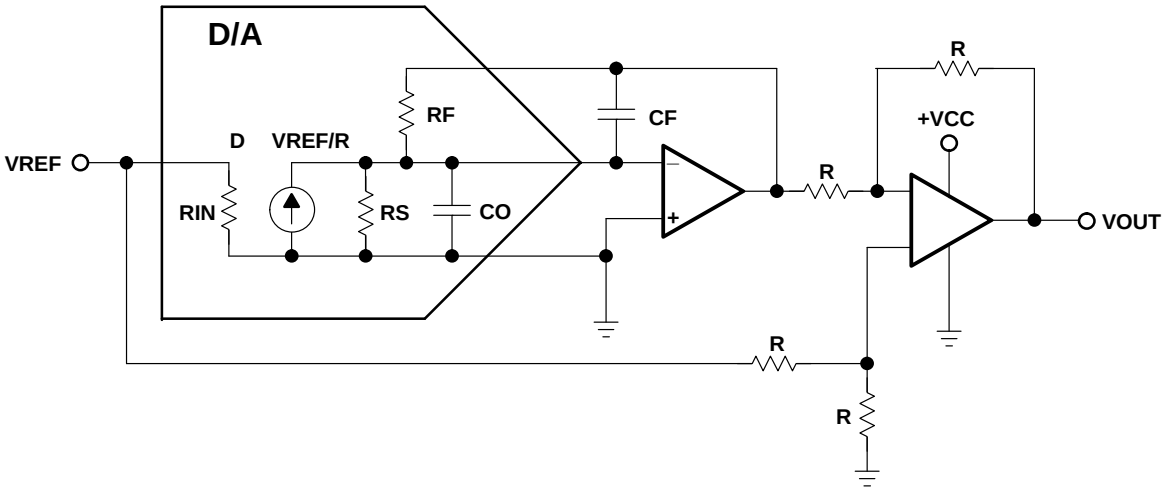

Figure 14–19. Single-Supply DAC Operation

In the circuit in Figure 14–19, the output of the buffer amplifier is shifted up in dc level by ½ VREF (not ½ VCC). VREF was selected because it is much more stable and accurate than VCC. The four resistors in the level shifter circuit must be highly accurate and matched, or this circuit will contribute to gain and offset errors. Thermal errors, however, cannot be compensated for, because the external resistors are probably going to have a different thermal drift than those on the IC. This technique is limited to applications that will see only a small change in ambient temperature.

Chapter 15

Sine Wave Oscillators

Ron Mancini and Richard Palmer

15.1 What is a Sine Wave Oscillator?

Op amp oscillators are circuits that are unstable — not the type that are sometimes unintentionally designed or created in the lab — but circuits intentionally designed to remain in an unstable state. Oscillators are useful for creating uniform signals that are used as a reference in applications such as audio, function generators, digital systems, and communication systems.

Two general classes of oscillators exist: sinusoidal and relaxation. Sinusoidal oscillators consist of amplifiers with RC or LC circuits that have adjustable oscillation frequencies, or crystals that have a fixed oscillation frequency. Relaxation oscillators generate triangular, sawtooth, square, pulse, or exponential waveforms, and they are not discussed here.

Op amp sine wave oscillators operate without an externally applied input signal. Some combination of positive and negative feedback is used to drive the op amp into an unstable state, causing the output to transition back and forth at a continuous rate. The amplitude and the oscillation frequency are set by the arrangement of passive and active components around a central op amp.

Op amp oscillators are restricted to the lower end of the frequency spectrum because op amps do not have the required bandwidth to achieve low phase shift at high frequencies. Voltage-feedback op amps are limited to a the low kHz range since their dominant, open loop pole may be as low as 10 Hz. The new current-feedback op amps have a much wider bandwidth, but they are very hard to use in oscillator circuits because they are sensitive to feedback capacitance and are beyond the scope of this chapter. Crystal oscillators are used in high frequency applications up to the hundreds of MHz range.

15.2 Requirements for Oscillation

The canonical, or simplest form, of a negative feedback system is used to demonstrate the requirements for oscillation to occur. The block diagram of this system is shown in Fig-

ure 15–1, and the corresponding classic expression for a feedback system is shown in Equation 15–1. The derivation and explanation of the block diagram and equation can be found in Chapter 5.

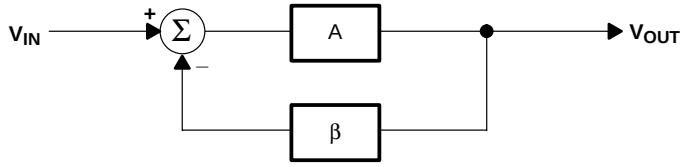

Figure 15–1. Canonical Form of a Feedback System with Positive or Negative Feedback

$$\frac{V_{OUT}}{V_{IN}} = \frac{A}{1 + A\beta} \qquad (15–1)$$

Oscillators do not require an externally applied input signal, but instead use some fraction of the output signal created by the feedback network as the input signal. It is the noise voltage that provides the inital boost signal to the circuit when positive feedback is employed. Over a period of time, the output builds up, oscillating at the frequency set by the circuit components[1].

Oscillation results when the feedback system is not able to find a stable state because its transfer function can not be satisfied. The system becomes unstable when the denominator in Equation 15–1 is 0. When (1 +Aβ) = 0, Aβ = –1. The key to designing an oscillator, then, is to ensure that Aβ = –1. This is called the Barkhausen criterion. This constraint requires the magnitude of the loop gain be 1 with a corresponding phase shift of 180° as indicated by the minus sign. An equivalent expression using complex math is $A\beta = 1\angle{-180}°$ for a negative feedback system. For a positive feedback system, the expression becomes $A\beta = 1\angle 0°$ and the sign is negative in Equation 15–1.

Once the phase shift is 180° and Aβ = |1|, the output voltage of the unstable system heads for infinite voltage in an attempt to destroy the world, and is only prevented from succeeding by an energy-limited power supply. When the output voltage approaches either power rail, the active devices in the amplifiers change gain, causing the value of A to change so the value of $A\beta \neq 1$; thus the charge to infinite voltage slows down and eventually halts. At this point, one of three things can occur. First, nonlinearity in saturation or cutoff can cause the system to become stable and lock up at the power rail. Second, the initial charge can cause the system to saturate (or cutoff) and stay that way for a long time before it becomes linear and heads for the opposite power rail. Third, the system stays linear and reverses direction heading for the opposite power rail. Alternative two produces highly distorted oscillations (usually quasi square waves), and the resulting oscillators are called relaxation oscillators. Alternative three produces sine wave oscillators.

15.3 Phase Shift in the Oscillator

The 180° phase shift in the equation $A\beta = 1\angle -180°$ is introduced by active and passive components. Like any well-designed feedback circuit, oscillators are made dependent on passive component phase shift because it is accurate and almost drift-free. The phase shift contributed by active components is minimized because it varies with temperature, has a wide initial tolerance, and is device dependent. Amplifiers are selected such that they contribute little or no phase shift at the oscillation frequency. These constraints limit the op amp oscillator to relatively low frequencies.

A single pole RL or RC circuit contributes up to 90° phase shift per pole, and because 180° of phase shift is required for oscillation, at least two poles must be used in the oscillator design. An LC circuit has two poles, thus it contributes up to 180° phase shift per pole pair. But LC and LR oscillators are not considered here because low frequency inductors are expensive, heavy, bulky, and very nonideal. LC oscillators are designed in high frequency applications, beyond the frequency range of voltage feedback op amps, where the inductor size, weight, and cost are less significant. Multiple RC sections are used in low frequency oscillator design in lieu of inductors.

Phase shift determines the oscillation frequency because the circuit oscillates at the frequency that accumulates 180° phase shift. The rate of change of phase with frequency, $d\phi/d\omega$, determines frequency stability. When buffered RC sections (an op amp buffer provides high input and low output impedance) are cascaded, the phase shift multiplies by the number of sections, *n* (see Figure 15–2).

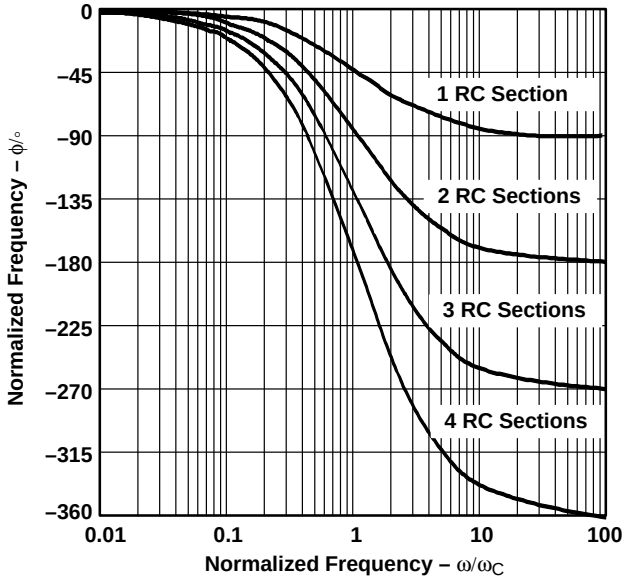

Figure 15–2. Phase Plot of RC Sections

The frequency of oscillation is very dependent upon the change in phase at the point where the phase shift is 180°. A tight frequency specification will require a large change in phase shift, $d\phi$, for a small change in frequency, $d\omega$, at 180°. Figure 15–2 demonstrates that, although two cascaded RC sections eventually provide 180° phase shift, $d\phi/d\omega$ at the oscillator frequency is unacceptably low. Thus, oscillators made with two cascaded RC sections have poor frequency stability. Three equal cascaded RC filter sections have a much higher $d\phi/d\omega$ (see Figure 15–2), and the resulting oscillator has improved frequency stability. Adding a fourth RC section produces an oscillator with an excellent $d\phi/d\omega$ (see Figure 15–2); thus this is the most stable RC oscillator configuration. Four sections are the maximum number used because op amps come in quad packages, and the four-section oscillator section yields four sine waves 45° phase shifted relative to each other. This oscillator can be used to obtain sine/cosine or quadrature sine waves.

Crystal or ceramic resonators make the most stable oscillators because resonators have an extremely high $d\phi/d\omega$ resulting from their nonlinear properties. Resonators are used for high frequency oscillators, but low frequency oscillators do not use resonators because of size, weight, and cost restrictions. Op amps are not generally used with crystal or ceramic resonator oscillators because op amps have low bandwidth. Experience shows that it is more cost effective to build a high frequency crystal oscillator, count the output down, and filter the output to obtain a low frequency than it is to use a low frequency resonator.

15.4 Gain in the Oscillator

The oscillator gain must equal 1 ($A\beta = 1\angle -180°$) at the oscillation frequency. Under normal conditions, the circuit becomes stable when the gain exceeds 1 and oscillations cease. However, when the gain exceeds 1 with a phase shift of –180°, the active device nonlinearity reduces the gain to 1 and the circuit oscillates. The nonlinearity happens when the amplifier swings close to either power rail because cutoff or saturation reduces the active device (transistor) gain. The paradox is that worst case design practice requires nominal gains exceeding 1 for manufacturability, but excess gain causes more distortion of the output sine wave.

When the gain is too low, oscillations cease under worst case conditions, and when the gain is too high, the output wave form looks more like a square wave than a sine wave. Distortion is a direct result of excess gain overdriving the amplifier; thus gain must be carefully controlled in low-distortion oscillators. Phase shift oscillators have distortion, but they achieve low-distortion output voltages because cascaded RC sections act as distortion filters. Also, buffered phase shift oscillators have low distortion because the gain is controlled and distributed among the buffers.

Most circuit configurations require an auxiliary circuit for gain adjustment when low-distortion outputs are desired. Auxiliary circuits range from inserting a nonlinear component in

the feedback loop, to automatic gain control (AGC) loops, to limiting by external components such as resistors and diodes. Consideration must also be given to the change in gain due to temperature variations and component tolerances, and the level of circuit complexity will be determined based on the required stability of the gain. The more stable the gain, the better the purity of the sine wave output.

15.5 Active Element (Op Amp) Impact on the Oscillator

Up to now, it has been assumed that the op amp has an infinite bandwidth and the output is not frequency dependent. In reality, the op amp has many poles, but it has been compensated so that they are dominated by a single pole over the specified bandwidth. Thus $A\beta$, is now frequency dependant through the op amp gain term, A. Equation 15–2 shows this dependance, where a is the maximum open loop gain, ω_a is the dominant pole frequency, and ω is the frequency of the signal. Figure 15–3 graphically depicts the frequency dependence of the op amp gain and phase. The closed loop gain, $A_{CL} = 1/\beta$ does not contain any poles or zeros and its therefore constant over frequency to the point where it impacts the op amp open-loop gain at ω_{3dB}. Here, the signal amplitude is attenuated by 3 dB and the phase shift introduced by the op amp is 45°. The amplitude and phase really begin to change one decade below this point at 0.1 ω_{3dB}, and the phase will continue to shift until it has reached 90° at 10 ω_{3dB}, one decade beyond the 3–dB point. The gain continues to roll off at –20 dB/decade until other poles and zeros come into play. The higher the closed-loop gin, the earlier A_{CL} intercepts the op amp gain.

$$A_{CL} = \frac{A}{1 + A\beta} = \frac{\frac{1}{\beta}}{1 + \frac{1}{A\beta}} = \frac{A_{CLideal}}{1 + \frac{A_{CLideal}}{A_{OL}}} \qquad (15–2)$$

The phase shift contributed by the op amp will impact the performance of the oscillator circuit by lowering the oscillation frequency, and the reduction in A_{CL} can make $A\beta < 1$ and the oscillator will not oscillate.

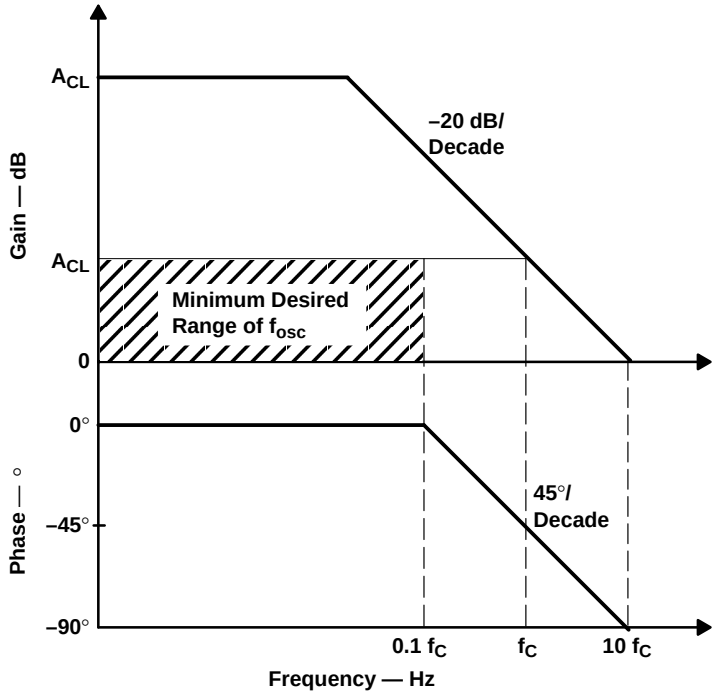

Figure 15–3. Op Amp Frequency Response

Most op amps are compensated and may have more than the 45° of phase shift at ω_{3dB}. The op amp should therefore be chosen with a gain bandwidth that is at least one decade above the oscillation frequency, as shown by the shaded area of Figure 15–3. The Wien bridge requires a gain bandwidth greater than $43\omega_{OSC}$ to maintain the gain and frequency within 10% of the ideal values [2]. Figure 15–4 compares the output distortion versus frequency of an LM328, a TLV247x, and a TLC071 op amp, which have bandwidths of 0.4 MHz and 2.8 MHz, and 10 MHz, respectively, in a Wien bridge oscillator with nonlinear feedback (see Section 15.7.1 for the circuit and transfer function) The oscillation frequency ranged from 16 Hz to 160 kHz. The graph illustrates the importance of choosing the correct op smp for the application. The LM328 achieved a maximum oscillation of 72 kHz and was attenuated more than 75%, while the TLV247x achieved 125 kHz with 18% attenuation. The wide bandwidth of the TLC071 provided a 138 kHz oscillation frequency with a mere 2% attenuation. The op amp must be chosen with the proper bandwidth or the output may oscillate at a frequency well below the design specification.

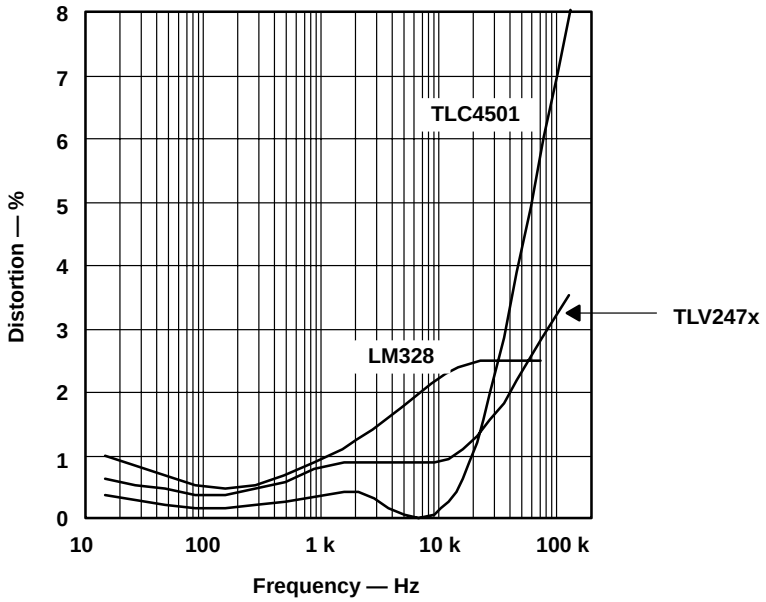

Figure 15–4. Op Amp Bandwidth and Oscillator Output

Care must be taken when using large feedback resistors since they interact with the input capacitance of the op amp to create poles with negative feedback, and both poles and zeros with positive feedback. Large resistor values can move these poles and zeros into the proximity of the oscillation frequency and impact the phase shift [3].

A final consideration is given to the slew-rate limitation of the op amp. The slew rate must be greater than $2\pi V_P f_0$, where V_P is the peak output voltage and f_0 is the oscillation frequency, or distortion of the output signal will result.

15.6 Analysis of the Oscillator Operation (Circuit)

Oscillators are created using various combinations of positive and negative feedback. Figure 15–5 shows the basic negative feedback amplifier block diagram with a positive feedback loop added. When positive and negative feedback are used, the gain of the negative feedback path is combined into one gain term (representing the closed loop gain) and Figure 15–5 reduces to Figure 15–1. The positive feedback network is then represented by $\beta = \beta_2$ and subsequent analysis is simplified. When negative feedback is used, then the positive feedback loop can be ignored since β_2 is 0. The case of positive and negative feedback combined is covered here since the negative feedback case was reviewed in Chapters 5 and 6.

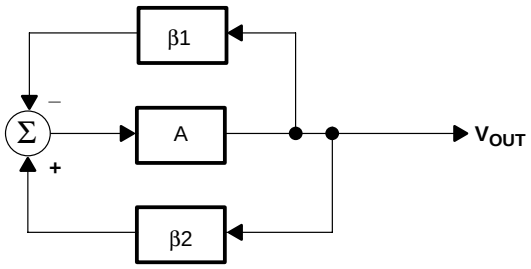

Figure 15–5. Block Diagram of an Oscillator: a) Positive and Negative Feedback Loops, and b) Simplified Diagram w

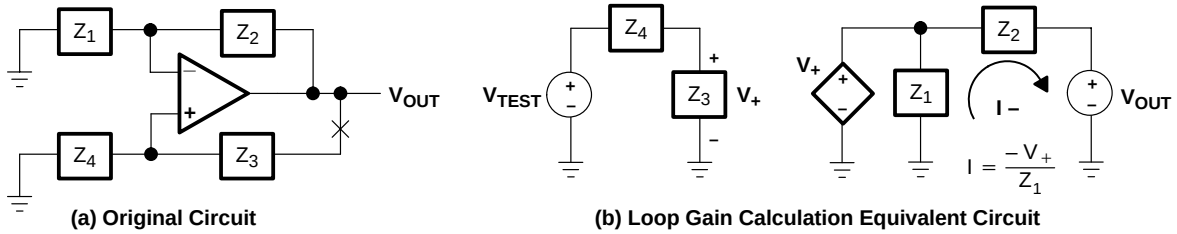
A general form of an op amp with positive and negative feedback is shown in Figure 15–6a. The first step is to break the loop at some point without altering the gain of the circuit. The positive feedback loop is broken at the point marked with an X. A test signal (V_{TEST}) is applied to the broken loop and the resulting output voltage (V_{OUT}) is measured with the equivalent circuit shown in Figure 15–6b.



(a) Original Circuit **(b) Loop Gain Calculation Equivalent Circuit**

Figure 15–6. Amplifier with Positive and Negative Feedback

V_+ is calculated first in Equation 15–3, and then is treated as an input signal to a noninverting amplifier, resulting in Equation 15–4. Equation 15–3 is substituted for V_+ into Equation 15–4 to get the transfer function in Equation 15–5. The actual circuit elements are then substituted for each impedance and the equation is simplified. These equations are valid when the op amp open-loop gain is large and the oscillation frequency is < 0.1 ω_{3dB}.

$$V_+ = V_{TEST}\left(\frac{Z_4}{Z_3 + Z_4}\right) \tag{15–3}$$

$$V_{OUT} = V_+\left(\frac{Z_1 + Z_2}{Z_1}\right) \tag{15–4}$$

$$\frac{V_{OUT}}{V_{TEST}} = \left(\frac{Z_3}{Z_3 + Z_4}\right)\left(\frac{Z_1 + Z_2}{Z_1}\right) \tag{15–5}$$

Phase shift oscillators generally use negative feedback, so the positive feedback factor (β_2) becomes zero. Oscillator circuits such as the Wien bridge use both negative (β_1) and positive (β_2) feedback to achieve a constant state of oscillation. This circuit is analyzed in detain in Section 15.7.1 using Equation 15–5.

15.7 Sine Wave Oscillator Circuits

There are many types of sine wave oscillator circuits and variations of these circuits — the choice depends upon the frequency and the desired purity of the output waveform. The focus of this section is on the more prominent oscillator circuits: Wien bridge, phase shift, and quadrature. The transfer function is derived for each case using the techniques described in Section 15.6 of this chapter and in Chapters 3, 5, and 6.

15.7.1 Wien Bridge Oscillator

The Wien bridge is one of the simplest and best known oscillators and is used extensively in circuits for audio applications. Figure 15–7 shows the basic Wien bridge circuit configuration. This circuit has only a few components and good frequency stability. The major drawback of the circuit is that the output amplitude is at the rails, saturating the op amp output transistors and causing high output distortion. Taming this distortion is more of a challenge than getting the circuit to oscillate. There are a couple of ways to minimize this effect, which will be covered later. It is now time to analyze this circuit and come up with the transfer function.

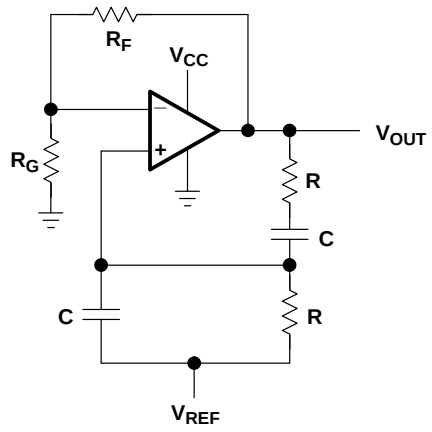


Figure 15–7. Wien Bridge Circuit Schematic

The Wien bridge circuit is of the form that is detailed in Section 15.6. The transfer function for the circuit is created using the technique described in that section. It is readily apparent that $Z_1 = R_G$, $Z_2 = R_F$, $Z_3 = (R_1 + 1/sC_1)$ and $Z_4 = (R_2 \| 1/sC_2)$. The loop is broken between

the output and Z_1, V_{TEST} is applied to Z_1, and V_{OUT} is calculated. The positive feedback voltage, V_+, is calculated first in Equations 15–6 through 15–8. Equation 15–6 shows the simple voltage divider at the noninverting input. Each term is then multiplied by (R_2C_2s + 1) and divided by R_2 to get Equation 15–7.

$$V_+ = V_{TEST}\left(\frac{Z_4}{Z_3 + Z_4}\right) = V_{TEST}\left[\frac{\left(\frac{R_2}{R_2C_2s+1}\right)}{\left(\frac{R_2}{R_2C_2s+1}\right) + \left(R_1 + \frac{1}{C_1s}\right)}\right] \quad (15–6)$$

$$\frac{V_+}{V_{TEST}} = \frac{1}{1 + R_1C_2S + \frac{R_1}{R_2} + \frac{1}{R_2C_1s} + \frac{C_2}{C_1}} \quad (15–7)$$

Substitute $s = j\omega_0$, where ω_0 is the oscillation frequency, $\omega_1 = 1/R_1C_2$, and $\omega_2 = 1/R_2C_1$ to get Equation 15–8.

$$\frac{V_+}{V_{TEST}} = \frac{1}{1 + \frac{R_1}{R_2} + \frac{C_2}{C_1} + j\left(\frac{\omega_0}{\omega_1} - \frac{\omega_2}{\omega_0}\right)} \quad (15–8)$$

Some interesting relationships now become apparent. The capacitor in the zero, represented by ω_1, and the capacitor in the pole, represented by ω_2, must each contribute 90° of phase shift toward the 180° required for oscillation at ω_0. This requires that $C_1 = C_2$ and $R_1 = R_2$. Setting ω_1 and ω_2 equal to ω_0 cancels the frequency terms, ideally removing any change in amplitude with frequency since the pole and zero negate one another. An overall feedback factor of $\beta = 1/3$ is the result (Equation 15–9).

$$\frac{V_+}{V_{TEST}} = \frac{1}{1 + \frac{R}{R} + \frac{C}{C} + j\left(\frac{\omega_0}{\omega} - \frac{\omega}{\omega_0}\right)} = \frac{1}{3 + j\left(\frac{\omega_0}{\omega_0} - \frac{\omega_0}{\omega_0}\right)} = \frac{1}{3} \quad (15–9)$$

The gain of the negative feedback portion, A, of the circuit must then be set such that $|A\beta| = 1$, requiring A = 3. R_F must be set to twice the value of R_G to satisfy the condition. The op amp in Figure 15–7 is single supply, so a dc reference voltage, V_{REF}, must be applied to bias the output for full-scale swing and minimal distortion. Applying V_{REF} to the positive input through R_2 restricts dc current flow to the negative feedback leg of the circuit. V_{REF} was set at 0.833V to bias the output at the midrail of the single supply, rail-to-rail input and output amplifier, or 2.5 V. See Cahpter 4 for details on dc biasing single-supply op amps. V_{REF} is shorted to ground for split supply applications.

The final circuit is shown in Figure 15–8, with component values selected to provide an oscillation frequency of $\omega_0 = 2\pi f_0$, where $f_0 = 1/(2\pi RC) = 15.9$ kHz. The circuit oscillated at 1.57 kHz due to slightly varying component values with 2% distortion. This high value is due to the extensive clipping of the output signal at both supply rails, producing several

large odd and even harmonics. The feedback resistor was then adjusted ±1%. Figure 15–9 shows the output voltage waveforms. The distortion grew as the saturation increased with increasing R_F, and oscillations ceased when R_F was decreased by more than 0.8%.

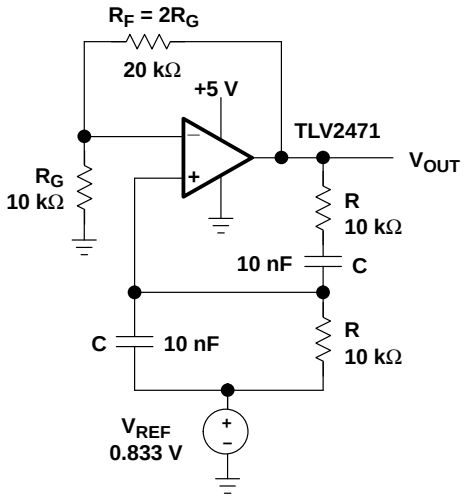

Figure 15–8. Final Wien Bridge Oscillator Circuit

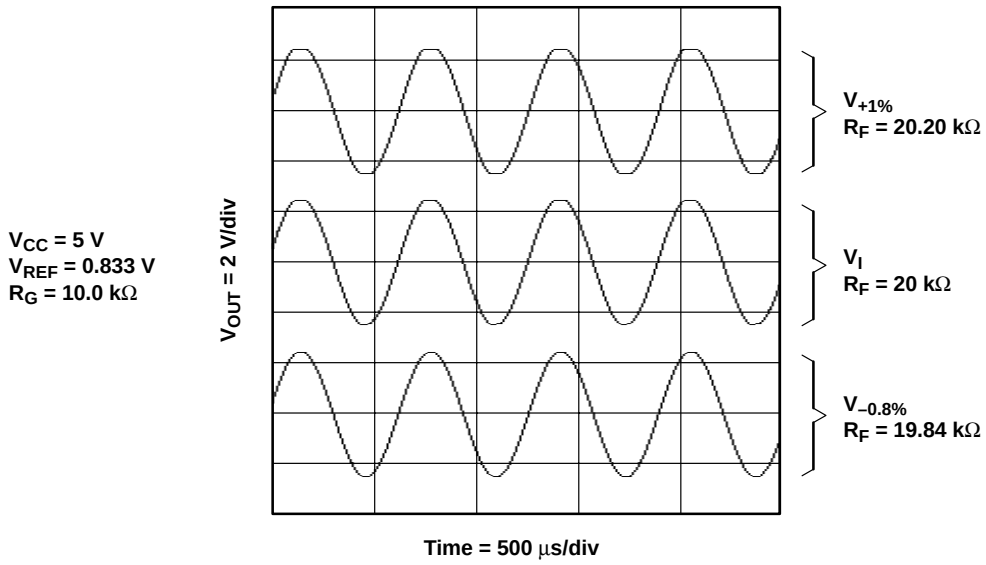

Figure 15–9. Wien Bridge Output Waveforms

Applying nonlinear feedback can minimize the distortion inherent in the basic Wien bridge circuit. A nonlinear component such as an incandescent lamp can be substituted into

the circuit for R_G as shown in Figure 15–10. The lamp resistance, R_{LAMP}, is nominally selected as half the feedback resistance, R_F, at the lamp current established by R_F and R_{LAMP}. When the power is first applied the lamp is cool and its resistance is small, so the gain is large (> 3). The current heats up the filament and the resistance increases, lowering the gain. The nonlinear relationship between the lamp current and resistance keeps output voltage changes small. Figure 15–11 shows the output of this amplifier with a distortion of 1% for f_{OSC} = 1.57 kHz. The distortion for this variation is reduced over the basic circuit by avoiding hard saturation of the op amp transistors.

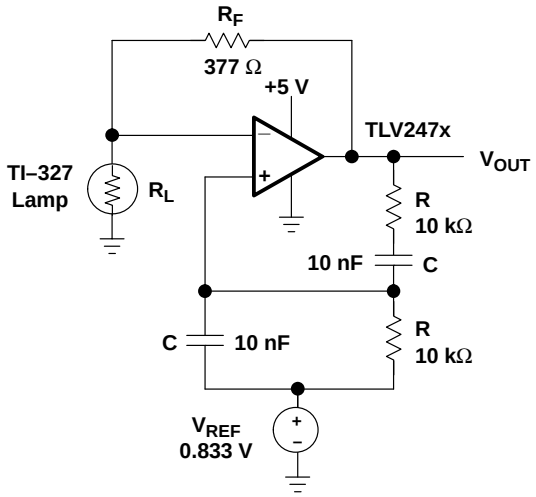

Figure 15–10. Wien Bridge Oscillator with Nonlinear Feedback

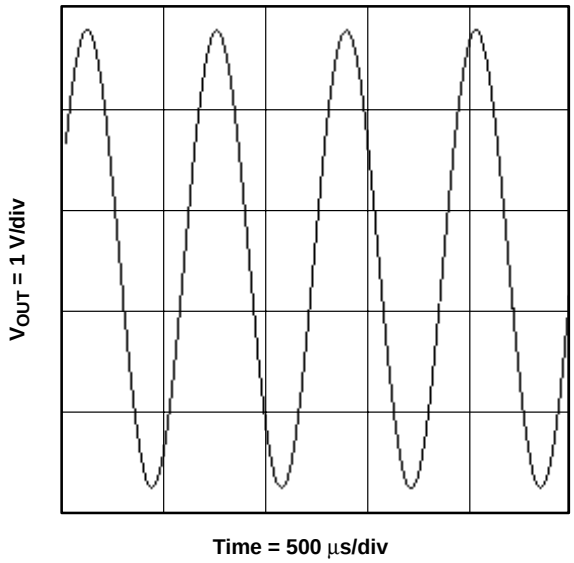

Figure 15–11. Output of the Circuit in Figure 15–10

The impedance of the lamp is mostly due to thermal effects. The output amplitude is then very temperature sensitive and will tend to drift. The gain must be set higher than 3 to compensate for any temperature variations, which increases the distortion in the circuit [4]. This type of circuit is useful when the temperature does not fluctuate over a wide range or when used in conjunction with an amplitude limiting circuit.

The lamp has an effective low frequency thermal time constant, $t_{thermal}$ (4). As f_{OSC} approaches $t_{thermal}$, distortion is greatly increased. Several lamps can be placed in series to increase $t_{thermal}$ and reduce distortion. The drawbacks are that the time required for oscillations to stabilize is increased and the output amplitude is reduced.

An automatic gain control (AGC) circuit must be used when neither of the two previous circuits yield low distortion. A typical Wien bridge oscillator with an AGC circuit is shown in Figure 15–12, with the output waveform of the circuit shown in Figure 15–13. The AGC is used to stabilize the magnitude of the sinusoidal output to an optimum gain level. The JFET serves as the AGC element, providing excellent control because of the wide range of the drain to source resistance (R_{DS}), which is controlled by the gate voltage. The JFET gate voltage is 0 V when the power is applied, and the JFET turns on with low R_{DS}. This places $R_{G2}+R_S+R_{DS}$ in parallel with R_{G1}, raising the gain to 3.05, and oscillations begin and gradually build up. As the output voltage gets large, the negative swing turns the diode on and the sample is stored on C_1, which provides a dc potential to the gate of Q_1. Resistor R_1 limits the current and establishes the time constant for charging C_1, which should be much greater than f_{OSC}. When the output voltage drifts high, R_{DS} increases, lowering the gain to a minimum of 2.87 ($1+R_F/R_{G1}$). The output stabilizes when the gain reaches 3. The distortion of the AGC is 0.8%, which is due to slight clipping at the positive rail.

The circuit of Figure 15–12 is biased with V_{REF} for a single-supply amplifier. A zener diode can be placed in series with D1 to limit the positive swing of the output and reduce distortion. A split supply can be easily implemented by grounding all points connected to V_{REF}. There are a wide variety of Wien bridge variations that exist to more precisely control the amplitude and allow selectable or even variable oscillation frequencies. Some circuits use diode limiting in place of a nonlinear feedback component. The diodes reduce the distortion by providing a soft limit for the output voltage.

15.7.2 Phase Shift Oscillator, Single Amplifier

Phase shift oscillators have less distortion than the Wien bridge oscillator, coupled with good frequency stability. A phase shift oscillator can be built with one op amp as shown in figure 15–14. Three RC sections are cascaded to get the steep $d\phi/d\omega$ slope as described in Section 15–3 to get a stable oscillation frequency. Any less and the oscillation frequency is high and interferes with the op amp BW limitations.

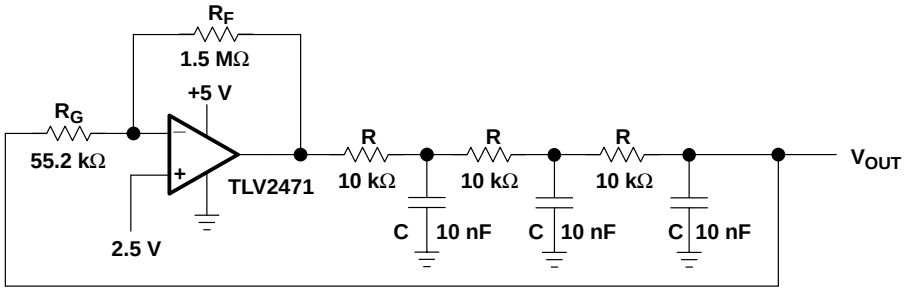

Figure 15–14. Phase Shift Oscillator (Single Op Amp)

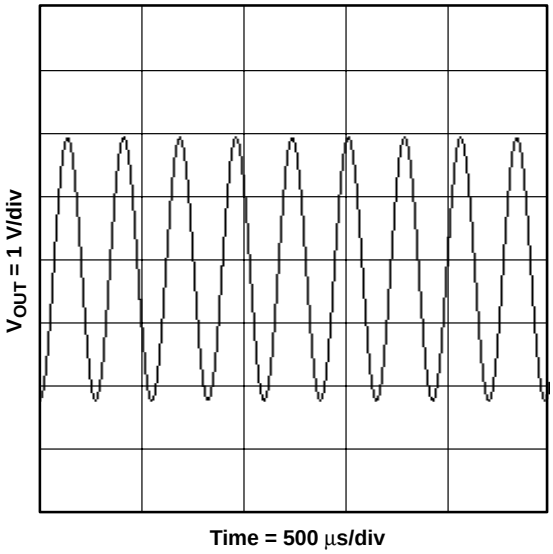

Figure 15–15. Output of the Circuit in Figure 15–14

$$A\beta = A\left(\frac{1}{RCs + 1}\right)^3 \quad (15–10)$$

The normal assumption is that the phase shift sections are independent of each other. Then Equation 15–10 is written. The loop phase shift is –180° when the phase shift of each section is –60°, and this occurs when $\omega = 2\pi f = 1.732/RC$ because the tangent of 60° = 1.732. The magnitude of β at this point is $(1/2)^3$, so the gain, A, must be equal to 8 for the system gain to be equal to one.

The oscillation frequency with the component values shown in Figure 15–14 is 3.76 kHz rather than the calculated oscillation frequency of 2.76 kHz as shown in Figure 15–14. Also, the gain required to start oscillation is 27 rather than the calculated gain of 8. These

discrepancies are partially due to component variations, but the biggest contributing factor is the incorrect assumption that the RC sections do not load each other. This circuit configuration was very popular when active components were large and expensive. But now op amps are inexpensive, small, and come four in a package, so the single op amp phase shift oscillator is losing popularity. The output distortion is a low 0.46%, considerably less than the Wein bridge circuit without amplitude stabilization.

15.7.3 Phase Shift Oscillator, Buffered

The buffered phase shift oscillator is much improved over the unbuffered version, the cost being a higher component count. The buffered phase shift oscillator is shown in Figure 15–16 and the resulting output waveform in Figure 15–17. The buffers prevent the RC sections from loading each other, hence the buffered phase shift oscillator performs closer to the calculated frequency and gain. The gain setting resistor, R_G, loads the third RC section. If the fourth buffer in a quad op amp buffers this RC section, the performance becomes ideal. Low-distortion sine waves can be obtained from either phase shift oscillator design, but the purest sine wave is taken from the output of the last RC section. This is a high-impedance node, so a high impedance input is mandated to prevent loading and frequency shifting with load variations.

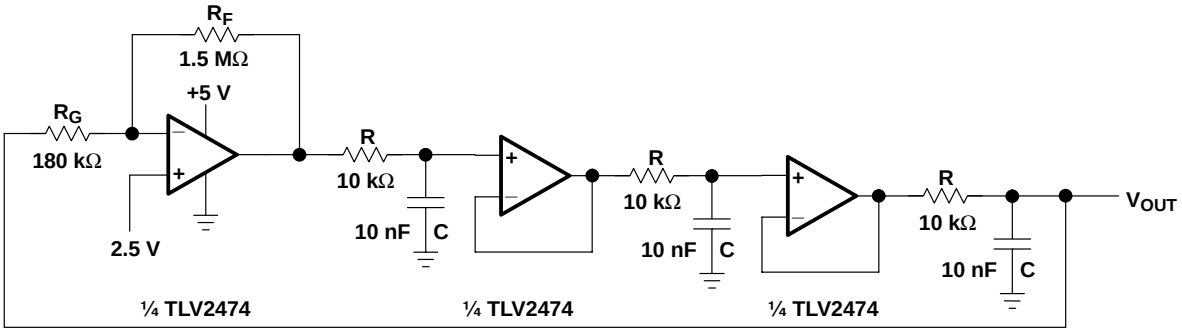

Figure 15–16. Phase Shift Oscillator, Buffered

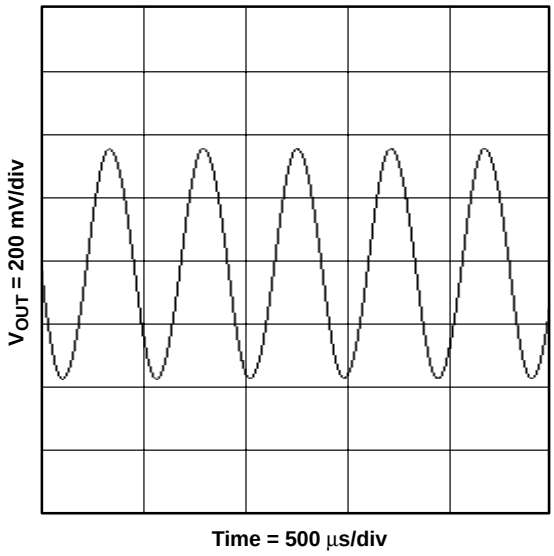

Figure 15–17. Output of the Circuit Figure 15–16

15.7.4 Bubba Oscillator

The bubba oscillator in Figure 15–18 is another phase shift oscillator, but it takes advantage of the quad op amp package to yield some unique advantages. Four RC sections require 45° phase shift per section, so this oscillator has an excellent $d\phi/dt$ resulting in minimized frequency drift. The RC sections each contribute 45° phase shift, so taking outputs from alternate sections yields low impedance quadrature outputs. When an output is taken from each op amp, the circuit delivers four 45° phase shifted sine waves. The loop equation is given in Equation 15–11. When $\omega = 1/RCs$, Equation 15–11 reduces to Equations 15–12 and 15–13.

$$A\beta = A\left(\frac{1}{RCs + 1}\right)^4 \tag{15–11}$$

$$|\beta| = \left|\left(\frac{1}{j + 4}\right)^4 = \frac{1}{\sqrt{2}^4} = \frac{1}{4}\right| \tag{15–12}$$

$$\phi = \tan^{-1}(1) = 45^\circ \tag{15–13}$$

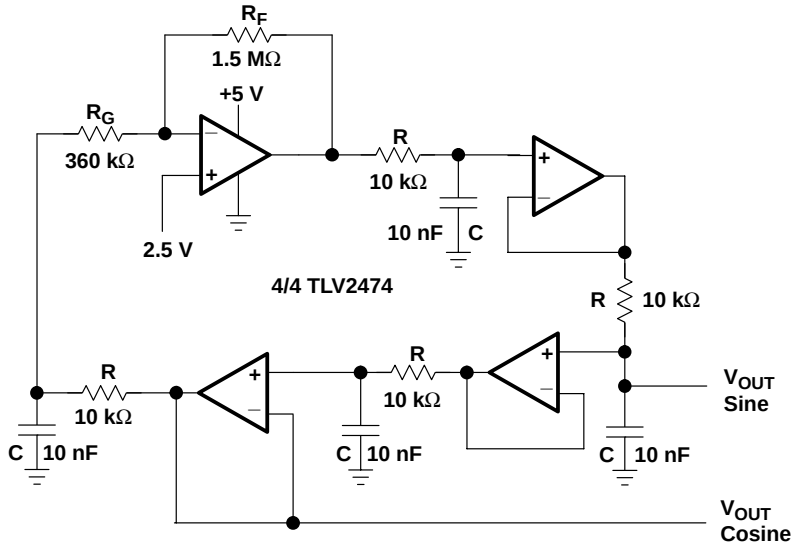

Figure 15–18. Bubba Oscillator

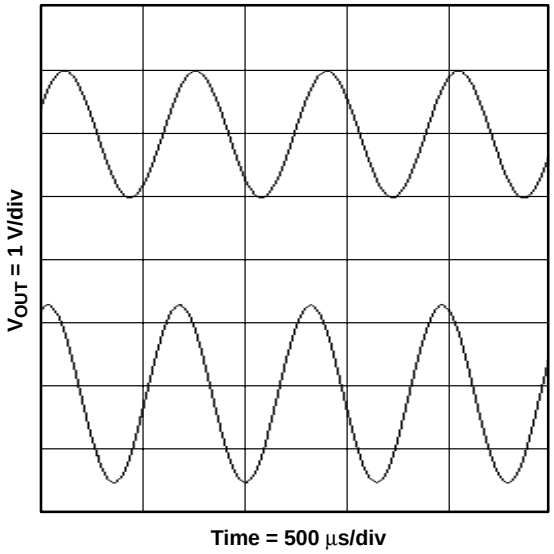

Figure 15–19. Output of the Circuit in Figure 15–18.

The gain, A, must equal 4 for oscillation to occur. The test circuit oscillated at 1.76 kHz rather than the ideal frequency of 1.72 kHz when the gain was 4.17 rather than the ideal gain 4. The output waveform is shown in Figure 15–19. Distortion is 1% for $V_{OUTSINE}$ and 0.1% for $V_{OUTCOSINE}$. With low gain, A, and low bias current op amps, the gain setting

resistor, R_G, does not load the last RC section, thus ensuring oscillator frequency accuracy. Very low distortion sine waves can be obtained from the junction of R and R_G. When low-distortion sine waves are required at all outputs, the gain should be distributed between all of the op amps. The noninverting input of the gain op amp is biased at 0.5 V to set the quiescent output voltage at 2.5 V for single supply operation, and should be ground for split supply op amps. Gain distribution requires biasing of the other op amps, but it has no effect on the oscillator frequency.

15.7.5 Quadrature Oscillator

The quadrature oscillator shown in Figure 15–20 is another type of phase shift oscillator, but the three RC sections are configured so each section contributes 90° of phase shift. This provides both sine and cosine waveform outputs (the outputs are quadrature, or 90° apart), which is a distinct advantage over other phase shift oscillators. The idea of the quadrature oscillator is to use the fact that the double integral of a sine wave is a negative sine wave of the same frequency and phase. The phase of the second integrator is then inverted and applied as positive feedback to induce oscillation [6].

The loop gain is calculated in Equation 15–14. When $R_1C_1 = R_2C_2 = R_3C_3$, Equation 15–14 reduces to Equation 15–15. When $\omega = 1/RC$, Equation 15–14 reduces to $1\angle -180$, so oscillation occurs at $\omega = 2\pi f = 1/RC$. The test circuit oscillated at 1.65 kHz rather than the calculated 1.59 kHz, as shown in Figure 15–21. This discrepancy is attributed to component variations. Both outputs have relatively high distortion that can be reduced with a gain stabilizing circuit. The sine output had 0.846% distortion and the cosine output had 0.46% distortion. Adjusting the gain can increase the amplitudes. The cost is bandwidth.

$$A\beta = A\left(\frac{1}{R_1C_1s}\right)\left(\frac{R_3C_3s + 1}{R_3C_3s\left(R_2C_2s + 1\right)}\right) \tag{15–14}$$

$$A\beta = A\left(\frac{1}{RCs}\right)^2 \tag{15–15}$$

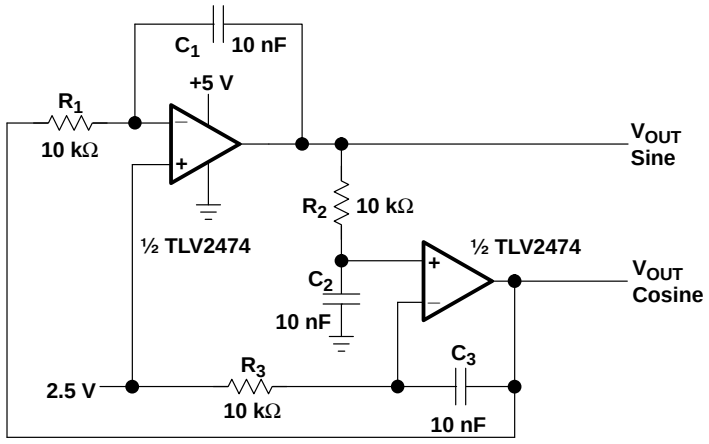

Figure 15–20. Quadrature Oscillator

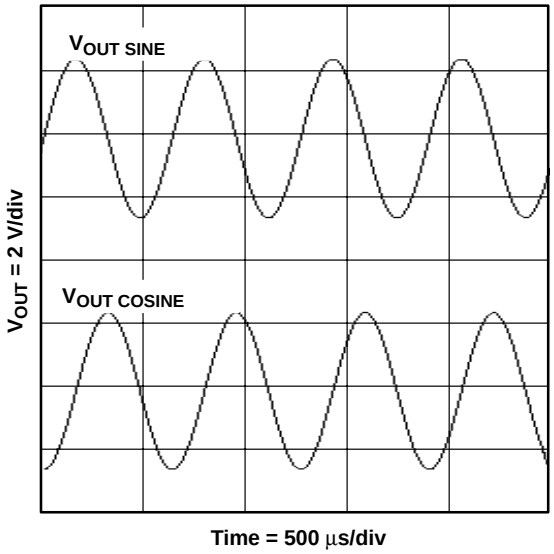

Figure 15–21. Output of the Circuit in Figure 15–20

15.7.6 Conclusion

Op amp oscillators are restricted to the lower end of the frequency spectrum because they do not have the required bandwidth to achieve low phase shift at high frequencies. The new current-feedback op amps have a much greater bandwidth than the voltage-feedback op amps, but are very difficult to use in oscillator circuits because of their sensitivity to feedback capacitance. Voltage-feedback op amps are limited to tens of Hz (at the most!) because of their low frequency rolloff. The bandwidth is reduced when op amps are cascaded due to the multiple contribution of phase shift.

The Wien bridge oscillator has few parts and good frequency stability, but the basic circuit has a high output distortion. AGC improves the distortion considerably, particularly at the lower frequency range. Nonlinear feedback offers the best performance over the mid and upper frequency ranges. The phase shift oscillator has lower output distortion and, without buffering, requires a high gain, which limits the use to very low frequencies. Decreasing cost of op amps and components has reduced the popularity of the phase shift oscillators. The quadrature oscillator only requires two op amps, has reasonable distortion, and offers both sine and cosine waveforms. The drawback is the low amplitude, which may require a higher gain and a reduction in bandwidth, or an additional gain stage.

May your oscillators always oscillate, and your amplifiers always amplify.

Chapter 16

Active Filter Design Techniques

Thomas Kugelstadt

16.1 Introduction

What is a filter?

> *A filter is a device that passes electric signals at certain frequencies or frequency ranges while preventing the passage of others*. — Webster.

Filter circuits are used in a wide variety of applications. In the field of telecommunication, band-pass filters are used in the audio frequency range (0 kHz to 20 kHz) for modems and speech processing. High-frequency band-pass filters (several hundred MHz) are used for channel selection in telephone central offices. Data acquisition systems usually require anti-aliasing low-pass filters as well as low-pass noise filters in their preceding signal conditioning stages. System power supplies often use band-rejection filters to suppress the 60-Hz line frequency and high frequency transients.

In addition, there are filters that do not filter any frequencies of a complex input signal, but just add a linear phase shift to each frequency component, thus contributing to a constant time delay. These are called all-pass filters.

At high frequencies (> 1 MHz), all of these filters usually consist of passive components such as inductors (L), resistors (R), and capacitors (C). They are then called LRC filters.

In the lower frequency range (1 Hz to 1 MHz), however, the inductor value becomes very large and the inductor itself gets quite bulky, making economical production difficult.

In these cases, active filters become important. Active filters are circuits that use an operational amplifier (op amp) as the active device in combination with some resistors and capacitors to provide an LRC-like filter performance at low frequencies (Figure 16–1).

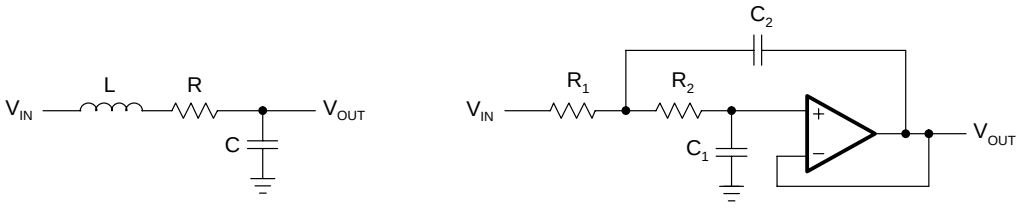

Figure 16–1. Second-Order Passive Low-Pass and Second-Order Active Low-Pass

This chapter covers active filters. It introduces the three main filter optimizations (Butterworth, Tschebyscheff, and Bessel), followed by five sections describing the most common active filter applications: low-pass, high-pass, band-pass, band-rejection, and all-pass filters. Rather than resembling just another filter book, the individual filter sections are written in a cookbook style, thus avoiding tedious mathematical derivations. Each section starts with the general transfer function of a filter, followed by the design equations to calculate the individual circuit components. The chapter closes with a section on practical design hints for single-supply filter designs.

16.2 Fundamentals of Low-Pass Filters

The most simple low-pass filter is the passive RC low-pass network shown in Figure 16–2.

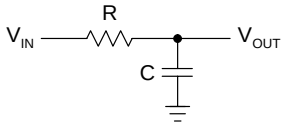

Figure 16–2. First-Order Passive RC Low-Pass

Its transfer function is:

$$A(s) = \frac{\frac{1}{RC}}{s + \frac{1}{RC}} = \frac{1}{1 + sRC}$$

where the complex frequency variable, $s = j\omega+\sigma$, allows for any time variable signals. For pure sine waves, the damping constant, σ, becomes zero and $s = j\omega$.

For a normalized presentation of the transfer function, *s* is referred to the filter's corner frequency, or –3 dB frequency, $\omega_{C,}$ and has these relationships:

$$s = \frac{s}{\omega_C} = \frac{j\omega}{\omega_C} = j\frac{f}{f_C} = j\Omega$$

With the corner frequency of the low-pass in Figure 16–2 being $f_C = 1/2\pi RC$, *s* becomes $s = sRC$ and the transfer function A(s) results in:

$$A(s) = \frac{1}{1 + s}$$

The magnitude of the gain response is:

$$|A| = \frac{1}{\sqrt{1 + \Omega^2}}$$

For frequencies $\Omega >> 1$, the rolloff is 20 dB/decade. For a steeper rolloff, ***n*** filter stages can be connected in series as shown in Figure 16–3. To avoid loading effects, op amps, operating as impedance converters, separate the individual filter stages.

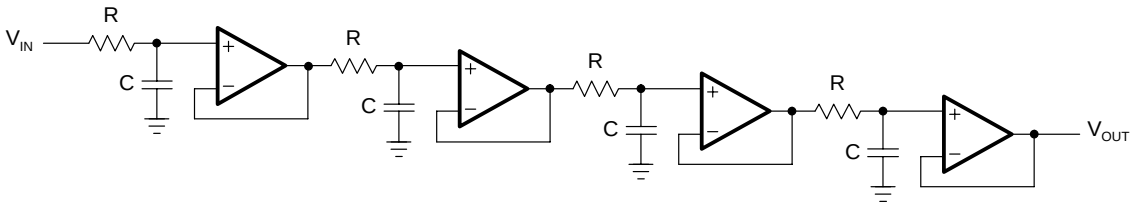

Figure 16–3. Fourth-Order Passive RC Low-Pass with Decoupling Amplifiers

The resulting transfer function is:

$$A(s) = \frac{1}{(1 + \alpha_1 s)(1 + \alpha_2 s) \ldots (1 + \alpha_n s)}$$

In the case that all filters have the same cut-off frequency, f_C, the coefficients become

$\alpha_1 = \alpha_2 = \ldots \alpha_n = \alpha = \sqrt{\sqrt{2} - 1}$, and f_C of each partial filter is $1/\alpha$ times higher than f_C of the overall filter.

Figure 16–4 shows the results of a fourth-order RC low-pass filter. The rolloff of each partial filter (Curve 1) is –20 dB/decade, increasing the roll-off of the overall filter (Curve 2) to 80 dB/decade.

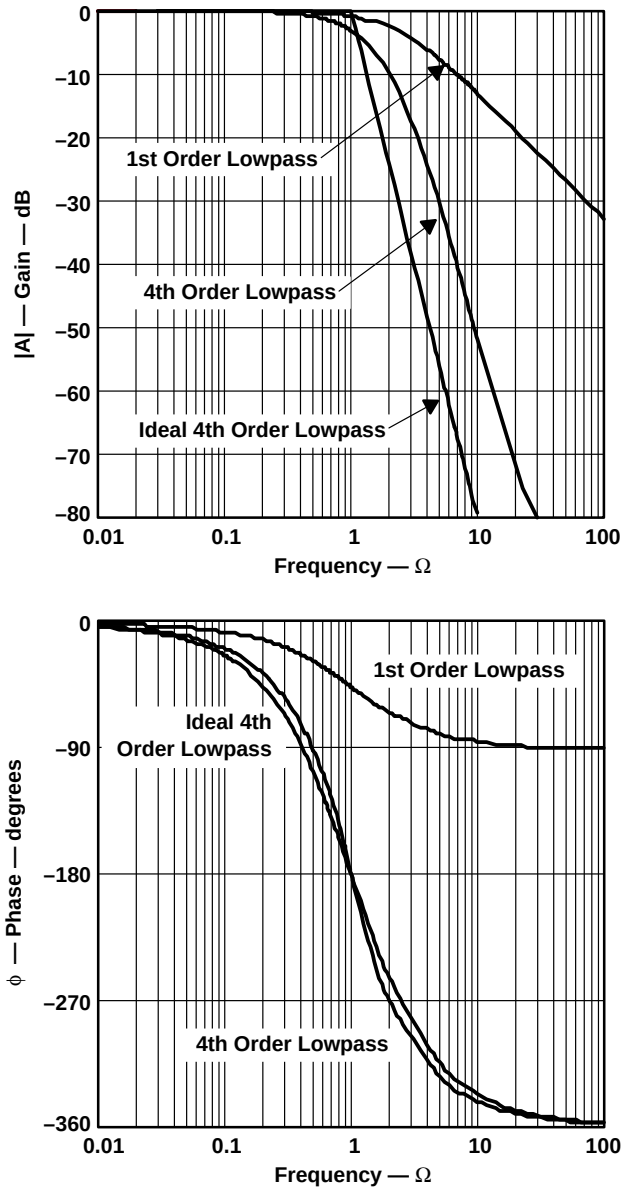
>
> **Filter response graphs plot gain versus the normalized frequency axis Ω ($\Omega = f/f_C$).**



Note: Curve 1: 1st-order partial low-pass filter, Curve 2: 4th-order overall low-pass filter, Curve 3: Ideal 4th-order low-pass filter

Figure 16–4. Frequency and Phase Responses of a Fourth-Order Passive RC Low-Pass Filter

The corner frequency of the overall filter is reduced by a factor of $\alpha \approx 2.3$ times versus the –3 dB frequency of partial filter stages.

In addition, Figure 16–4 shows the transfer function of an ideal fourth-order low-pass function (Curve 3).

In comparison to the ideal low-pass, the RC low-pass lacks in the following characteristics:

- The passband gain varies long before the corner frequency, f_C, thus amplifying the upper passband frequencies less than the lower passband.
- The transition from the passband into the stopband is not sharp, but happens gradually, moving the actual 80-dB roll off by 1.5 octaves above f_C.
- The phase response is not linear, thus increasing the amount of signal distortion significantly.

The gain and phase response of a low-pass filter can be optimized to satisfy *one* of the following three criteria:

1) A maximum passband flatness,
2) An immediate passband-to-stopband transition,
3) A linear phase response.

For that purpose, the transfer function must allow for complex poles and needs to be of the following type:

$$A(s) = \frac{A_0}{(1 + a_1 s + b_1 s^2)(1 + a_2 s + b_2 s^2) \ldots (1 + a_n s + b_n s^2)} = \frac{A_0}{\prod_i (1 + a_i s + b_i s^2)}$$

where A_0 is the passband gain at dc, and a_i and b_i are the filter coefficients.

Since the denominator is a product of quadratic terms, the transfer function represents a series of cascaded second-order low-pass stages, with a_i and b_i being positive real coefficients. These coefficients define the complex pole locations for each second-order filter stage, thus determining the behavior of its transfer function.

The following three types of predetermined filter coefficients are available listed in table format in Section 16.9:

- The Butterworth coefficients, optimizing the passband for maximum flatness
- The Tschebyscheff coefficients, sharpening the transition from passband into the stopband
- The Bessel coefficients, linearizing the phase response up to f_C

The transfer function of a passive RC filter does not allow further optimization, due to the lack of complex poles. The only possibility to produce conjugate complex poles using pas-

sive components is the application of LRC filters. However, these filters are mainly used at high frequencies. In the lower frequency range (< 10 MHz) the inductor values become very large and the filter becomes uneconomical to manufacture. In these cases active filters are used.

Active filters are RC networks that include an active device, such as an operational amplifier (op amp).

Section 16.3 shows that the products of the RC values and the corner frequency must yield the predetermined filter coefficients a_i and b_i, to generate the desired transfer function.

The following paragraphs introduce the most commonly used filter optimizations.

16.2.1 Butterworth Low-Pass FIlters

The Butterworth low-pass filter provides maximum passband flatness. Therefore, a Butterworth low-pass is often used as anti-aliasing filter in data converter applications where precise signal levels are required across the entire passband.

Figure 16–5 plots the gain response of different orders of Butterworth low-pass filters versus the normalized frequency axis, Ω ($\Omega = f / f_C$); the higher the filter order, the longer the passband flatness.

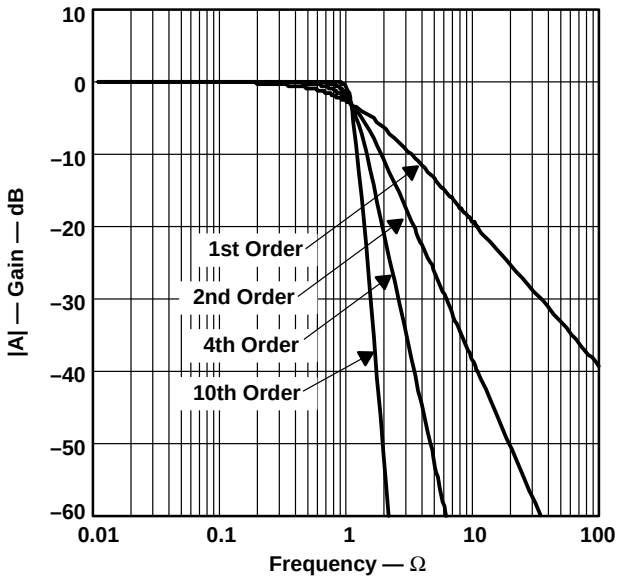


Figure 16–5. Amplitude Responses of Butterworth Low-Pass Filters

16.2.2 Tschebyscheff Low-Pass Filters

The Tschebyscheff low-pass filters provide an even higher gain rolloff above f_C. However, as Figure 16–6 shows, the passband gain is not monotone, but contains ripples of constant magnitude instead. For a given filter order, the higher the passband ripples, the higher the filter's rolloff.

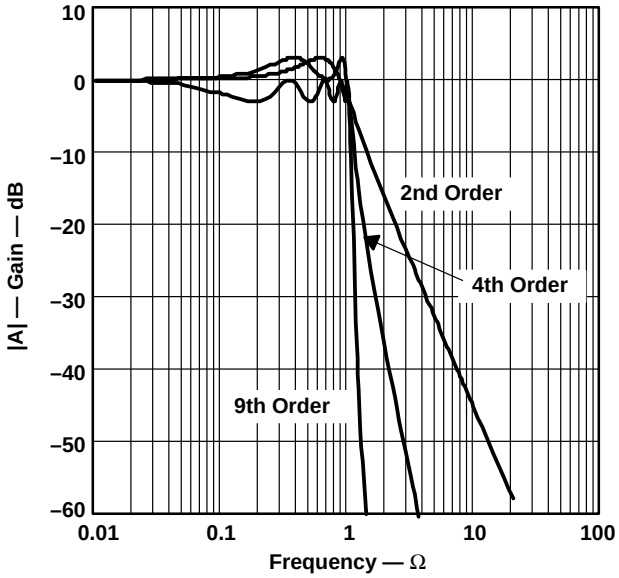

Figure 16–6. Gain Responses of Tschebyscheff Low-Pass Filters

With increasing filter order, the influence of the ripple magnitude on the filter rolloff diminishes.

Each ripple accounts for one second-order filter stage. Filters with even order numbers generate ripples above the 0-dB line, while filters with odd order numbers create ripples below 0 dB.

Tschebyscheff filters are often used in filter banks, where the frequency content of a signal is of more importance than a constant amplification.

16.2.3 Bessel Low-Pass Filters

The Bessel low-pass filters have a linear phase response (Figure 16–7) over a wide frequency range, which results in a constant group delay (Figure 16–8) in that frequency range. Bessel low-pass filters, therefore, provide an optimum square-wave transmission behavior. However, the passband gain of a Bessel low-pass filter is not as flat as that of the Butterworth low-pass, and the transition from passband to stopband is by far not as sharp as that of a Tschebyscheff low-pass filter (Figure 16–9).

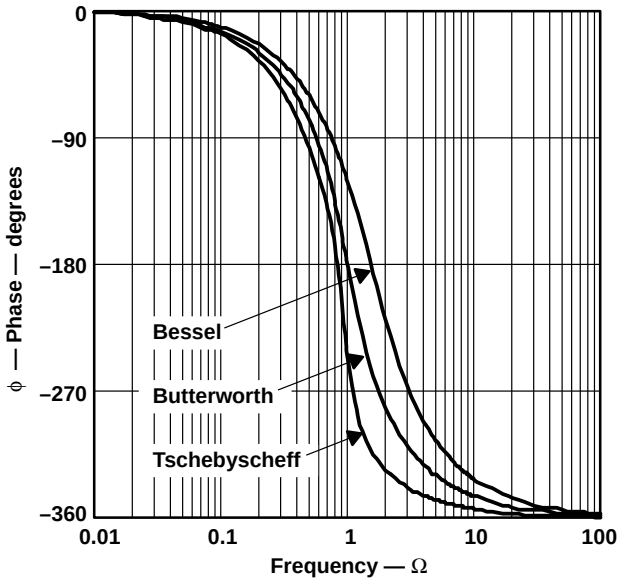

Figure 16–7. Comparison of Phase Responses of Fourth-Order Low-Pass Filters

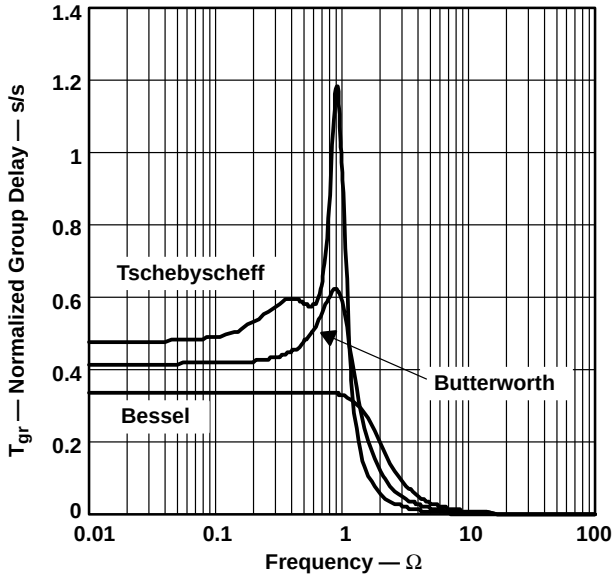

Figure 16–8. Comparison of Normalized Group Delay (Tgr) of Fourth-Order Low-Pass Filters

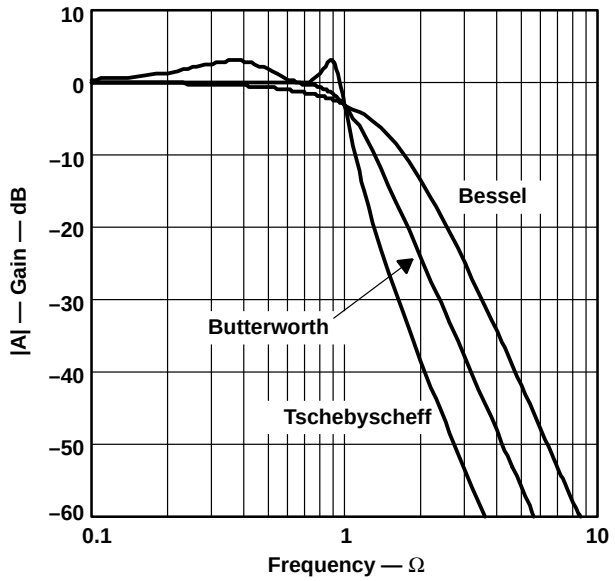

Figure 16–9. Comparison of Gain Responses of Fourth-Order Low-Pass Filters

16.2.4 Quality Factor *Q*

The quality factor *Q* is an equivalent design parameter to the filter order *n.* Instead of designing an n^{th} order Tschebyscheff low-pass, the problem can be expressed as designing a Tschebyscheff low-pass filter with a certain Q.

For band-pass filters, Q is defined as the ratio of the mid frequency, $f_{m,}$ to the bandwidth at the two –3 dB points:

$$Q = \frac{f_m}{(f_2 - f_1)}$$

For low-pass and high-pass filters, Q represents the pole quality and is defined as:

$$Q = \frac{\sqrt{b_i}}{a_i}$$

High Qs can be graphically presented as the distance between the 0-dB line and the peak point of the filter's gain response. An example is given in Figure 16–10, which shows a tenth-order Tschebyscheff low-pass filter and its five partial filters with their individual Qs.

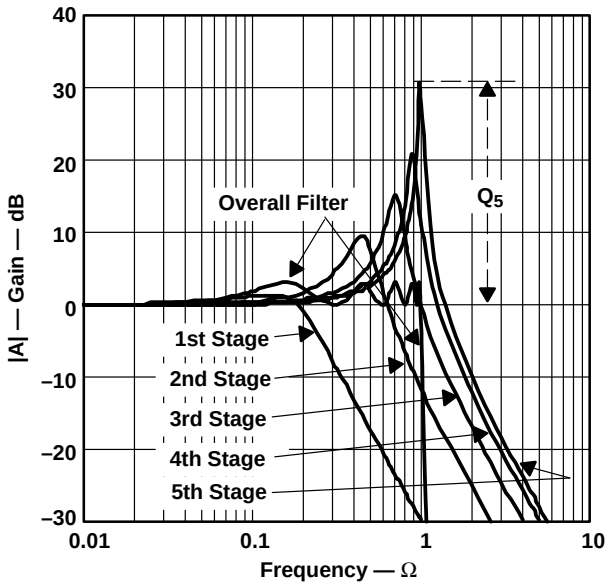

Figure 16–10. Graphical Presentation of Quality Factor Q on a Tenth-Order Tschebyscheff Low-Pass Filter with 3-dB Passband Ripple

The gain response of the fifth filter stage peaks at 31 dB, which is the logarithmic value of Q_5:

$$Q_5[\text{dB}] = 20 \cdot \log Q_5$$

Solving for the numerical value of Q5 yields:

$$Q_5 = 10^{\frac{31}{20}} = 35.48$$

which is within 1% of the theoretical value of Q = 35.85 given in Section 16.9, Table 16–9, last row.

The graphical approximation is good for Q > 3. For lower Qs, the graphical values differ from the theoretical value significantly. However, only higher Qs are of concern, since the higher the Q is, the more a filter inclines to instability.

16.2.5 Summary

The general transfer function of a low-pass filter is :

$$A(s) = \frac{A_0}{\prod_i \left(1 + a_i s + b_i s^2\right)} \qquad (16\text{–}1)$$

The filter coefficients a_i and b_i distinguish between Butterworth, Tschebyscheff, and Bessel filters. The coefficients for all three types of filters are tabulated down to the tenth order in Section 16.9, Tables 16–4 through 16–10.

The multiplication of the denominator terms with each other yields an n^{th} order polynomial of S, with n being the filter order.

While n determines the gain rolloff above f_C with $-n \cdot 20\ dB/decade$, a_i and b_i determine the gain behavior in the passband.

In addition, the ratio $\frac{\sqrt{b_i}}{a_i} = Q$ is defined as the pole quality. The higher the Q value, the more a filter inclines to instability.

16.3 Low-Pass Filter Design

Equation 16–1 represents a cascade of second-order low-pass filters. The transfer function of a single stage is:

$$A_i(s) = \frac{A_0}{\left(1 + a_i s + b_i s^2\right)} \qquad (16–2)$$

For a first-order filter, the coefficient b is always zero (b_1=0), thus yielding:

$$A(s) = \frac{A_0}{1 + a_1 s} \qquad (16–3)$$

The first-order and second-order filter stages are the building blocks for higher-order filters.

Often the filters operate at unity gain (A_0=1) to lessen the stringent demands on the op amp's open-loop gain.

Figure 16–11 shows the cascading of filter stages up to the sixth order. A filter with an even order number consists of second-order stages only, while filters with an odd order number include an additional first-order stage at the beginning.

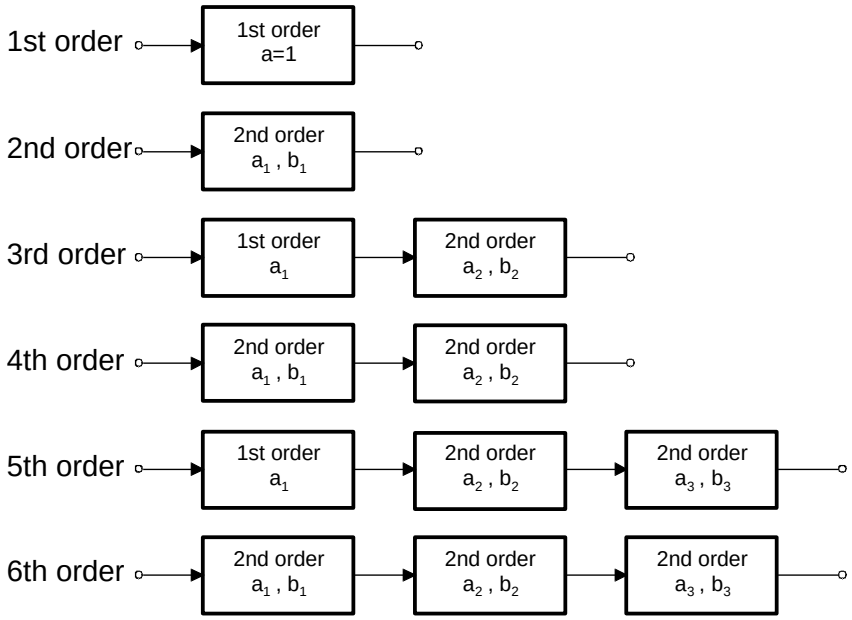

Figure 16–11. Cascading Filter Stages for Higher-Order Filters

Figure 16–10 demonstrated that the higher the corner frequency of a partial filter, the higher its Q. Therefore, to avoid the saturation of the individual stages, the filters need to be placed in the order of rising Q values. The Q values for each filter order are listed (in rising order) in Section 16–9, Tables 16–4 through 16–10.

16.3.1 First-Order Low-Pass Filter

Figures 16–12 and 16–13 show a first-order low-pass filter in the inverting and in the noninverting configuration.

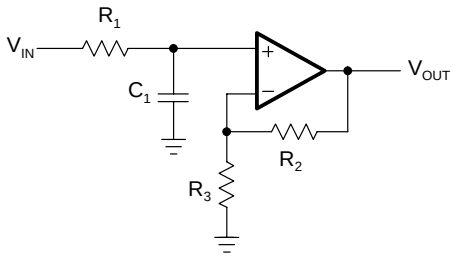

Figure 16–12. First-Order Noninverting Low-Pass Filter

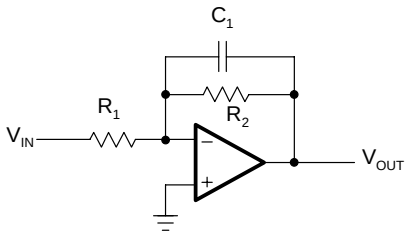

Figure 16–13. First-Order Inverting Low-Pass Filter

The transfer functions of the circuits are:

$$A(s) = \frac{1 + \frac{R_2}{R_3}}{1 + \omega_c R_1 C_1 s} \quad \text{and} \quad A(s) = \frac{-\frac{R_2}{R_1}}{1 + \omega_c R_2 C_1 s}$$

The negative sign indicates that the inverting amplifier generates a 180° phase shift from the filter input to the output.

The coefficient comparison between the two transfer functions and Equation 16–3 yields:

$$A_0 = 1 + \frac{R_2}{R_3} \quad \text{and} \quad A_0 = -\frac{R_2}{R_1}$$

$$a_1 = \omega_c R_1 C_1 \quad \text{and} \quad a_1 = \omega_c R_2 C_1$$

To dimension the circuit, specify the corner frequency (f_C), the dc gain (A_0), and capacitor C_1, and then solve for resistors R_1 and R_2:

$$R_1 = \frac{a_1}{2\pi f_c C_1} \quad \text{and} \quad R_2 = \frac{a_1}{2\pi f_c C_1}$$

$$R_2 = R_3(A_0 - 1) \quad \text{and} \quad R_1 = -\frac{R_2}{A_0}$$

The coefficient a_1 is taken from one of the coefficient tables, Tables 16–4 through 16–10 in Section 16.9.

Note, that all filter types are identical in their first order and $a_1 = 1$. For higher filter orders, however, $a_1 \neq 1$ because the corner frequency of the first-order stage is different from the corner frequency of the overall filter.

Example 16–1. First-Order Unity-Gain Low-Pass Filter

For a first-order unity-gain low-pass filter with f_C = 1 kHz and C_1 = 47 nF, R_1 calculates to:

$$R_1 = \frac{a_1}{2\pi f_c C_1} = \frac{1}{2\pi \cdot 10^3 \text{Hz} \cdot 47 \cdot 10^{-9} \text{F}} = 3.38\ \text{k}\Omega$$

However, to design the first stage of a third-order unity-gain Bessel low-pass filter, assuming the same values for f_C and C_1, requires a different value for R_1. In this case, obtain a_1 for a third-order Bessel filter from Table 16–4 in Section 16.9 (Bessel coefficients) to calculate R_1:

$$R_1 = \frac{a_1}{2\pi f_c C_1} = \frac{0.756}{2\pi \cdot 10^3 \text{Hz} \cdot 47 \cdot 10^{-9} \text{F}} = 2.56\ \text{k}\Omega$$

When operating at unity gain, the noninverting amplifier reduces to a voltage follower (Figure 16–14), thus inherently providing a superior gain accuracy. In the case of the inverting amplifier, the accuracy of the unity gain depends on the tolerance of the two resistors, R_1 and R_2.

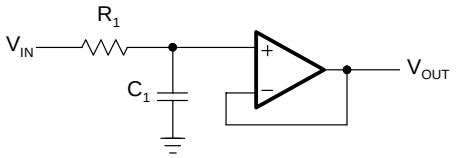

Figure 16–14. First-Order Noninverting Low-Pass Filter with Unity Gain

16.3.2 Second-Order Low-Pass Filter

There are two topologies for a second-order low-pass filter, the Sallen-Key and the Multiple Feedback (MFB) topology.

16.3.2.1 Sallen-Key Topology

The general Sallen-Key topology in Figure 16–15 allows for separate gain setting via $A_0 = 1+R_4/R_3$. However, the unity-gain topology in Figure 16–16 is usually applied in filter designs with high gain accuracy, unity gain, and low Qs (Q < 3).

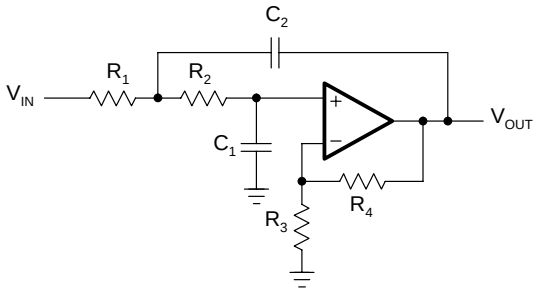

Figure 16–15. General Sallen-Key Low-Pass Filter

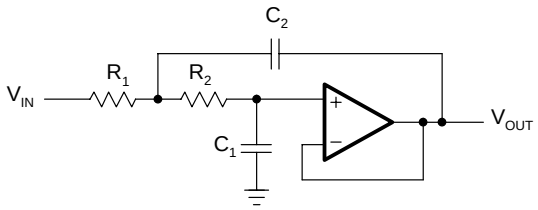

Figure 16–16. Unity-Gain Sallen-Key Low-Pass Filter

The transfer function of the circuit in Figure 16–15 is:

$$A(s) = \frac{A_0}{1 + \omega_c\left[C_1(R_1 + R_2) + (1 - A_0)\,R_1C_2\right]s + \omega_c{}^2\,R_1R_2C_1C_2s^2}$$

For the unity-gain circuit in Figure 16–16 (A_0=1), the transfer function simplifies to:

$$A(s) = \frac{1}{1 + \omega_cC_1(R_1 + R_2)\,s + \omega_c{}^2\,R_1R_2C_1C_2s^2}$$

The coefficient comparison between this transfer function and Equation 16–2 yields:

$$A_0 = 1$$
$$a_1 = \omega_cC_1(R_1 + R_2)$$
$$b_1 = \omega_c{}^2R_1R_2C_1C_2$$

Given C_1 and C_2, the resistor values for R_1 and R_2 are calculated through:

$$R_{1,2} = \frac{a_1C_2 \mp \sqrt{a_1{}^2C_2{}^2 - 4b_1C_1C_2}}{4\pi f_cC_1C_2}$$

In order to obtain real values under the square root, C_2 must satisfy the following condition:

$$C_2 \geq C_1 \frac{4b_1}{a_1^2}$$

Example 16–2. Second-Order Unity-Gain Tschebyscheff Low-Pass Filter

The task is to design a second-order unity-gain Tschebyscheff low-pass filter with a corner frequency of f_C = 3 kHz and a 3-dB passband ripple.

From Table 16–9 (the Tschebyscheff coefficients for 3-dB ripple), obtain the coefficients a_1 and b_1 for a second-order filter with a_1 = 1.0650 and b_1 = 1.9305.

Specifying C_1 as 22 nF yields in a C_2 of:

$$C_2 \geq C_1 \frac{4b_1}{a_1^2} = 22 \cdot 10^{-9}\text{nF} \cdot \frac{4 \cdot 1.9305}{1.065^2} \cong 150\ \text{nF}$$

Inserting a_1 and b_1 into the resistor equation for $R_{1,2}$ results in:

$$R_1 = \frac{1.065 \cdot 150 \cdot 10^{-9} - \sqrt{\left(1.065 \cdot 150 \cdot 10^{-9}\right)^2 - 4 \cdot 1.9305 \cdot 22 \cdot 10^{-9} \cdot 150 \cdot 10^{-9}}}{4\pi \cdot 3 \cdot 10^3 \cdot 22 \cdot 10^{-9} \cdot 150 \cdot 10^{-9}} = 1.26\ \text{k}\Omega$$

and

$$R_2 = \frac{1.065 \cdot 150 \cdot 10^{-9} + \sqrt{\left(1.065 \cdot 150 \cdot 10^{-9}\right)^2 - 4 \cdot 1.9305 \cdot 22 \cdot 10^{-9} \cdot 150 \cdot 10^{-9}}}{4\pi \cdot 3 \cdot 10^3 \cdot 22 \cdot 10^{-9} \cdot 150 \cdot 10^{-9}} = 1.30\ \text{k}\Omega$$

with the final circuit shown in Figure 16–17.

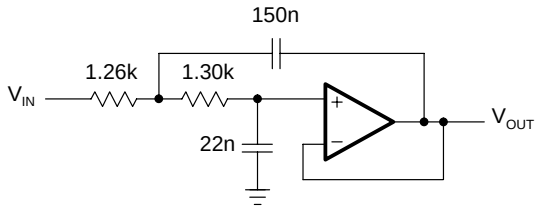

Figure 16–17. Second-Order Unity-Gain Tschebyscheff Low-Pass with 3-dB Ripple

A special case of the general Sallen-Key topology is the application of equal resistor values and equal capacitor values: $R_1 = R_2 = R$ and $C_1 = C_2 = C$.

The general transfer function changes to:

$$A(s) = \frac{A_0}{1 + \omega_c RC(3 - A_0)s + (\omega_c RC)^2 s^2} \qquad \text{with} \qquad A_0 = 1 + \frac{R_4}{R_3}$$

The coefficient comparison with Equation 16–2 yields:

$$a_1 = \omega_c RC(3 - A_0)$$

$$b_1 = (\omega_c RC)^2$$

Given C and solving for R and A_0 results in:

$$R = \frac{\sqrt{b_1}}{2\pi f_c C} \qquad \text{and} \qquad A_0 = 3 - \frac{a_1}{\sqrt{b_1}} = 3 - \frac{1}{Q}$$

Thus, A_0 depends solely on the pole quality Q and vice versa; Q, and with it the filter type, is determined by the gain setting of A_0:

$$Q = \frac{1}{3 - A_0}$$

The circuit in Figure 16–18 allows the filter type to be changed through the various resistor ratios R_4/R_3.

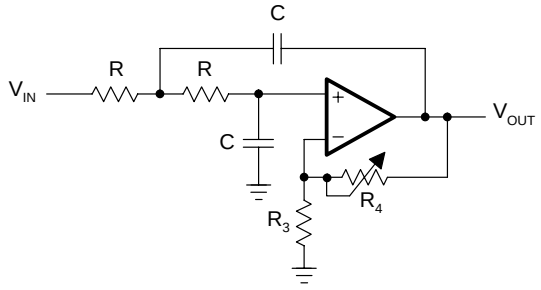

Figure 16–18. Adjustable Second-Order Low-Pass Filter

Table 16–1 lists the coefficients of a second-order filter for each filter type and gives the resistor ratios that adjust the Q.

Table 16–1. Second-Order FIlter Coefficients

SECOND-ORDER	BESSEL	BUTTERWORTH	3-dB TSCHEBYSCHEFF
a_1	1.3617	1.4142	1.065
b_1	0.618	1	1.9305
Q	0.58	0.71	1.3
R_4/R_3	0.268	0.568	0.234

16.3.2.2 Multiple Feedback Topology

The MFB topology is commonly used in filters that have high Qs and require a high gain.

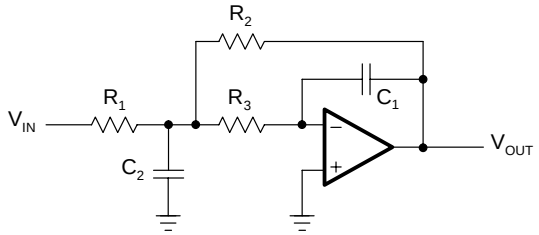

Figure 16–19. Second-Order MFB Low-Pass Filter

The transfer function of the circuit in Figure 16–19 is:

$$A(s) = -\frac{\frac{R_2}{R_1}}{1 + \omega_c C_1\left(R_2 + R_3 + \frac{R_2 R_3}{R_1}\right)s + \omega_c{}^2\, C_1 C_2 R_2 R_3 s^2}$$

Through coefficient comparison with Equation 16–2 one obtains the relation:

$$A_0 = -\frac{R_2}{R_1}$$

$$a_1 = \omega_c C_1\left(R_2 + R_3 + \frac{R_2 R_3}{R_1}\right)$$

$$b_1 = \omega_c{}^2\, C_1 C_2 R_2 R_3$$

Given C_1 and C_2, and solving for the resistors R_1–R_3:

$$R_2 = \frac{a_1 C_2 - \sqrt{a_1{}^2\, C_2{}^2 - 4 b_1 C_1 C_2 (1 - A_0)}}{4\pi f_c C_1 C_2}$$

$$R_1 = \frac{R_2}{-A_0}$$

$$R_3 = \frac{b_1}{4\pi^2 f_c{}^2\, C_1 C_2 R_2}$$

In order to obtain real values for R_2, C_2 must satisfy the following condition:

$$C_2 \geq C_1 \frac{4b_1\left(1 - A_0\right)}{{a_1}^2}$$

16.3.3 Higher-Order Low-Pass Filters

Higher-order low-pass filters are required to sharpen a desired filter characteristic. For that purpose, first-order and second-order filter stages are connected in series, so that the product of the individual frequency responses results in the optimized frequency response of the overall filter.

In order to simplify the design of the partial filters, the coefficients a_i and b_i for each filter type are listed in the coefficient tables (Tables 16–4 through 16–10 in Section 16.9), with each table providing sets of coefficients for the first 10 filter orders.

Example 16–3. Fifth-Order Filter

The task is to design a fifth-order unity-gain Butterworth low-pass filter with the corner frequency f_C = 50 kHz.

First the coefficients for a fifth-order Butterworth filter are obtained from Table 16–5, Section 16.9:

	a_i	b_i
Filter 1	$a_1 = 1$	$b_1 = 0$
Filter 2	$a_2 = 1.6180$	$b_2 = 1$
Filter 3	$a_3 = 0.6180$	$b_3 = 1$

Then dimension each partial filter by specifying the capacitor values and calculating the required resistor values.

First Filter

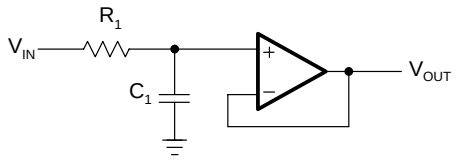

Figure 16–20. First-Order Unity-Gain Low-Pass

With C_1 = 1nF,

$$R_1 = \frac{a_1}{2\pi f_c C_1} = \frac{1}{2\pi \cdot 50 \cdot 10^3 \text{Hz} \cdot 1 \cdot 10^{-9} \text{F}} = 3.18\ \text{k}\Omega$$

The closest 1% value is 3.16 kΩ.

Second Filter

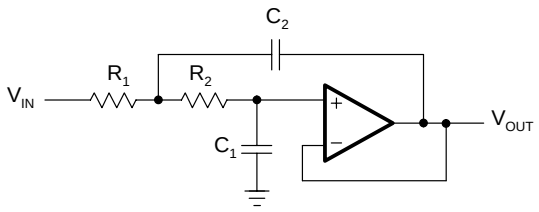

Figure 16–21. Second-Order Unity-Gain Sallen-Key Low-Pass Filter

With C_1 = 820 pF,

$$C_2 \geq C_1 \frac{4b_2}{a_2^2} = 820 \cdot 10^{-12} \text{F} \cdot \frac{4 \cdot 1}{1.618^2} = 1.26 \text{ nF}$$

The closest 5% value is 1.5 nF.

With C_1 = 820 pF and C_2 = 1.5 nF, calculate the values for R1 and R2 through:

$$R_1 = \frac{a_2 C_2 - \sqrt{a_2^2 C_2^2 - 4b_2 C_1 C_2}}{4\pi f_c C_1 C_2} \quad \text{and} \quad R_1 = \frac{a_2 C_2 + \sqrt{a_2^2 C_2^2 - 4b_2 C_1 C_2}}{4\pi f_c C_1 C_2}$$

and obtain

$$R_1 = \frac{1.618 \cdot 1.5 \cdot 10^{-9} - \sqrt{\left(1.618 \cdot 1.5 \cdot 10^{-9}\right)^2 - 4 \cdot 1 \cdot 820 \cdot 10^{-12} \cdot 1.5 \cdot 10^{-9}}}{4\pi \cdot 50 \cdot 10^3 \cdot 820 \cdot 10^{-12} \cdot 1.5 \cdot 10^{-9}} = 1.87 \text{ k}\Omega$$

$$R_2 = \frac{1.618 \cdot 1.5 \cdot 10^{-9} + \sqrt{\left(1.618 \cdot 1.5 \cdot 10^{-9}\right)^2 - 4 \cdot 1 \cdot 820 \cdot 10^{-12} \cdot 1.5 \cdot 10^{-9}}}{4\pi \cdot 50 \cdot 10^3 \cdot 820 \cdot 10^{-12} \cdot 1.5 \cdot 10^{-9}} = 4.42 \text{ k}\Omega$$

R_1 and R_2 are available 1% resistors.

Third Filter

The calculation of the third filter is identical to the calculation of the second filter, except that a_2 and b_2 are replaced by a_3 and b_3, thus resulting in different capacitor and resistor values.

Specify C_1 as 330 pF, and obtain C_2 with:

$$C_2 \geq C_1 \frac{4b_3}{a_3^2} = 330 \cdot 10^{-12} \text{F} \cdot \frac{4 \cdot 1}{0.618^2} = 3.46 \text{ nF}$$

The closest 10% value is 4.7 nF.

With C_1 = 330 pF and C_2 = 4.7 nF, the values for R1 and R2 are:

- R_1 = 1.45 kΩ, with the closest 1% value being 1.47 kΩ
- R_2 = 4.51 kΩ, with the closest 1% value being 4.53 kΩ

Figure 16–22 shows the final filter circuit with its partial filter stages.

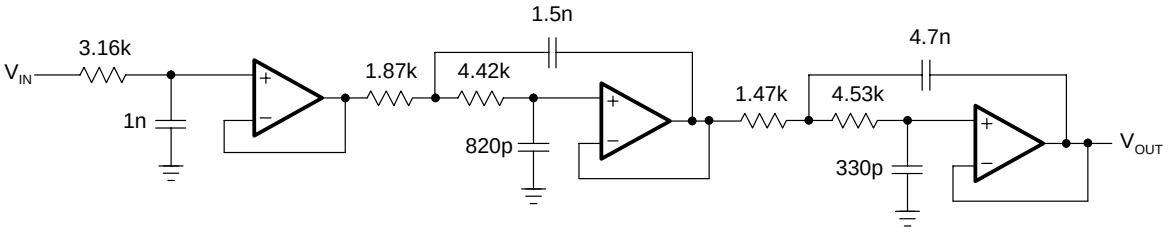

Figure 16–22. Fifth-Order Unity-Gain Butterworth Low-Pass Filter

16.4 High-Pass Filter Design

By replacing the resistors of a low-pass filter with capacitors, and its capacitors with resistors, a high-pass filter is created.

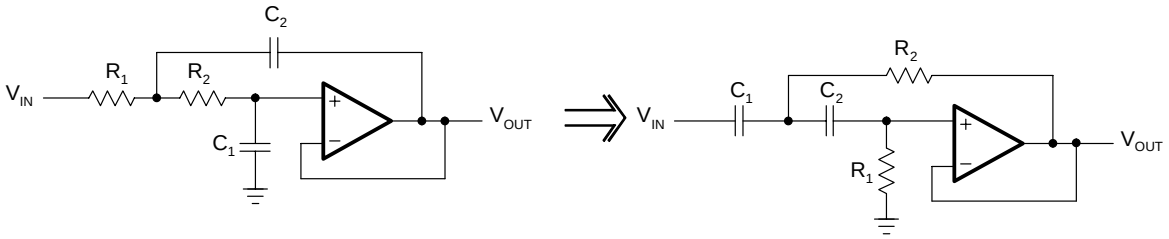

Figure 16–23. Low-Pass to High-Pass Transition Through Components Exchange

To plot the gain response of a high-pass filter, mirror the gain response of a low-pass filter at the corner frequency, Ω=1, thus replacing Ω with 1/Ω and S with 1/S in Equation 16–1.

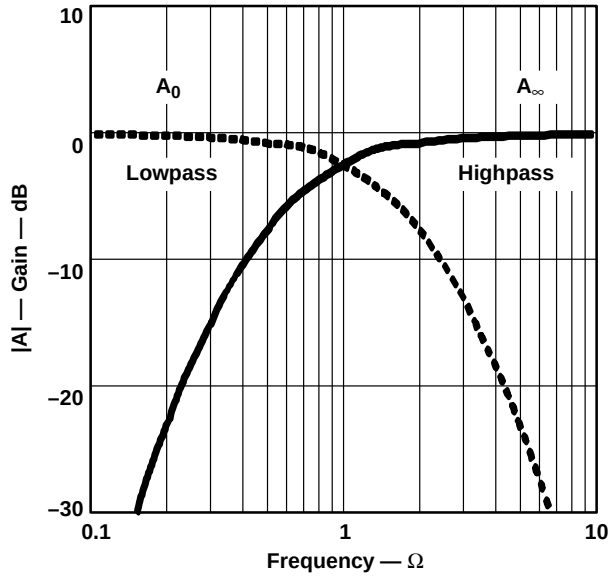

Figure 16–24. Developing The Gain Response of a High-Pass Filter

The general transfer function of a high-pass filter is then:

$$A(s) = \frac{A_\infty}{\prod_i \left(1 + \frac{a_i}{s} + \frac{b_i}{s^2}\right)} \qquad (16–4)$$

with A_∞ being the passband gain.

Since Equation 16–4 represents a cascade of second-order high-pass filters, the transfer function of a single stage is:

$$A_i(s) = \frac{A_\infty}{\left(1 + \frac{a_i}{s} + \frac{b_i}{s^2}\right)} \qquad (16–5)$$

With b=0 for all first-order filters, the transfer function of a first-order filter simplifies to:

$$A(s) = \frac{A_0}{1 + \frac{a_i}{s}} \qquad (16–6)$$

16.4.1 First-Order High-Pass Filter

Figure 16–25 and 16–26 show a first-order high-pass filter in the noninverting and the inverting configuration.

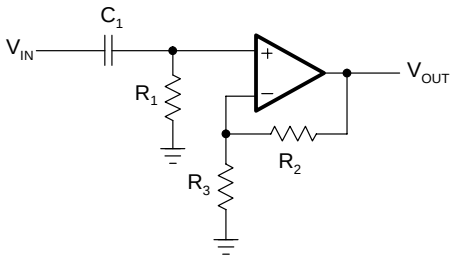

Figure 16–25. First-Order Noninverting High-Pass Filter

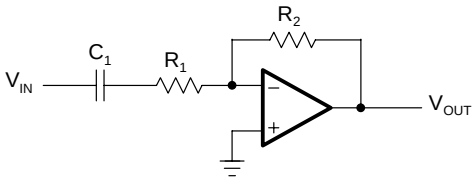

Figure 16–26. First-Order Inverting High-Pass Filter

The transfer functions of the circuits are:

$$A(s) = \frac{1 + \frac{R_2}{R_3}}{1 + \frac{1}{\omega_c R_1 C_1} \cdot \frac{1}{s}} \qquad \text{and} \qquad A(s) = -\frac{\frac{R_2}{R_1}}{1 + \frac{1}{\omega_c R_1 C_1} \cdot \frac{1}{s}}$$

The negative sign indicates that the inverting amplifier generates a 180° phase shift from the filter input to the output.

The coefficient comparison between the two transfer functions and Equation 16–6 provides two different passband gain factors:

$$A_\infty = 1 + \frac{R_2}{R_3} \qquad \text{and} \qquad A_\infty = -\frac{R_2}{R_1}$$

while the term for the coefficient a_1 is the same for both circuits:

$$a_1 = \frac{1}{\omega_c R_1 C_1}$$

To dimension the circuit, specify the corner frequency (f_C), the dc gain (A_∞), and capacitor (C_1), and then solve for R_1 and R_2:

$$R_1 = \frac{1}{2\pi f_c a_1 C_1}$$

$$R_2 = R_3(A_\infty - 1) \qquad \text{and} \qquad R_2 = -R_1 A_\infty$$

16.4.2 Second-Order High-Pass Filter

High-pass filters use the same two topologies as the low-pass filters: Sallen-Key and Multiple Feedback. The only difference is that the positions of the resistors and the capacitors have changed.

16.4.2.1 Sallen-Key Topology

The general Sallen-Key topology in Figure 16–27 allows for separate gain setting via $A_0 = 1+R_4/R_3$.

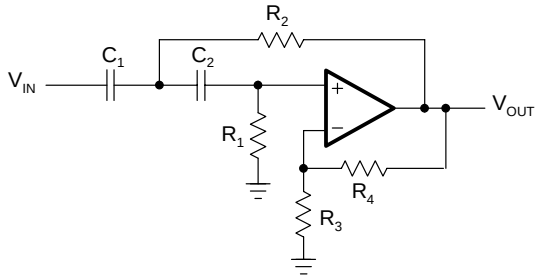

Figure 16–27. General Sallen-Key High-Pass Filter

The transfer function of the circuit in Figure 16–27 is:

$$A(s) = \frac{\alpha}{1 + \frac{R_2(C_1+C_2)+R_1C_2(1-\alpha)}{\omega_c R_1 R_2 C_1 C_2}\cdot\frac{1}{s} + \frac{1}{\omega_c^2 R_1 R_2 C_1 C_2}\cdot\frac{1}{s^2}} \qquad \text{with} \qquad \alpha = 1 + \frac{R_4}{R_3}$$

The unity-gain topology in Figure 16–28 is usually applied in low-Q filters with high gain accuracy.

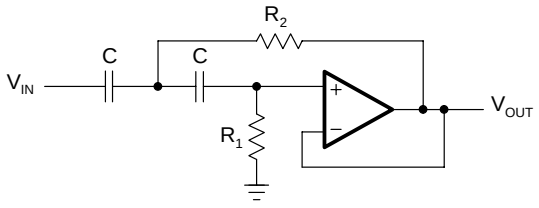

Figure 16–28. Unity-Gain Sallen-Key High-Pass Filter

To simplify the circuit design, it is common to choose unity-gain ($\alpha = 1$), and $C_1 = C_2 = C$. The transfer function of the circuit in Figure 16–28 then simplifies to:

$$A(s) = \frac{1}{1 + \frac{2}{\omega_c R_1 C} \cdot \frac{1}{s} + \frac{1}{\omega_c^2 R_1 R_2 C^2} \cdot \frac{1}{s^2}}$$

The coefficient comparison between this transfer function and Equation 16–5 yields:

$$A_\infty = 1$$

$$a_1 = \frac{2}{\omega_c R_1 C}$$

$$b_1 = \frac{1}{\omega_c^2 R_1 R_2 C^2}$$

Given C, the resistor values for R_1 and R_2 are calculated through:

$$R_1 = \frac{1}{\pi f_c C a_1}$$

$$R_2 = \frac{a_1}{4\pi f_c C b_1}$$

16.4.2.2 Multiple Feedback Topology

The MFB topology is commonly used in filters that have high Qs and require a high gain.

To simplify the computation of the circuit, capacitors C_1 and C_3 assume the same value ($C_1 = C_3 = C$) as shown in Figure 16–29.

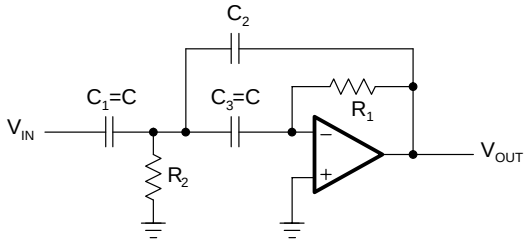

Figure 16–29. Second-Order MFB High-Pass Filter

The transfer function of the circuit in Figure 16–29 is:

$$A(s) = \frac{-\frac{C}{C_2}}{1 + \frac{2C_2 + C}{\omega_c R_1 C_2 C} \cdot \frac{1}{s} + \frac{1}{\omega_c^2 R_2 R_1 C_2 C} \cdot \frac{1}{s^2}}$$

Through coefficient comparison with Equation 16–5, obtain the following relations:

$$A_\infty = \frac{C}{C_2}$$

$$a_1 = \frac{2C + C_2}{\omega_c R_1 C C_2}$$

$$b_1 = \frac{2C + C_2}{\omega_c R_1 C C_2}$$

Given capacitors C and C_2, and solving for resistors R_1 and R_2:

$$R_1 = \frac{1 - 2A_\infty}{2\pi f_c \cdot C \cdot a_1}$$

$$R_2 = \frac{a_1}{2\pi f_c \cdot b_1 C_2 (1 - 2A_\infty)}$$

The passband gain (A_∞) of a MFB high-pass filter can vary significantly due to the wide tolerances of the two capacitors C and C_2. To keep the gain variation at a minimum, it is necessary to use capacitors with tight tolerance values.

16.4.3 Higher-Order High-Pass Filter

Likewise, as with the low-pass filters, higher-order high-pass filters are designed by cascading first-order and second-order filter stages. The filter coefficients are the same ones used for the low-pass filter design, and are listed in the coefficient tables (Tables 16–4 through 16–10 in Section 16.9).

Example 16–4. Third-Order High-Pass Filter with f_C = 1 kHz

The task is to design a third-order unity-gain Bessel high-pass filter with the corner frequency f_C = 1 kHz. Obtain the coefficients for a third-order Bessel filter from Table 16–4, Section 16.9:

	a_i	b_i
Filter 1	$a_1 = 0.756$	$b_1 = 0$
Filter 2	$a_2 = 0.9996$	$b_2 = 0.4772$

and compute each partial filter by specifying the capacitor values and calculating the required resistor values.

First Filter

With C_1 = 100 nF,

$$R_1 = \frac{1}{2\pi f_c a_1 C_1} = \frac{1}{2\pi \cdot 10^3 Hz \cdot 0.756 \cdot 100 \cdot 10^{-9} F} = 2.105\ k\Omega$$

Closest 1% value is 2.1 kΩ.

Second Filter

With C = 100nF,

$$R_1 = \frac{1}{\pi f_c C a_1} = \frac{1}{\pi \cdot 10^3 \cdot 100 \cdot 10^{-9} \cdot 0.756} = 3.18\ k\Omega$$

Closest 1% value is 3.16 kΩ.

$$R_2 = \frac{a_1}{4\pi f_c C b_1} = \frac{0.9996}{4\pi \cdot 10^3 \cdot 100 \cdot 10^{-9} \cdot 0.4772} = 1.67\ k\Omega$$

Closest 1% value is 1.65 kΩ.

Figure 16–30 shows the final filter circuit.

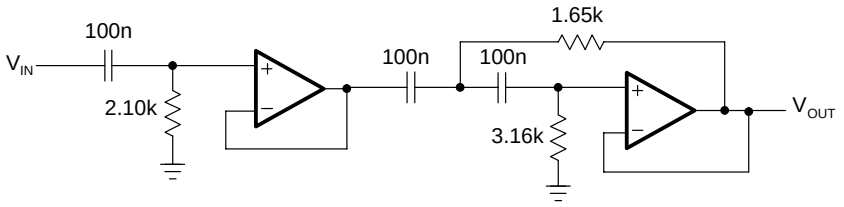

Figure 16–30. Third-Order Unity-Gain Bessel High-Pass

16.5 Band-Pass Filter Design

In Section 16.4, a high-pass response was generated by replacing the term *S* in the low-pass transfer function with the transformation *1/S*. Likewise, a band-pass characteristic is generated by replacing the S term with the transformation:

$$\frac{1}{\Delta\Omega}\left(s + \frac{1}{s}\right) \qquad (16–7)$$

In this case, the passband characteristic of a low-pass filter is transformed into the upper passband half of a band-pass filter. The upper passband is then mirrored at the mid frequency, f_m (Ω=1), into the lower passband half.

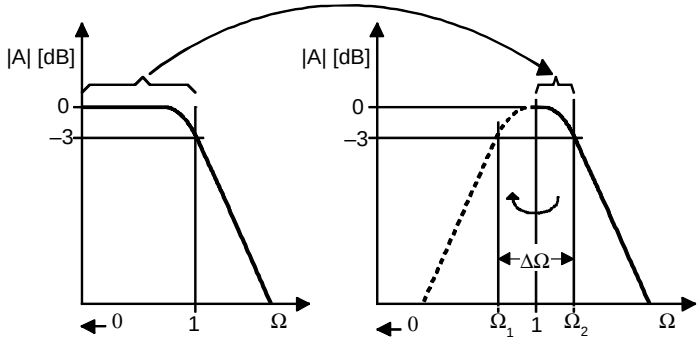

Figure 16–31. Low-Pass to Band-Pass Transition

The corner frequency of the low-pass filter transforms to the lower and upper –3 dB frequencies of the band-pass, Ω_1 and Ω_2. The difference between both frequencies is defined as the normalized bandwidth $\Delta\Omega$:

$$\Delta\Omega = \Omega_2 - \Omega_1$$

The normalized mid frequency, where Q = 1, is:

$$\Omega_m = 1 = \Omega_2 \cdot \Omega_1$$

In analogy to the resonant circuits, the quality factor Q is defined as the ratio of the mid frequency (f_m) to the bandwidth (B):

$$Q = \frac{f_m}{B} = \frac{f_m}{f_2 - f_1} = \frac{1}{\Omega_2 - \Omega_1} = \frac{1}{\Delta\Omega} \qquad (16\text{–}8)$$

The simplest design of a band-pass filter is the connection of a high-pass filter and a low-pass filter in series, which is commonly done in wide-band filter applications. Thus, a first-order high-pass and a first-order low-pass provide a second-order band-pass, while a second-order high-pass and a second-order low-pass result in a fourth-order band-pass response.

In comparison to wide-band filters, narrow-band filters of higher order consist of cascaded second-order band-pass filters that use the Sallen-Key or the Multiple Feedback (MFB) topology.

16.5.1 Second-Order Band-Pass Filter

To develop the frequency response of a second-order band-pass filter, apply the transformation in Equation 16–7 to a first-order low-pass transfer function:

$$A(s) = \frac{A_0}{1 + s}$$

Replacing s with $\frac{1}{\Delta\Omega}\left(s + \frac{1}{s}\right)$

yields the general transfer function for a second-order band-pass filter:

$$A(s) = \frac{A_0 \cdot \Delta\Omega \cdot s}{1 + \Delta\Omega \cdot s + s^2} \qquad (16–9)$$

When designing band-pass filters, the parameters of interest are the gain at the mid frequency (A_m) and the quality factor (Q), which represents the selectivity of a band-pass filter.

Therefore, replace A_0 with A_m and $\Delta\Omega$ with 1/Q (Equation 16–7) and obtain:

$$A(s) = \frac{\frac{A_m}{Q} \cdot s}{1 + \frac{1}{Q} \cdot s + s^2} \qquad (16–10)$$

Figure 16–32 shows the normalized gain response of a second-order band-pass filter for different Qs.

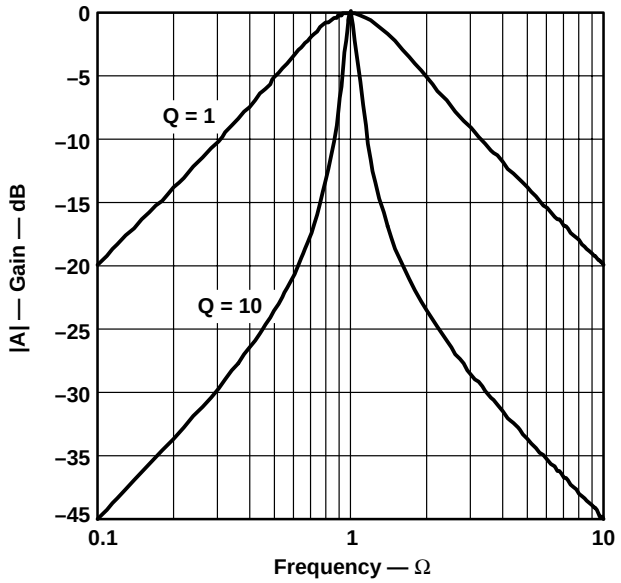

Figure 16–32. Gain Response of a Second-Order Band-Pass Filter

The graph shows that the frequency response of second-order band-pass filters gets steeper with rising Q, thus making the filter more selective.

16.5.1.1 Sallen-Key Topology

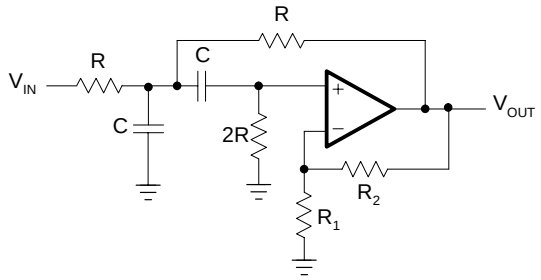

Figure 16–33. Sallen-Key Band-Pass

The Sallen-Key band-pass circuit in Figure 16–33 has the following transfer function:

$$A(s) = \frac{G \cdot RC\omega_m \cdot s}{1 + RC\omega_m(3 - G) \cdot s + R^2C^2\omega_m{}^2 \cdot s^2}$$

Through coefficient comparison with Equation 16–10, obtain the following equations:

$$\text{mid-frequency: } f_m = \frac{1}{2\pi RC}$$

$$\text{inner gain: } G = 1 + \frac{R_2}{R_1}$$

$$\text{gain at } f_{m:} \quad A_m = \frac{G}{3 - G}$$

$$\text{filter quality: } Q = \frac{1}{3 - G}$$

The Sallen-Key circuit has the advantage that the quality factor (Q) can be varied via the inner gain (G) without modifying the mid frequency (fm). A drawback is, however, that Q and A_m cannot be adjusted independently.

Care must be taken when G approaches the value of 3, because then A_m becomes infinite and causes the circuit to oscillate.

To set the mid frequency of the band-pass, specify f_m and C and then solve for R:

$$R = \frac{1}{2\pi f_m C}$$

Because of the dependency between Q and A_m, there are two options to solve for R_2: either to set the gain at mid frequency:

$$R_2 = \frac{2A_m - 1}{1 + A_m}$$

or to design for a specified Q:

$$R_2 = \frac{2Q - 1}{Q}$$

16.5.1.2 Multiple Feedback Topology

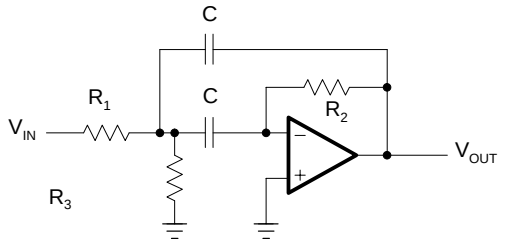

Figure 16–34. MFB Band-Pass

The MFB band-pass circuit in Figure 16–34 has the following transfer function:

$$A(s) = \frac{-\frac{R_2R_3}{R_1+R_3}C\omega_m \cdot s}{1 + \frac{2R_1R_3}{R_1+R_3}C\omega_m \cdot s + \frac{R_1R_2R_3}{R_1+R_3}C^2 \cdot \omega_m{}^2 \cdot s^2}$$

The coefficient comparison with Equation 16–9, yields the following equations:

$$\text{mid-frequency: } f_m = \frac{1}{2\pi C}\sqrt{\frac{R_1 + R_3}{R_1R_2R_3}}$$

$$\text{gain at } f_m: \quad -A_m = \frac{R_2}{2R_1}$$

$$\text{filter quality: } \quad Q = \pi f_m R_2 C$$

$$\text{bandwidth: } \quad B = \frac{1}{\pi R_2 C}$$

The MFB band-pass allows to adjust Q, A_m, and f_m independently. Bandwidth and gain factor do not depend on R_3. Therefore, R_3 can be used to modify the mid frequency with-

out affecting bandwidth, B, or gain, A_m. For low values of Q, the filter can work without R3, however, Q then depends on A_m via:

$$-A_m = 2Q^2$$

Example 16–5. Second-Order MFB Band-Pass Filter with f_m = 1 kHz

To design a second-order MFB band-pass filter with a mid frequency of f_m = 1 kHz, a quality factor of Q = 10, and a gain of A_m = –2, assume a capacitor value of C = 100 nF, and solve the previous equations for R_1 through R_3 in the following sequence:

$$R_2 = \frac{Q}{\pi f_m C} = \frac{10}{\pi \cdot 1\ \text{kHz} \cdot 100\ \text{nF}} = 31.8\ \text{k}\Omega$$

$$R_1 = \frac{R_2}{-2A_m} = \frac{31.8\ \text{k}\Omega}{4} = 7.96\ \text{k}\Omega$$

$$R_3 = \frac{-A_m R_1}{2Q^2 + A_m} = \frac{2 \cdot 7.96\ \text{k}\Omega}{200 - 2} = 80.4\ \Omega$$

16.5.2 Fourth-Order Band-Pass Filter (Staggered Tuning)

Figure 16–32 shows that the frequency response of second-order band-pass filters gets steeper with rising Q. However, there are band-pass applications that require a flat gain response close to the mid frequency as well as a sharp passband-to-stopband transition. These tasks can be accomplished by higher-order band-pass filters.

Of particular interest is the application of the low-pass to band-pass transformation onto a second-order low-pass filter, since it leads to a fourth-order band-pass filter.

Replacing the *S* term in Equation 16–2 with Equation 16–7 gives the general transfer function of a fourth-order band-pass:

$$A(s) = \frac{\frac{s^2 \cdot A_0 (\Delta\Omega)^2}{b_1}}{1 + \frac{a_1}{b_1}\Delta\Omega \cdot s + \left[2 + \frac{(\Delta\Omega)^2}{b_1}\right] \cdot s^2 + \frac{a_1}{b_1}\Delta\Omega \cdot s^3 + s^4} \qquad (16\text{–}11)$$

Similar to the low-pass filters, the fourth-order transfer function is split into two second-order band-pass terms. Further mathematical modifications yield:

$$A(s) = \frac{\frac{A_{mi}}{Q_i} \cdot \alpha s}{\left[1 + \frac{\alpha s}{Q_1} + (\alpha s)^2\right]} \cdot \frac{\frac{A_{mi}}{Q_i} \cdot \frac{s}{\alpha}}{\left[1 + \frac{1}{Q_i}\left(\frac{s}{\alpha}\right) + \left(\frac{s}{\alpha}\right)^2\right]} \qquad (16\text{–}12)$$

Equation 16–12 represents the connection of two second-order band-pass filters in series, where

- A_{mi} is the gain at the mid frequency, f_{mi}, of each partial filter
- Q_i is the pole quality of each filter
- α and $1/\alpha$ are the factors by which the mid frequencies of the individual filters, f_{m1} and f_{m2}, derive from the mid frequency, f_m, of the overall bandpass.

In a fourth-order band-pass filter with high Q, the mid frequencies of the two partial filters differ only slightly from the overall mid frequency. This method is called staggered tuning.

Factor α needs to be determined through successive approximation, using equation 16–13:

$$\alpha^2 + \left[\frac{\alpha \cdot \Delta\Omega \cdot a_1}{b_1(1 + \alpha^2)}\right]^2 + \frac{1}{\alpha^2} - 2 - \frac{(\Delta\Omega)^2}{b^1} = 0 \qquad (16\text{–}13)$$

with a_1 and b_1 being the second-order low-pass coefficients of the desired filter type.

To simplify the filter design, Table 16–2 lists those coefficients, and provides the α values for three different quality factors, Q = 1, Q = 10, and Q = 100.

Table 16–2. Values of α For Different Filter Types and Different Qs

Bessel				**Butterworth**				**Tschebyscheff**			
a_1	1.3617			**a_1**	1.4142			**a_1**	1.0650		
b_1	0.6180			**b_1**	1.0000			**b_1**	1.9305

After α has been determined, all quantities of the partial filters can be calculated using the following equations:

The mid frequency of filter 1 is:

$$f_{m1} = \frac{f_m}{\alpha} \tag{16–14}$$

the mid frequency of filter 2 is:

$$f_{m2} = f_m \cdot \alpha \tag{16–15}$$

with f_m being the mid frequency of the overall forth-order band-pass filter.

The individual pole quality, Q_i, is the same for both filters:

$$Q_i = Q \cdot \frac{(1 + \alpha^2)b_1}{\alpha \cdot a_1} \tag{16–16}$$

with Q being the quality factor of the overall filter.

The individual gain (A_{mi}) at the partial mid frequencies, f_{m1} and f_{m2}, is the same for both filters:

$$A_{mi} = \frac{Q_i}{Q} \cdot \sqrt{\frac{A_m}{B_1}} \tag{16–17}$$

with A_m being the gain at mid frequency, f_m, of the overall filter.

Example 16–6. Fourth-Order Butterworth Band-Pass Filter

The task is to design a fourth-order Butterworth band-pass with the following parameters:

- mid frequency, f_m = 10 kHz
- bandwidth, B = 1000 Hz
- and gain, A_m = 1

From Table 16–2 the following values are obtained:

- a1 = 1.4142
- b1 = 1
- α = 1.036

In accordance with Equations 16–14 and 16–15, the mid frequencies for the partial filters are:

$$f_{mi} = \frac{10\ \text{kHz}}{1.036} = 9.653\ \text{kHz} \qquad \text{and} \qquad f_{m2} = 10\ \text{kHz} \cdot 1.036 = 10.36\ \text{kHz}$$

The overall Q is defined as $Q = f_m/B$, and for this example results in Q = 10.

Using Equation 16–16, the Q_i of both filters is:

$$Q_i = 10 \cdot \frac{(1 + 1.036^2) \cdot 1}{1.036 \cdot 1.4142} = 14.15$$

With Equation 16–17, the passband gain of the partial filters at f_{m1} and f_{m2} calculates to:

$$A_{mi} = \frac{14.15}{10} \cdot \sqrt{\frac{1}{1}} = 1.415$$

The Equations 16–16 and 16–17 show that Q_i and A_{mi} of the partial filters need to be independently adjusted. The only circuit that accomplishes this task is the MFB band-pass filter in Paragraph 16.5.1.2.

To design the individual second-order band-pass filters, specify C = 10 nF, and insert the previously determined quantities for the partial filters into the resistor equations of the MFB band-pass filter. The resistor values for both partial filters are calculated below.

Filter 1:

$$R_{21} = \frac{Q_i}{\pi f_{m1} C} = \frac{14.15}{\pi \cdot 9.653\ \text{kHz} \cdot 10\ \text{nF}} = 46.7\ \text{k}\Omega$$

$$R_{11} = \frac{R_{21}}{-2A_{mi}} = \frac{46.7\ \text{k}\Omega}{-2 \cdot -1.415} = 16.5\ \text{k}\Omega$$

$$R_{31} = \frac{-A_{mi} R_{11}}{2Q_i^2 + A_{mi}} = \frac{1.415 \cdot 16.5\ \text{k}\Omega}{2 \cdot 14.15^2 + 1.415} = 58.1\ \Omega$$

Filter 2:

$$R_{22} = \frac{Q_i}{\pi f_{m2} C} = \frac{14.15}{\pi \cdot 10.36\ \text{kHz} \cdot 10\ \text{nF}} = 43.5\ \text{k}\Omega$$

$$R_{12} = \frac{R_{22}}{-2A_{mi}} = \frac{43.5\ \text{k}\Omega}{-2 \cdot -1.415} = 15.4\ \text{k}\Omega$$

$$R_{32} = \frac{-A_{mi} R_{12}}{2Q_i^2 + A_{mi}} = \frac{1.415 \cdot 15.4\ \text{k}\Omega}{2 \cdot 14.15^2 + 1.415} = 54.2\ \Omega$$

Figure 16–35 compares the gain response of a fourth-order Butterworth band-pass filter with Q = 1 and its partial filters to the fourth-order gain of Example 16–4 with Q = 10.

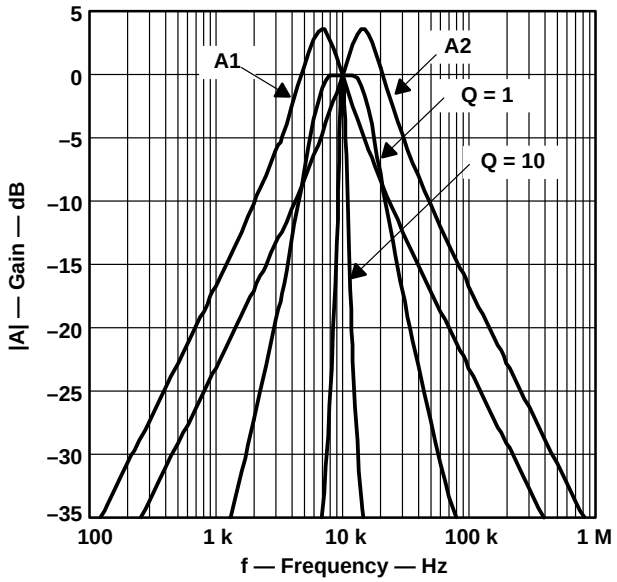

Figure 16–35. Gain Responses of a Fourth-Order Butterworth Band-Pass and its Partial Filters

16.6 Band-Rejection Filter Design

A band-rejection filter is used to suppress a certain frequency rather than a range of frequencies.

Two of the most popular band-rejection filters are the active twin-T and the active Wien-Robinson circuit, both of which are second-order filters.

To generate the transfer function of a second-order band-rejection filter, replace the *S* term of a first-order low-pass response with the transformation in 16–18:

$$\frac{\Delta\Omega}{s + \frac{1}{s}} \tag{16–18}$$

which gives:

$$A(s) = \frac{A_0(1 + s^2)}{1 + \Delta\Omega \cdot s + s^2} \tag{16–19}$$

Thus the passband characteristic of the low-pass filter is transformed into the lower passband of the band-rejection filter. The lower passband is then mirrored at the mid frequency, f_m (Ω=1), into the upper passband half (Figure 16–36).

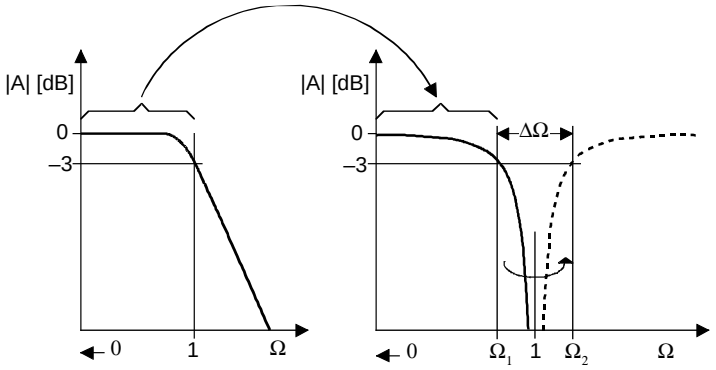

Figure 16–36. Low-Pass to Band-Rejection Transition

The corner frequency of the low-pass transforms to the lower and upper –3-dB frequencies of the band-rejection filter Ω_1 and Ω_2. The difference between both frequencies is the normalized bandwidth $\Delta\Omega$:

$$\Delta\Omega = \Omega_{max} - \Omega_{min}$$

Identical to the selectivity of a band-pass filter, the quality of the filter rejection is defined as:

$$Q = \frac{f_m}{B} = \frac{1}{\Delta\Omega}$$

Therefore, replacing $\Delta\Omega$ in Equation 16–19 with 1/Q yields:

$$A(s) = \frac{A_0(1 + s^2)}{1 + \frac{1}{Q}\cdot s + s^2} \qquad (16–20)$$

16.6.1 Active Twin-T Filter

The original twin-T filter, shown in Figure 16–37, is a passive RC-network with a quality factor of Q = 0.25. To increase Q, the passive filter is implemented into the feedback loop of an amplifier, thus turning into an active band-rejection filter, shown in Figure 16–38.

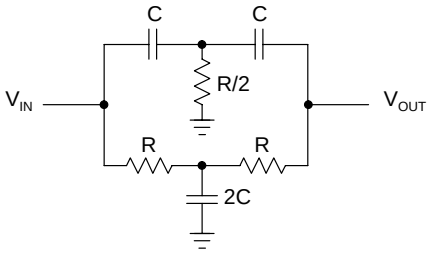

Figure 16–37. Passive Twin-T Filter

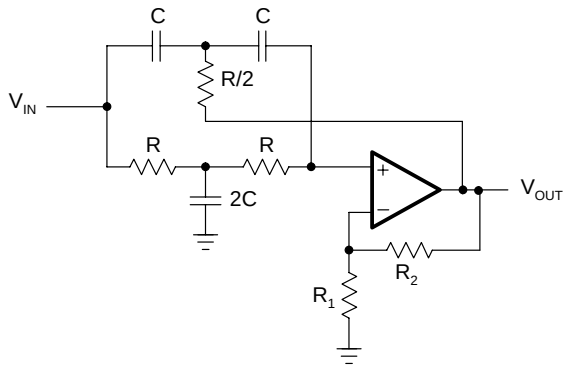

Figure 16–38. Active Twin-T Filter

The transfer function of the active twin-T filter is:

$$A(s) = \frac{k(1 + s^2)}{1 + 2(2 - k)\cdot s + s^2} \qquad (16–21)$$

Comparing the variables of Equation 16–21 with Equation 16–20 provides the equations that determine the filter parameters:

$$\text{mid-frequency:} \quad f_m = \frac{1}{2\pi RC}$$

$$\text{inner gain:} \quad G = 1 + \frac{R_2}{R_1}$$

$$\text{passband gain:} \quad A_0 = G$$

$$\text{rejection quality:} \quad Q = \frac{1}{2(2 - G)}$$

The twin-T circuit has the advantage that the quality factor (Q) can be varied via the inner gain (G) without modifying the mid frequency (f_m). However, Q and A_m cannot be adjusted independently.

To set the mid frequency of the band-pass, specify f_m and C, and then solve for R:

$$R = \frac{1}{2\pi f_m C}$$

Because of the dependency between Q and A_m, there are two options to solve for R_2: either to set the gain at mid frequency:

$$R_2 = (A_0 - 1)R_1$$

or to design for a specific Q:

$$R_2 = R_1\left(1 - \frac{1}{2Q}\right)$$

16.6.2 Active Wien-Robinson Filter

The Wien-Robinson bridge in Figure 16–39 is a passive band-rejection filter with differential output. The output voltage is the difference between the potential of a constant voltage divider and the output of a band-pass filter. Its Q-factor is close to that of the twin-T circuit. To achieve higher values of Q, the filter is connected into the feedback loop of an amplifier.

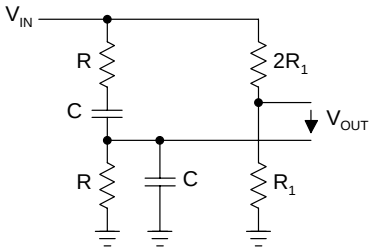

Figure 16–39. Passive Wien-Robinson Bridge

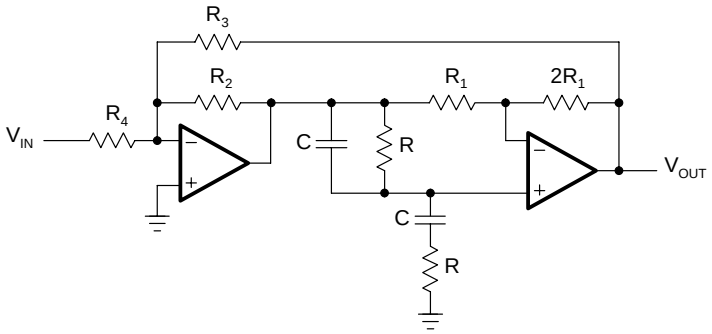

Figure 16–40. Active Wien-Robinson Filter

The active Wien-Robinson filter in Figure 16–40 has the transfer function:

$$A(s) = -\frac{\frac{\beta}{1+\alpha}\left(1 + s^2\right)}{1 + \frac{3}{1+\alpha}\cdot s + s^2} \qquad (16\text{–}22)$$

$$\text{with } \alpha = \frac{R_2}{R_3} \quad \text{and} \quad \beta = \frac{R_2}{R_4}$$

Comparing the variables of Equation 16–22 with Equation 16–20 provides the equations that determine the filter parameters:

mid-frequency: $f_m = \frac{1}{2\pi RC}$

passband gain: $A_0 = -\frac{\beta}{1+\alpha}$

rejection quality: $Q = \frac{1+\alpha}{3}$

To calculate the individual component values, establish the following design procedure:

1) Define f_m and C and calculate R with:

$$R = \frac{1}{2\pi f_m C}$$

2) Specify Q and determine α via:

$$\alpha = 3Q - 1$$

3) Specify A_0 and determine β via:

$$\beta = -A_0 \cdot 3Q$$

4) Define R_2 and calculate R_3 and R_4 with:

$$R_3 = \frac{R_2}{\alpha}$$

and

$$R_4 = \frac{R_2}{\beta}$$

In comparison to the twin-T circuit, the Wien-Robinson filter allows modification of the passband gain, A_0, without affecting the quality factor, Q.

If f_m is not completely suppressed due to component tolerances of R and C, a fine-tuning of the resistor $2R_2$ is required.

Figure 16–41 shows a comparison between the filter response of a passive band-rejection filter with Q = 0.25, and an active second-order filter with Q = 1, and Q = 10.

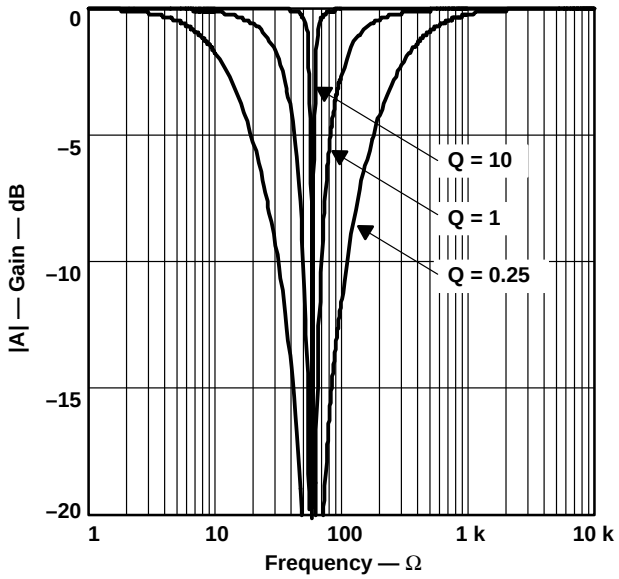

Figure 16–41. Comparison of Q Between Passive and Active Band-Rejection Filters

16.7 All-Pass Filter Design

In comparison to the previously discussed filters, an all-pass filter has a constant gain across the entire frequency range, and a phase response that changes linearly with frequency.

Because of these properties, all-pass filters are used in phase compensation and signal delay circuits.

Similar to the low-pass filters, all-pass circuits of higher order consist of cascaded first-order and second-order all-pass stages. To develop the all-pass transfer function from a low-pass response, replace A_0 with the conjugate complex denominator.

The general transfer function of an allpass is then:

$$A(s) = \frac{\prod_i \left(1 - a_i s + b_i s^2\right)}{\prod_i \left(1 + a_i s + b_i s^2\right)} \qquad (16\text{–}23)$$

with a_i and b_i being the coefficients of a partial filter. The all-pass coefficients are listed in Table 16–10 of Section 16.9.

Expressing Equation 16–23 in magnitude and phase yields:

$$A(s) = \frac{\prod_i \sqrt{\left(1 - b_i\Omega^2\right)^2 + a_i^2\Omega^2} \cdot e^{-ja}}{\prod_i \sqrt{\left(1 - b_i\Omega^2\right)^2 + a_i^2\Omega^2} \cdot e^{+ja}} \quad (16–24)$$

This gives a constant gain of 1, and a phase shift,ϕ, of:

$$\phi = -2\alpha = -2\sum_i \arctan\frac{a_i\Omega}{1 - b_i\Omega^2} \quad (16–25)$$

To transmit a signal with minimum phase distortion, the all-pass filter must have a constant group delay across the specified frequency band. The group delay is the time by which the all-pass filter delays each frequency within that band.

The frequency at which the group delay drops to $1/\sqrt{2}$–times its initial value is the corner frequency, f_C.

The group delay is defined through:

$$t_{gr} = -\frac{d\phi}{d\omega} \quad (16–26)$$

To present the group delay in normalized form, refer t_{gr} to the period of the corner frequency, T_C, of the all-pass circuit:

$$T_{gr} = \frac{t_{gr}}{T_c} = t_{gr} \cdot f_c = t_{gr} \cdot \frac{\omega_c}{2\pi} \quad (16–27)$$

Substituting t_{gr} through Equation 16–26 gives:

$$T_{gr} = -\frac{1}{2\pi} \cdot \frac{d\phi}{d\Omega} \quad (16–28)$$

Inserting the φ term in Equation 16–25 into Equation 16–28 and completing the derivation, results in:

$$T_{gr} = \frac{1}{\pi} \sum_{i} \frac{a_i\left(1 + b_i\Omega^2\right)}{1 + \left(a_1{}^2 - 2b_1\right)\cdot\Omega^2 + b_1{}^2\Omega^4} \qquad (16–29)$$

Setting $\Omega = 0$ in Equation 16–29 gives the group delay for the low frequencies, $0 < \Omega < 1$, which is:

$$T_{gr0} = \frac{1}{\pi} \sum_{i} a_i \qquad (16–30)$$

The values for T_{gr0} are listed in Table 16–10, Section 16.9, from the first to the tenth order.

In addition, Figure 16–42 shows the group delay response versus the frequency for the first ten orders of all-pass filters.

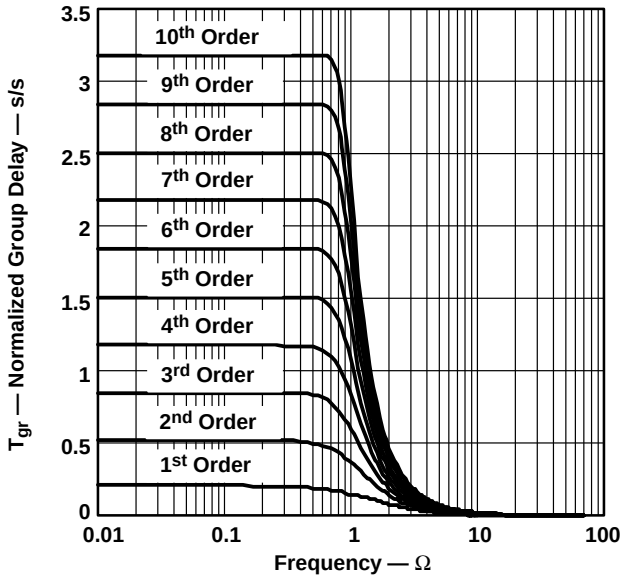

Figure 16–42. Frequency Response of the Group Delay for the First 10 Filter Orders

16.7.1 First-Order All-Pass Filter

Figure 16–43 shows a first-order all-pass filter with a gain of +1 at low frequencies and a gain of –1 at high frequencies. Therefore, the magnitude of the gain is 1, while the phase changes from 0° to –180°.

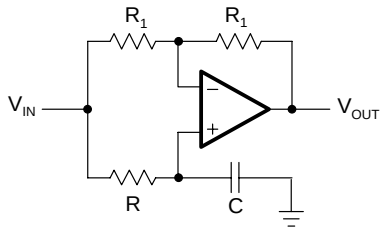

Figure 16–43. First-Order All-Pass

The transfer function of the circuit above is:

$$A(s) = \frac{1 - RC\omega_c \cdot s}{1 + RC\omega_c \cdot s}$$

The coefficient comparison with Equation 16–23 (b_1=1), results in:

$$a_i = RC \cdot 2\pi f_c \qquad (16–31)$$

To design a first-order all-pass, specify f_C and C and then solve for R:

$$R = \frac{a_i}{2\pi f_c \cdot C} \qquad (16–32)$$

Inserting Equation 16–31 into 16–30 and substituting ω_C with Equation 16–27 provides the maximum group delay of a first-order all-pass filter:

$$t_{gr0} = 2RC \qquad (16–33)$$

16.7.2 Second-Order All-Pass Filter

Figure 16–44 shows that one possible design for a second-order all-pass filter is to subtract the output voltage of a second-order band-pass filter from its input voltage.

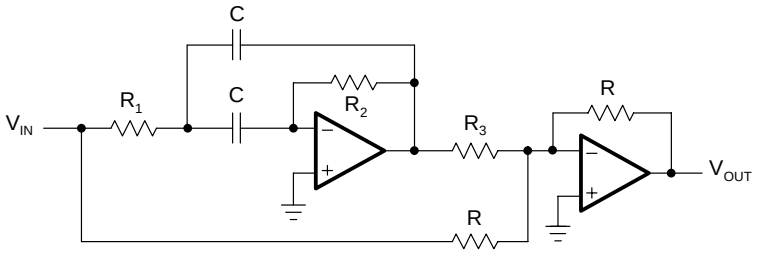

Figure 16–44. Second-Order All-Pass Filter

The transfer function of the circuit in Figure 16–44 is:

$$A(s) = \frac{1 + \left(2R_1 - \alpha R_2\right)C\omega_c \cdot s + R_1R_2C^2{\omega_c}^2 \cdot s^2}{1 + 2R_1C\omega_c \cdot s + R_1R_2C^2{\omega_c}^2 \cdot s^2}$$

The coefficient comparison with Equation 16–23 yields:

$$a_1 = 4\pi f_c R_1 C \tag{16–34}$$

$$b_1 = a_1 \pi f_c R_2 C \tag{16–35}$$

$$\alpha = \frac{{a_1}^2}{b_1} = \frac{R}{R_3} \tag{16–36}$$

To design the circuit, specify f_C, C, and R, and then solve for the resistor values:

$$R_1 = \frac{a_1}{4\pi f_c C} \tag{16–37}$$

$$R_2 = \frac{b_1}{a_1 \pi f_c C} \tag{16–38}$$

$$R_3 = \frac{R}{\alpha} \tag{16–39}$$

Inserting Equation 16–34 into Equation16–30 and substituting ω_C with Equation 16–27 gives the maximum group delay of a second-order all-pass filter:

$$t_{gr0} = 4R_1C \tag{16–40}$$

16.7.3 Higher-Order All-Pass Filter

Higher-order all-pass filters consist of cascaded first-order and second-order filter stages.

Example 16–7. 2-ms Delay All-Pass Filter

A signal with the frequency spectrum, 0 < f < 1 kHz, needs to be delayed by 2 ms. To keep the phase distortions at a minimum, the corner frequency of the all-pass filter must be $f_C \geq 1$ kHz.

Equation 16–27 determines the normalized group delay for frequencies below 1 kHz:

$$T_{gro} = \frac{t_{gr0}}{T_C} = 2\ \text{ms} \cdot 1\ \text{kHz} = 2.0$$

Figure 16–42 confirms that a seventh-order all-pass is needed to accomplish the desired delay. The exact value, however, is $T_{gr0} = 2.1737$. To set the group delay to precisely 2 ms, solve Equation 16–27 for f_C and obtain the corner frequency:

$$f_C = \frac{T_{gr0}}{t_{gr0}} = 1.087 \text{ kHz}$$

To complete the design, look up the filter coefficients for a seventh-order all-pass filter, specify C, and calculate the resistor values for each partial filter.

Cascading the first-order all-pass with the three second-order stages results in the desired seventh-order all-pass filter.

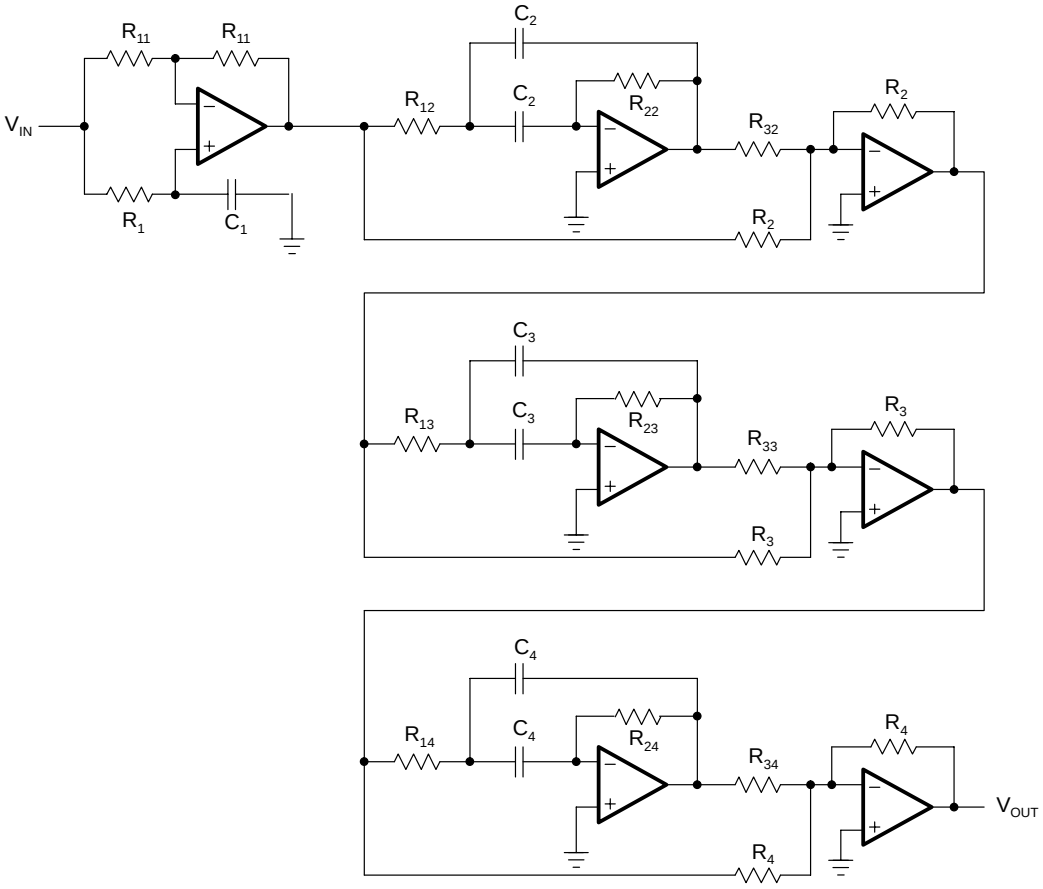

Figure 16–45. Seventh-Order All-Pass Filter

16.8 Practical Design Hints

This section introduces dc-biasing techniques for filter designs in single-supply applications, which are usually not required when operating with dual supplies. It also provides recommendations on selecting the type and value range of capacitors and resistors as well as the decision criteria for choosing the correct op amp.

16.8.1 Filter Circuit Biasing

The filter diagrams in this chapter are drawn for dual supply applications. The op amp operates from a positive and a negative supply, while the input and the output voltage are referenced to ground (Figure 16–46).

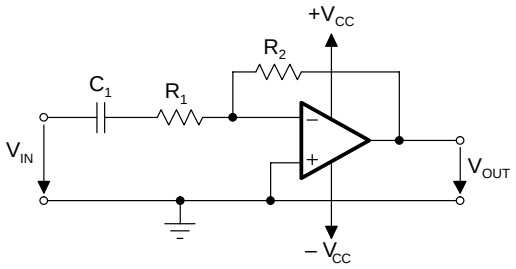

Figure 16–46. Dual-Supply Filter Circuit

For the single supply circuit in Figure 16–47, the lowest supply voltage is ground. For a symmetrical output signal, the potential of the noninverting input is level-shifted to midrail.

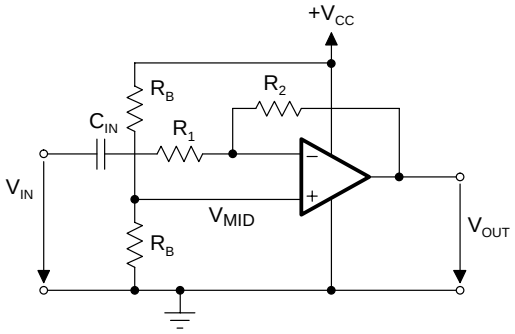

Figure 16–47. Single-Supply Filter Circuit

The coupling capacitor, C_{IN} in Figure 16–47, ac-couples the filter, blocking any unknown dc level in the signal source. The voltage divider, consisting of the two equal-bias resistors R_B, divides the supply voltage to V_{MID} and applies it to the inverting op amp input.

For simple filter input structures, passive RC networks often provide a low-cost biasing solution. In the case of more complex input structures, such as the input of a second-order

low-pass filter, the RC network can affect the filter characteristic. Then it is necessary to either include the biasing network into the filter calculations, or to insert an input buffer between biasing network and the actual filter circuit, as shown in Figure 16–48.

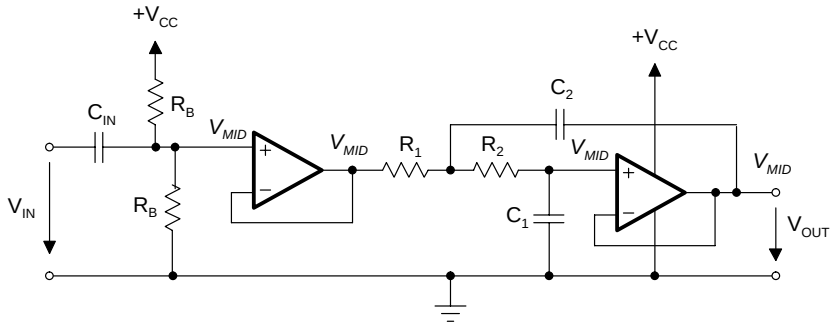

Figure 16–48. Biasing a Sallen-Key Low-Pass

C_{IN} ac-couples the filter, blocking any dc level in the signal source. V_{MID} is derived from V_{CC} via the voltage divider. The op amp operates as a voltage follower and as an impedance converter. V_{MID} is applied via the dc path, R_1 and R_2, to the noninverting input of the filter amplifier.

Note that the parallel circuit of the resistors, R_B , together with C_{IN} create a high-pass filter. To avoid any effect on the low-pass characteristic, the corner frequency of the input high-pass must be low versus the corner frequency of the actual low-pass.

The use of an input buffer causes no loading effects on the low-pass filter, thus keeping the filter calculation simple.

In the case of a higher-order filter, all following filter stages receive their bias level from the preceding filter amplifier.

Figure 16–49 shows the biasing of an multiple feedback (MFB) low-pass filter.

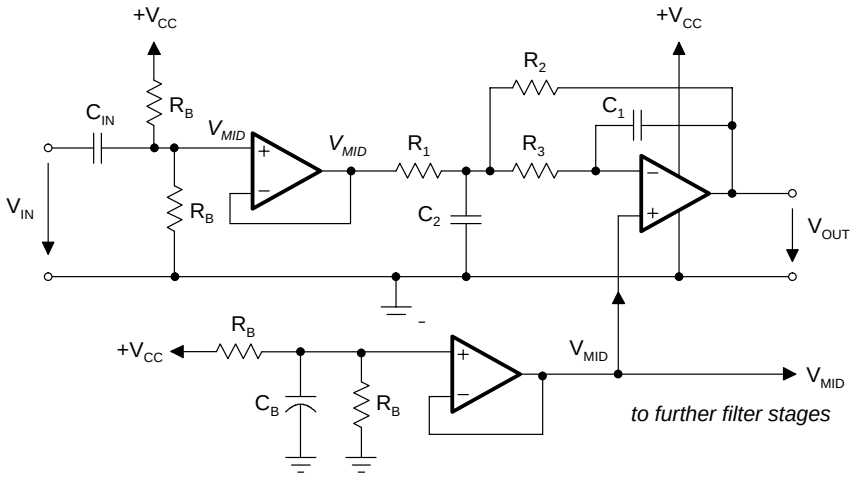

Figure 16–49. Biasing a Second-Order MFB Low-Pass Filter

The input buffer decouples the filter from the signal source. The filter itself is biased via the noninverting amplifier input. For that purpose, the bias voltage is taken from the output of a V_{MID} generator with low output impedance. The op amp operates as a difference amplifier and subtracts the bias voltage of the input buffer from the bias voltage of the V_{MID} generator, thus yielding a dc potential of V_{MID} at zero input signal.

A low-cost alternative is to remove the op amp and to use a passive biasing network instead. However, to keep loading effects at a minimum, the values for R_B must be significantly higher than without the op amp.

The biasing of a Sallen-Key and an MFB high-pass filter is shown in Figure 16–50.

The input capacitors of high-pass filters already provide the ac-coupling between filter and signal source. Both circuits use the V_{MID} generator from Figure 16–50 for biasing. While the MFB circuit is biased at the noninverting amplifier input, the Sallen-Key high-pass is biased via the only dc path available, which is R_1. In the ac circuit, the input signals travel via the low output impedance of the op amp to ground.

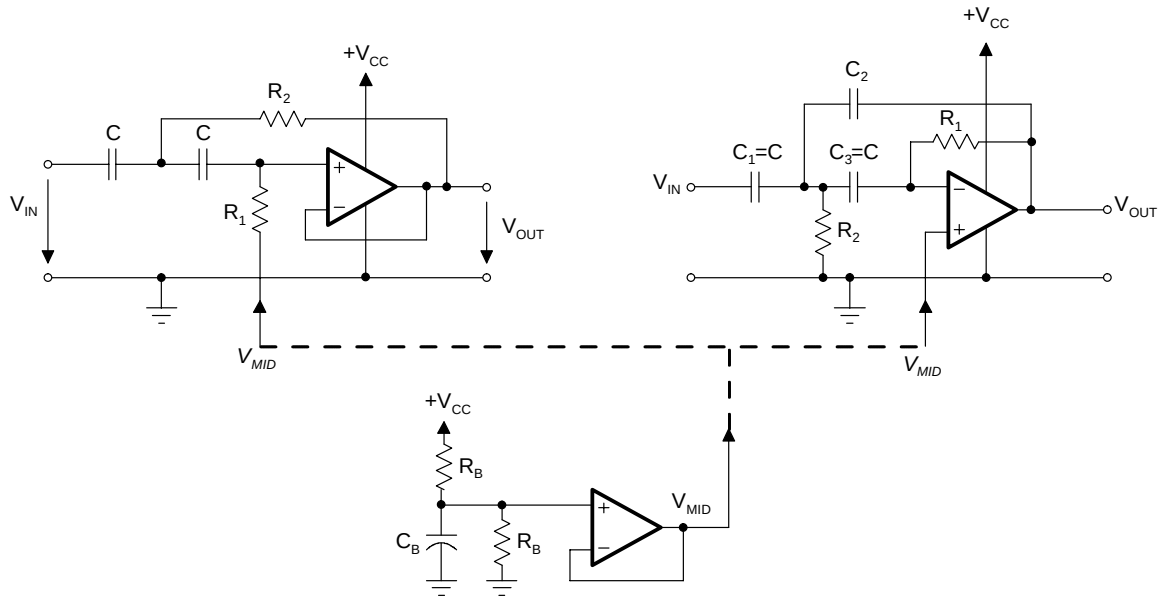

Figure 16–50. Biasing a Sallen-Key and an MFB High-Pass Filter

16.8.2 Capacitor Selection

The tolerance of the selected capacitors and resistors depends on the filter sensitivity and on the filter performance.

Sensitivity is the measure of the vulnerability of a filter's performance to changes in component values. The important filter parameters to consider are the corner frequency, f_C, and Q.

For example, when Q changes by $\pm$ 2% due to a $\pm$ 5% change in the capacitance value, then the sensitivity of Q to capacity changes is expressed as: $s\frac{Q}{C} = \frac{2\%}{5\%} = 0.4\frac{\%}{\%}$. The following sensitivity approximations apply to second-order Sallen-Key and MFB filters:

$$s\frac{Q}{C} \approx s\frac{Q}{R} \approx s\frac{f_c}{C} \approx s\frac{f_c}{R} \approx \pm\ 0.5\frac{\%}{\%}$$

Although 0.5 %/% is a small difference from the ideal parameter, in the case of higher-order filters, the combination of small Q and f_C differences in each partial filter can significantly modify the overall filter response from its intended characteristic.

Figures 16.51 and 16.52 show how an intended eighth-order Butterworth low-pass can turn into a low-pass with Tschebyscheff characteristic mainly due to capacitance changes from the partial filters.

Figure 16–51 shows the differences between the ideal and the actual frequency responses of the four partial filters. The overall filter responses are shown in Figure 16–52.

The difference between ideal and real response peaks with 0.35 dB at approximately 30 kHz, which is equivalent to an enormous 4.1% gain error can be seen.

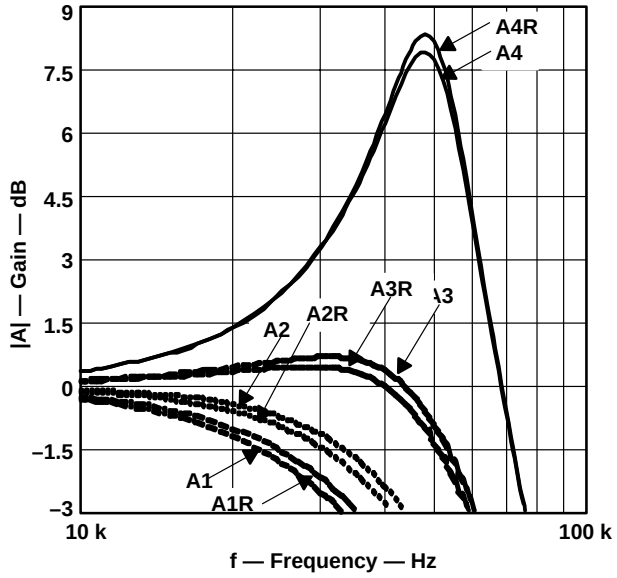

Figure 16–51. Differences in Q and f_C in the Partial Filters of an Eighth-Order Butterworth Low-Pass Filter

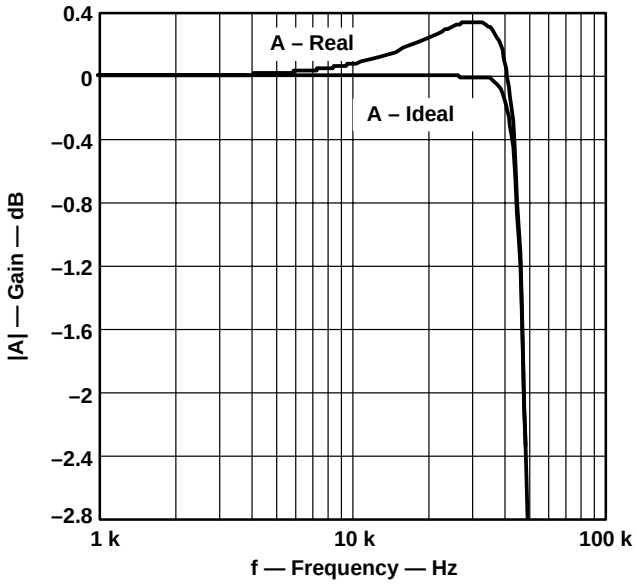

Figure 16–52. Modification of the Intended Butterworth Response to a Tschebyscheff-Type Characteristic

If this filter is intended for a data acquisition application, it could be used at best in a 4-bit system. In comparison, if the maximum full-scale error of a 12-bit system is given with ½ LSB, then maximum pass-band deviation would be – 0.001 dB, or 0.012%.

To minimize the variations of f_C and Q, NPO (COG) ceramic capacitors are recommended for high-performance filters. These capacitors hold their nominal value over a wide temperature and voltage range. The various temperature characteristics of ceramic capacitors are identified by a three-symbol code such as: COG, X7R, Z5U, and Y5V.

COG-type ceramic capacitors are the most precise. Their nominal values range from 0.5 pF to approximately 47 nF with initial tolerances from ± 0.25 pF for smaller values and up to ±1% for higher values. Their capacitance drift over temperature is typically 30ppm/°C.

X7R-type ceramic capacitors range from 100 pF to 2.2 µF with an initial tolerance of +1% and a capacitance drift over temperature of ±15%.

For higher values, tantalum electrolytic capacitors should be used.

Other precision capacitors are silver mica, metallized polycarbonate, and for high temperatures, polypropylene or polystyrene.

Since capacitor values are not as finely subdivided as resistor values, the capacitor values should be defined prior to selecting resistors. If precision capacitors are not available to provide an accurate filter response, then it is necessary to measure the individual capacitor values, and to calculate the resistors accordingly.

For high performance filters, 0.1% resistors are recommended.

16.8.3 Component Values

Resistor values should stay within the range of 1 kΩ to 100 kΩ. The lower limit avoids excessive current draw from the op amp output, which is particularly important for single-supply op amps in power-sensitive applications. Those amplifiers have typical output currents of between 1 mA and 5 mA. At a supply voltage of 5 V, this current translates to a minimum of 1 kΩ.

The upper limit of 100 kΩ is to avoid excessive resistor noise.

Capacitor values can range from 1 nF to several µF. The lower limit avoids coming too close to parasitic capacitances. If the common-mode input capacitance of the op amp, used in a Sallen-Key filter section, is close to 0.25% of C1, (C1 / 400), it must be considered for accurate filter response. The MFB topology, in comparison, does not require input-capacitance compensation.

16.8.4 Op Amp Selection

The most important op amp parameter for proper filter functionality is the unity-gain bandwidth. In general, the open-loop gain (A_{OL}) should be 100 times (40 dB above) the peak gain (Q) of a filter section to allow a maximum gain error of 1%.

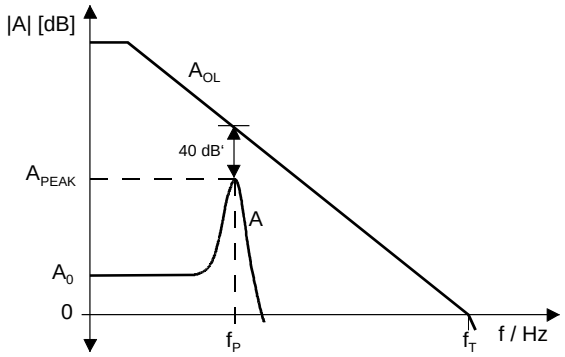

Figure 16–53. Open-Loop Gain (A_{OL}) and Filter Response (A)

The following equations are good rules of thumb to determine the necessary unity-gain bandwidth of an op amp for an individual filter section.

1) First-order filter:

$$f_T = 100 \cdot Gain \cdot f_c$$

2) Second-order filter (Q < 1):

$$f_T = 100 \cdot Gain \cdot f_c \cdot k_i \qquad \text{with} \qquad k_i = \frac{f_{ci}}{f_c}$$

3) Second-order filter (Q > 1):

$$f_T = 100 \cdot Gain \cdot \frac{f_c}{a_i} \sqrt{\frac{Q_i^2 - 0.5}{Q_i^2 - 0.25}}$$

For example, a fifth-order, 10-kHz, Tschebyscheff low-pass filter with 3-dB passband ripple and a dc gain of $A_0 = 2$ has its worst case Q in the third filter section. With $Q_3 = 8.82$ and $a_3 = 0.1172$, the op amp needs to have a unity-gain bandwidth of:

$$f_T = 100 \cdot 2 \cdot \frac{10\ kHz}{0.1172} \sqrt{\frac{8.82^2 - 0.5}{8.82^2 - 0.25}} = 17\ MHz$$

In comparison, a fifth-order unity-gain, 10-kHz, Butterworth low-pass filter has a worst case Q of $Q_3 = 1.62$; $a_3 = 0.618$. Due to the lower Q value, f_T is also lower and calculates to only:

$$f_T = 100 \cdot \frac{10\ \text{kHz}}{0.618} \sqrt{\frac{1.62^2 - 0.5}{1.62^2 - 0.25}} = 1.5\ \text{MHz}$$

Besides good dc performance, low noise, and low signal distortion, another important parameter that determines the speed of an op amp is the slew rate (SR). For adequate full-power response, the slew rate must be greater than:

$$SR = \pi \cdot V_{PP} \cdot f_C$$

For example, a single-supply, 100-kHz filter with 5 V_{PP} output requires a slew rate of at least:

$$SR = \pi \cdot 5V \cdot 100\ \text{kHz} = 1.57 \frac{V}{\mu s}$$

Texas Instruments offers a wide range of op amps for high-performance filters in single supply applications. Table 16–3 provides a selection of single-supply amplifiers sorted in order of rising slew rate.

16.9 Filter Coefficient Tables

The following tables contain the coefficients for the three filter types, Bessel, Butterworth and Tschebyscheff. The Tschebyscheff tables (Table 16–9) are split into categories for the following passband ripples: 0.5 dB, 1 dB, 2 dB, and 3 dB.

The table headers consist of the following quantities:

- n is the filter order
- i is the number of the partial filter.
- a_i, b_i are the filter coefficients.
- k_i is the ratio of the corner frequency of a partial filter, f_{Ci} , to the corner frequency of the overall filter, f_C. This ratio is used to determine the unity-gain bandwidth of the op amp, as well as to simplify the test of a filter design by measuring f_{Ci} and comparing it to f_C.
- Q_i is the quality factor of the partial filter.
- f_i / f_C this ratio is used for test purposes of the allpass filters, where f_i is the frequency, at which the phase is 180° for a second-order filter, respectively 90° for a first-order all-pass.
- T_{gr0} is the normalized group delay of the overall all-pass filter.

Circuit Board Layout Techniques

Bruce Carter

17.1 General Considerations

Prior discussions have focused on how to design op amp circuitry, how to use ICs, and the usage of associated passive components. There is one additional circuit component that must be considered for the design to be a success — the printed circuit board on which the circuit is to be located.

17.1.1 The PCB is a Component of the Op Amp Design

Op amp circuitry is analog circuitry, and is very different from digital circuitry. It must be partitioned in its own section of the board, using special layout techniques.

Printed circuit board effects become most apparent in high-speed analog circuits, but common mistakes described in this chapter can even affect the performance of audio circuits. The purpose of this chapter is to discuss some of the more common mistakes made by designers and how they degrade performance, and provide simple fixes to avoid the problems.

In all but very rare cases, the PCB layout for analog circuitry must be designed such that the effect of the PCB is transparent to the circuit. Any effect caused by the PCB itself should be minimized, so that the operation of the analog circuitry in production will be the same as the performance of the design and prototype.

17.1.2 Prototype, Prototype, PROTOTYPE!

Normal design cycles, particularly of large digital boards, dictate layout of the PCB as soon as possible. The digital circuitry has been simulated, but in most cases, the production PCB itself is the prototype, and may even be sold to a customer. Digital designers can correct small mistakes by implementing *cuts and jumpers*, reprogramming gate arrays or flash memories, and go on to the next project. This is not the case with analog circuitry. Some of the common design mistakes discussed in this chapter cannot be corrected by the cut and jumper method. They can and will render the entire PCB unusable. It is very

important for the digital designer, who is used to cuts and jumpers, to read and understand this chapter prior to releasing a board to a layout service.

A little care, taken up front, can save a board worth thousands of dollars from becoming scrap because of blunders in a tiny section of analog circuitry. This author has been the unfortunate recipient of a simple analog circuit designed by another engineer, who was accustomed to the cut and jumper method of correcting his mistakes. This resulted in a design that was full of mistakes. Not only was the op amp hooked up with inverting and noninverting inputs reversed, but an RC time constant had to be added to prevent a race condition. Repercussions from these mistakes, and associated rework problems, caused literally hundreds of hours to be lost from a tight production schedule. Prototyping this circuit would have taken less than a day. PROTOTYPE ALL ANALOG CIRCUITRY!

17.1.3 Noise Sources

Noise is the primary limitation on analog circuitry performance. Internal op amp noise is covered in Chapter 10. Other types of noise include:

- Conducted Emissions — noise that the analog circuitry generates through its connections to other circuits. This is usually negligible in analog circuitry, unless it is high power (such as an audio amplifier that draws heavy currents from its power supply).
- Radiated Emissions — noise that the analog circuitry generates, or transmits, through the air. This is also usually negligible in analog circuitry, unless it is high frequency such as video.
- Conducted Susceptibility — noise from external circuitry that is conducted into the analog circuit through its connections to other circuits. Analog circuitry must be connected to the “outside world” by at least a ground connection, a power connection, an input, and an output. Noise can be conducted into the circuit through all of these paths, as well as any others that are present.
- Radiated Susceptibility — noise that is received through the air (or transmitted into the analog circuitry) from external sources. Analog circuitry, in many cases, resides on a PCB that may have high-speed digital logic including DSP chips. High-speed clocks and switching digital signals create considerable radio frequency interference (RFI). Other sources of radiated noise are endless: the switching power supply in a digital system, cellular telephones, broadcast radio and TV, fluorescent lighting, nearby PCs, lightning in thunderstorms, and so on. Even if the analog circuitry is primarily audio in frequency, RFI may produce noticeable noise in the output.

17.2 PCB Mechanical Construction

It is important to choose a PCB with the right mechanical characteristics for the application.

17.2.1 Materials — Choosing the Right One for the Application

PC Board materials are available in various grades, as defined by the National Electrical Manufacturers Association (NEMA). It would be very convenient for designers if this organization was closely allied with the electronics industry — controlling parameters such as resistivity and dielectric constant of the material. Unfortunately, that is not the case. NEMA is an electrical safety organization, and the different PCB grades primarily describe the flammability, high temperature stability, and moisture absorption of the board. Therefore, specifying a given NEMA grade does not guarantee electrical parameters of the material. If this becomes critical for an application, consult the manufacturer of the raw board stock.

Laminated materials are designated with *FR* (flame resistant) and *G* grades. FR–1 is the least flame resistant, and FR–5 is the most. G10 and G11 have special characteristics as described in Table 17–1.

Table 17–1. PCB Materials

GRADE DESIGNATION	MATERIAL/COMMENTS
FR–1	Paper/phenolic: room temperature punchable, poor moisture resistance.
FR–2	Paper/phenolic: suitable for single-sided PCB consumer equipment, good moisture resistance.
FR–3	Paper/epoxy: designed for balance of good mechanical and electrical characteristics.
FR–4	Glass cloth/epoxy: excellent mechanical and electrical properties.
FR–5	Glass cloth/epoxy: high strength at elevated temperatures, self-extinguishing.
G10	Glass cloth/epoxy: high insulation resistance, highest bond strength of glass laminates, high humidity resistance.
G11	Glass cloth/epoxy: high flexural strength retention at high temperature, extreme resistance to solvents.

Do not use FR–1. There are many examples of boards with burned spots, where high wattage components have heated a section of the board for a period of time. This grade of PCB material has more in common with cardboard than anything else.

FR–4 is commonly used in industrial-quality equipment, while FR–2 is used in high-volume consumer applications. These two board materials appear to be industry standards. Deviating from these standards can limit the number of raw board material suppliers and PCB houses that can fabricate the board because their tooling is already set up for these materials. Nevertheless, there are applications in which one of the other grades may make sense. For very high frequency applications, it may even be necessary to consider

Teflon or even ceramic board substrate. One thing can be counted on, however: the more exotic the board substrate, the more expensive it will be.

In selecting a board material, pay careful attention to the moisture absorption. Just about every desirable performance characteristic of the board will be negatively impacted by moisture. This includes surface resistance of the board, dielectric leakage, high-voltage breakdown and arcing, and mechanical stability. Also, pay attention to the operating temperature. High operating temperatures can occur in unexpected places, such as in proximity to large digital ICs that are switching at high speeds. Be aware that heat rises, so if one of those 500-pin monster ICs is located directly under a sensitive analog circuit, both the PCB and circuit characteristics may vary with the temperature.

After the board substrate material has been selected, the next decision is how thick to make the copper foil laminated to it. For most applications, 1-ounce copper is sufficient. If the circuit consumes a lot of power, 2-ounce may be better. Avoid ½-ounce copper, because it tends to break between the trace and the pad.

17.2.2 How Many Layers are Best?

Depending on the complexity of the overall circuitry being designed, a designer must decide how many layers the PCB should be.

17.2.2.1 Single-Sided

Very simple consumer electronics are sometimes fabricated on single-sided PCBs, keeping the raw board material inexpensive (FR–1 or FR–2) with thin copper cladding. These designs frequently include many jumper wires, simulating the circuit routing on a double-sided board. This technique is only recommended for low-frequency circuitry. For reasons described below, this type of design is extremely susceptible to radiated noise. It is harder to design a board of this type, because of the many things can go wrong. Many complex designs have been successfully implemented with this technique, but they require a lot of forethought. An example is a television set that puts all of the analog circuitry on a single-sided board at the bottom of the case, and uses the metallized CRT itself to shield the board from a separate digital tuning board near the top of the set. Be prepared to get creative if the design demands high volume, low cost PCBs.

If a single-sided PCB is a requirement, remember the trace resistance! The op amp is not a 3-terminal device (inverting input, noninverting input, and output). It is a 7-terminal device as shown in Figure 17–1.

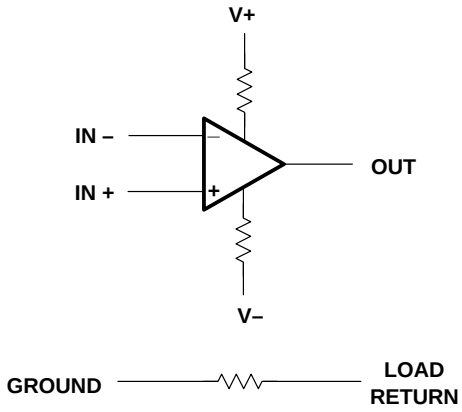

Figure 17–1. Op Amp Terminal Model

Resistance in the power leads of the device must be taken into account, as well as resistance between the return for the inputs and the load. Both the input and load must return somewhere. If these are at different potentials due to trace resistance, there can be problems.

17.2.2.2 Double-Sided

The next level of complexity is double-sided. Although there are some double-sided FR–2 boards, they are more commonly fabricated with FR–4 material. The increased strength of FR–4 material supports vias better. Doubled-sided boards are easier to route because there are two layers of foil, and it is possible to route signals by crossing traces on different layers. Crossing traces, however, is not recommended for analog circuitry. Wherever possible, the bottom layer should be devoted to a ground plane, and all other signals routed on the top layer. A ground plane provides several benefits:

- Ground is frequently the most common connection in the circuit. Having it continuous on the bottom layer usually makes the most sense for circuit routing.
- It increases mechanical strength of the board.
- It lowers the impedance of all ground connections in the circuit, which reduces undesirable conducted noise.
- It adds a distributed capacitance to every net in the circuit — helping to suppress radiated noise.
- It acts a shield to radiated noise coming from underneath the board.

17.2.2.3 Multi-Layer

Double-sided boards, in spite of their benefits, are not the best method of construction, especially for sensitive or high-speed designs. The most common board thickness is 1.5 mm. This separation is too great for full realization of some of the benefits listed above. Distributed capacitance, for example, is very low due to the separation.

Critical designs call for multi-layer boards. Some of the reasons are obvious:

- Better routing for power as well as ground connections. If the power is also on a plane, it is available to all points in the circuit simply by adding vias.
- Other layers are available for signal routing, making routing easier.
- There will be distributed capacitance between the power and ground planes, reducing high frequency noise.

There are other reasons for multi-layer boards, however, that may not be obvious or intuitive.

- Better EMI/RFI rejection. There is due to the *image plane effect*, which has been known since the time of Marconi. When a conductor is placed close to a parallel conductive surface, most of the high frequency currents will return directly under the conductor, flowing in the opposite direction. This mirror image of the conductor within the plane creates a transmission line. Since currents are equal and opposite in the transmission line, it is relatively immune to radiated noise. It also couples the signal very efficiently. The image plane effect works equally well with ground and power planes, but they must be continuous. Any gap or discontinuity causes the beneficial effects to quickly vanish. There is more on this in the following paragraphs.
- Reduced overall project cost for small production runs. Although multi-layer boards are more expensive to manufacture, EMI/RFI requirements from the FCC or other agencies may require expensive testing of the design. If there are problems, it can force a complete redesign of the PCB, leading to additional rounds of testing. A multi-layer PCB can have as much as 20-dB better EMI/RFI performance over a 2-layer PCB. If production volumes are going to be small, it makes sense to make a better PCB to begin with, than try to cut costs and take the risk of failing $25,000 to $50,000 tests.

17.2.3 Board Stack-Up — The Order of Layers

There has been a lot of confusion in the past over what is the optimum order for PCB layers. Take, for example, a 4-layer board consisting of two signal layers, a power plane, and a ground plane. Is it better to route the signal traces between the layers, thus providing shielding for the signal traces – or is it better to make the ground and power planes the two inner planes?

In considering this question, it is important to remember that no matter what is decided, there will still be signals exposed on one or both of the top and bottom planes. The leads of the op amp PCB package, and the traces on the board leading to nearby passive com-

ponents and feed-throughs will be exposed. Therefore, any shielding effects are compromised. It is far better to take advantage of the distributed capacitance between the power and ground plane by making them internal.

Another advantage of placing the planes internally is that the signal traces are available for probing and modification on the top and bottom layers. Anyone who has had to change connections on buried traces will appreciate this feature.

For more than four layers, it is a general rule to shield higher speed signals between the ground and power planes, and route slower signals on the outer layers.

17.3 Grounding

Good grounding is a system-level design consideration. It should be planned into the product from the first conceptual design reviews.

17.3.1 The Most Important Rule: Keep Grounds Separate

Separate grounding for analog and digital portions of circuitry is one of the simplest and most effective methods of noise suppression. One or more layers on multi-layer PCBs are usually devoted to ground planes. If the designer is not careful, the analog circuitry will be connected directly to these ground planes. The analog circuitry return, after all, is the same net in the netlist as digital return. Autorouters respond accordingly and connect all of the grounds together, creating a disaster.

After the fact separation of grounds on a mixed digital and analog board is almost impossible. Every ground connection in the analog circuitry must be lifted from the board and connected together. For surface mount boards, this results in a colossal mess of “tombstoned” passive components and floating IC leads.

17.3.2 Other Ground Rules

- Ground and power planes are at the same ac potential, due to decoupling capacitors and distributed capacitance. Therefore, it is important to isolate the power planes as well.
- Do not overlap digital and analog planes (Figure 17–2). Place analog power coincident with analog ground, and digital power coincident with digital ground. If any portion of analog and digital planes overlap, the distributed capacitance between the overlapping portions will couple high-speed digital noise into the analog circuitry. This defeats the purpose of isolated planes.

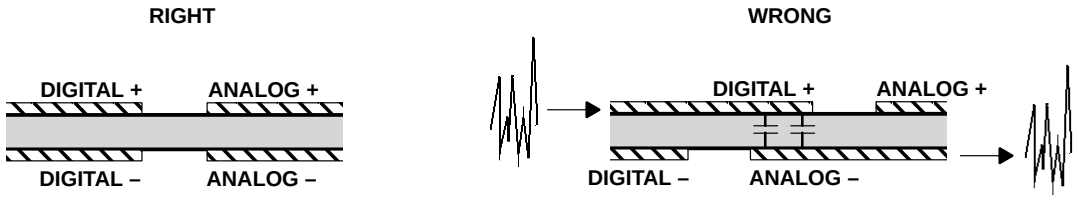

Figure 17–2. Digital and Analog Plane Placement

- *Separate grounds* does not mean that the grounds are electrically separate in the system. They have to be common at some point, preferably a single, low-impedance point. System-wise, there is only one ground, and it is the electrical safety ground in an ac-powered system or battery ground in a dc-powered system. Everything else "returns" to that ground. It would be a good idea to develop the discipline to refer to everything that is not a *ground* as a *return*. All returns should be connected together at a single point, which is system ground. At some point, this will be the chassis. It is important to avoid ground loops by multiple connections to the chassis. Ensuring only one chassis ground point is one of the most difficult aspects of system design.

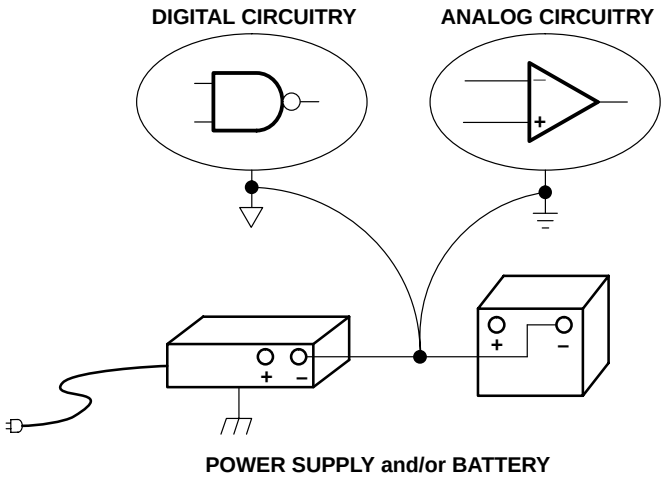

Figure 17–3. Separate Grounds

- If at all possible, dedicate separate connector pins to separate returns, and combine the returns only at system ground. Aging and repeated mating causes connector pins to increase in contact resistance, so several pins are needed. Many digital boards consist of many layers and hundreds or thousands of nets. The addition of one more net is seldom an issue, but the addition of several connector pins almost always is. If this cannot be done, then it will be necessary to make the two returns a single net on the PCB — with very special routing precautions.
- It is important to keep digital signals away from analog portions of the circuit. It makes little sense to isolate planes, keep analog traces short, and place passive

components carefully if there are high-speed digital traces running right next to the sensitive analog traces. Digital signals must be routed around analog circuitry, and not overlap analog ground and power planes. If not, the design will include a new schematic symbol shown in Figure 17–4 — the broadcasting antenna!

Most digital clocks are high enough in frequency that even small capacitances between traces and planes can couple significant noise. Remember that it is not only the fundamental frequency of the clock that can cause a potential problem, but also the higher frequency harmonics.

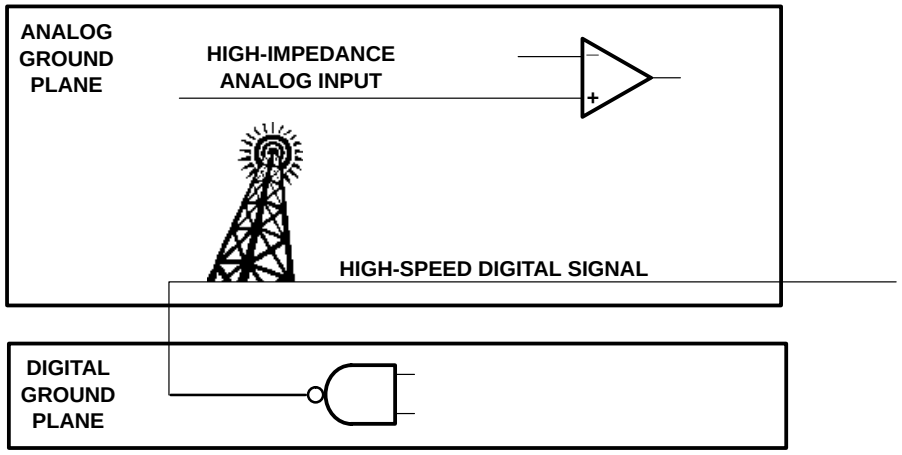

Figure 17–4. Broadcasting From PCB Traces

- It is a good idea to locate analog circuitry as close as possible to the I/O connections of the board. Digital designers, used to high current ICs, will be tempted to make a 50-mil trace run several inches to the analog circuitry thinking that reducing the resistance in the trace will help get rid of noise. What they have actually done is create a long, skinny capacitor that couples noise from digital ground and power planes into the op amp, making the problem worse!

17.3.3 A Good Example

Figure 17–5 shows one possible board layout. In this system, all electronics, including the power supply, reside on one PCB. Three separate and isolated ground/power planes are employed: one for power, one for digital, and one for analog. Power and ground connections from digital and analog sections of the board are combined only in the supply section, and are combined in close proximity. High-frequency conducted noise on the power lines is limited by inductors (chokes). In this case, the designer has even located low frequency analog circuitry close to low speed digital, keeping high frequency digital and analog physically apart on the board. This is a good, careful design that has a high likelihood of success — providing that good layout and decoupling rules are also followed.

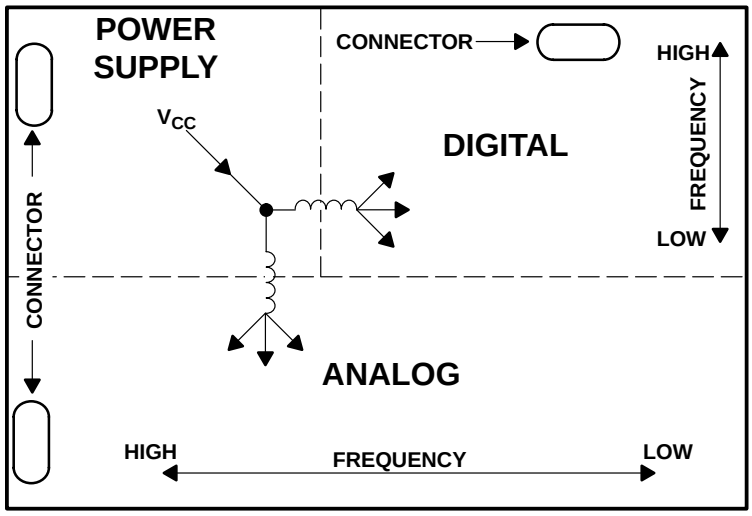

Figure 17–5. A Careful Board Layout

17.3.4 A Notable Exception

There is one case where it is necessary to combine analog and digital signals on the analog ground plane. Analog to digital (A/D) and digital to analog (D/A) converters are packaged as ICs with analog and digital ground pins coming out of the package. One might assume, based on the previous discussion, that the digital ground pin should be connected to digital ground and the analog ground pin to analog ground. That, however, is not correct.

The pin names *analog ground* and *digital ground* refer to internal connections in the IC, not the plane to which they should be connected. Both should connect to the analog ground plane. The connection would have been made inside the IC, but it is impossible to get low enough impedance at the typical geometries inside ICs. The IC designer actually counts on the end user to supply a low impedance connection outside the IC. Otherwise, the performance of the converter will be worse than specified.

One might suspect that the digital portions of the converter would make circuit performance worse by coupling digital switching noise onto the analog ground and power plane. Converter designers realize this, and design digital portions without a lot of output power to minimize switching transients. If the converter does not drive large fanouts, this should not be a problem. Be sure to properly decouple the logic supply for the converter to analog ground (see the following paragraphs).

17.4 The Frequency Characteristics of Passive Components

Choosing the right passive components for an analog design is important. In most cases, a *right* passive component will fit on the same pads as a *wrong* passive component, but not always. Start the design process by carefully considering the high frequency characteristics of passive components, and putting the correct part outline on the board from the start.

Most designers are totally ignorant of the frequency limitations of the passive components they use in analog circuitry. Passive components have limited frequency ranges, and operation of the part outside of that range can have some very unexpected results. One might think that this discussion only applies to high-speed analog circuits. But high frequencies that are radiated or conducted into a low-speed circuit will affect passive components as well. For example: a simple op amp low-pass filter may well turn into a high-pass filter at RF frequencies.

17.4.1 Resistors

High-frequency performance of resistors is approximated by the schematic shown in Figure 17–6.

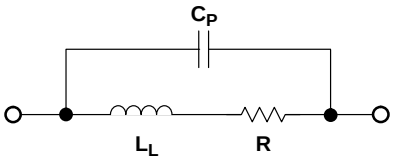

Figure 17–6. Resistor High-Frequency Performance

Resistors are typically one of three types: wire-wound, carbon composition, and film. It does not take a lot of imagination to understand how wire-wound resistors can become inductive because they are coils of resistive wire. Most designers are not aware of the internal construction of film resistors, which are also coils of thin metallic film. Therefore, film resistors are also inductive at high frequencies. The inductance of film resistors is lower, however, and values under 2 kΩ are usually suitable for high frequency work.

The end caps of resistors are parallel, and there will be an associated capacitance. Usually, the resistance will make the parasitic capacitor so “leaky” that the capacitance does not matter. For very high resistances, the capacitance will appear in parallel with the resistance, lowering its impedance at high frequencies.

17.4.2 Capacitors

High-frequency performance of capacitors is approximated by the schematic shown in FIgure 17–7.

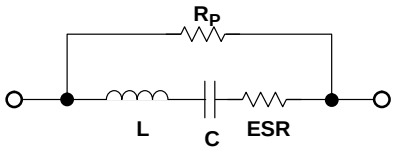

Figure 17–7. Capacitor High-Frequency Performance

Capacitors are used in analog circuitry for power supply decoupling and as filter components. For an ideal capacitor, reactance decreases by the formula:

$$X_C = \frac{1}{(2\pi fC)} \qquad (17–1)$$

Where:

X_C	capacitive reactance in Ohms
F	frequency in Hz
C	capacitance in microfarads

Therefore, a 10-µF electrolytic capacitor has a reactance of 1.6 Ω at 10 kHz, and 160-µΩ at 100 MHz. Right?

In reality, one will never see the 160 µΩ with the electrolytic capacitor. Film and electrolytic capacitors have layers of material wound around each other, which creates a parasitic inductance. Self-inductance effects of ceramic capacitors are much smaller, giving them a higher operating frequency. There is also some leakage current from plate to plate, which appears as a resistance in parallel with the capacitor, as well as resistance within the plates themselves, which add a parasitic series resistance. The electrolyte itself in electrolytic capacitors is not perfectly conductive (to reduce leakage current). These resistances combine to create the equivalent series resistance (ESR). The capacitors used for decoupling should be low ESR types, as any series resistance limits the effectiveness of the capacitor for ripple and noise rejection. Elevated temperatures also severely increase ESR, and can be permanently destructive to capacitors. Therefore, if an aluminum electrolytic will be subjected to high temperatures, use the high-temperature grade (105°C), not the low temperature grade (85°C).

For leaded parts, the leads themselves also add a parasitic inductance. For small values of capacitance, it is important to keep the lead lengths short. The combination of parasitic inductance and capacitance can produce resonant circuits! Assuming a lead self-inductance of 8 nH/cm (see the following paragraphs), a 0.01-µF capacitor with two 1-cm leads will resonate at 12.5 MHz. This effect was well known to engineers many decades ago,

who designed vacuum tube-based products with leaded components. Woe be to any hobbyist restoring antique radios that is unaware of this effect!

If electrolytic capacitors are used in a design, make sure that the polarity is correctly observed. The positive terminal of the capacitor must be connected to the more positive of two dc potentials. If there is any doubt whatsoever which polarity is correct, design calculations must continue until it is known, or a prototype must be built. Incorrect polarity of electrolytic capacitors will cause them to conduct dc current, in most cases destroying the part — and probably the rest of the circuit as well. If there is a rare case in which there will be both polarities present, use a nonpolarized electrolytic (which is constructed by connecting two polarized electrolytic capacitors in series). Of course, one can always connect two capacitors in series on the PCB, keeping in mind that the effective capacitance will be cut in half for equal values of capacitor.

17.4.3 Inductors

High frequency performance of inductors is approximated by the schematic shown in Figure 17–8.

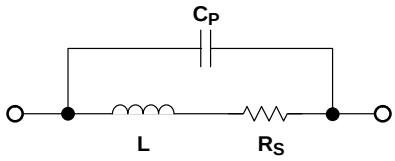

Figure 17–8. Inductor High-Frequency Performance

Inductive reactance is described by the formula:

$$X_L = 2\pi fL \qquad (17–2)$$

Where:

X_L	inductive reactance in Ohms
F	frequency in Hz
L	inductance in Henrys

Therefore, a 10-mH inductor has a reactance of 628 Ω at 10 kHz, which increases to 6.28 MΩ at 100 MHz. Right?

In reality, one will never see the 6.28 MΩ with this inductor. Parasitic resistances are easy to understand — the inductor is constructed of wire, which has a given resistance per unit length. Parasitic capacitance is harder to visualize, unless one considers the fact that each turn of wire in the inductor is located next to adjacent turns, forming a capacitor. This parasitic capacitance limits the upper frequency of this inductor to under 1 MHz. Even small wire-wound inductors start to become ineffective in the 10 MHz to 100 MHz range.

17.4.4 Unexpected PCB Passive Components

In addition to the obvious passive components above, the PCB itself has characteristics that form components every bit as real as those discussed previously — just not as obvious.

17.4.4.1 PCB Trace Characteristics

The layout pattern on a PCB can make it susceptible to radiated noise. A good layout is one that minimizes the susceptibility of analog circuitry to as many radiated noise sources as possible. Unfortunately, there is always a level of RF energy that will be able to upset the normal operation of the circuit. If good design techniques are followed, that level will be one that the circuit never encounters in normal operation.

17.4.4.1.1 *Trace Antennas*

A board is susceptible because the pattern of traces and component leads form antennas. Antenna theory is a complex subject, well beyond the scope of this book. Nevertheless, a few basics are presented here.

One basic type of antenna is the whip, or straight conductor. This antenna works because a straight conductor has parasitic inductance, and therefore can concentrate flux from external sources. The impedance of any straight conductor has a resistive and an inductive component:

$$Z = R + j\omega L \tag{17–3}$$

For dc and low frequencies, resistance is the major factor. As the frequency increases, however, the inductance becomes more important. Somewhere in the range of 1 kHz to 10 kHz, the inductive reactance exceeds the resistance, so the conductor is no longer a low resistance connection, but rather an inductor.

The formula for the inductance of a PCB trace is:

$$L(\mu H) = 0.0002X \cdot \left[\ln\left(\frac{2X}{W + H}\right) + 0.2235\left(\frac{W + H}{X}\right) + 0.5 \right] \tag{17–4}$$

Where:

X	length of the trace
W	width of the trace
H	thickness of the trace

The inductance is relatively unaffected by the diameter, since it varies as the logarithm of the circumference. Common wires and PCB traces vary between 6 nH and 12 nH per centimeter.

For example, a 10 cm PCB trace has a resistance of 57 mΩ and an inductance of 8 nH per cm. At 100 kHz, the inductive reactance reaches 50 mΩ. At frequencies above 100 kHz, the trace is inductive — not resistive.

A rule of thumb for whip antennas is that they begin to couple significant energy at about 1/20 of the wavelength of the received signal, peaking at ¼ the wavelength. Therefore, the 10-cm conductor of the previous paragraph will begin to be a fairly good antenna at frequencies above 150 MHz. Remember that although the clock generator on a digital PCB may not be operating at a frequency as high as 150 MHz, it approximates a square wave. Square waves will have harmonics throughout the frequency range where PCB conductors become efficient antennas. If through-hole components are mounted in a way that leaves significant lead length, those component leads also become antennas, particularly if they are bent.

Another major type of antenna is the loop. The inductance of a straight conductor is dramatically increased by bending it into partial or complete loops. Increased inductance lowers the frequency at which the conductor couples radiated signals into the circuit.

Without realizing it, most digital designers are well versed in loop antenna theory. They know not to make loops in critical signal pathways. Some designers, however, that would never think of making a loop with a high speed clock or reset signal will turn right around and create a loop by the technique they use for layout of the analog section of the board. Loop antennas constructed as loops of wire are easy to visualize. What is not as obvious is that slot antennas are just as efficient. Consider the three cases shown in Figure 17–9.

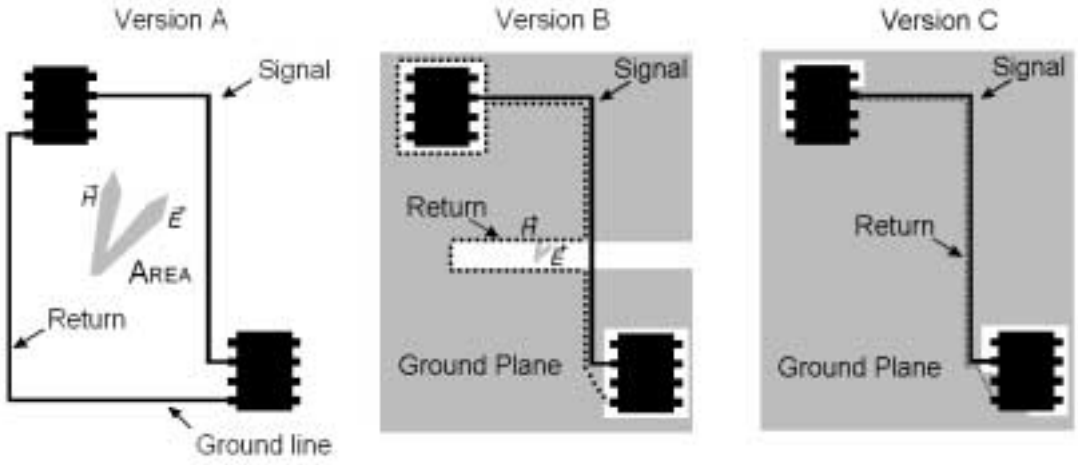

Figure 17–9. Loop and Slot Antenna Board Trace Layouts

Version **A** is a poor design. It does not use an analog ground plane at all. A loop is formed by the ground and signal traces. An electric field *E* and perpendicular magnetic field *H* are created, and form the basis of a loop antenna. A rule of thumb for loop antennas is that the length of each leg is equal to half the most efficiently received wavelength. Remember, however, that even at 1/20 of the wavelength, the loop will still be a fairly efficient antenna.

Version **B** is a better design, but there is intrusion into the ground plane, presumably to make room for a signal trace. A much smaller slot antenna is formed by the difference in pathways between signal and return. A second loop is created by the cutout for the IC.

Version **C** is the best design. Signal and return are coincident with each other, eliminating loop antenna effects completely. Note that there is still a cutout for the IC, but it is located away from the return path for the signal.

17.4.4.1.2 *Trace Reflections*

Reflections and matching are closely related to loop antenna theory, but different enough to warrant their own discussion.

When a PCB trace turns a corner at a 90° angle, a reflection can occur. This is primarily due to the change of width of the trace. At the apex of the turn, the trace width is increased to 1.414 times its width. This upsets the transmission line characteristics, especially the distributed capacitance and self–inductance of the trace — resulting in the reflection. It is a given that not all PCB traces can be straight, and so they will have to turn corners. Most CAD systems give some rounding effect on the trace. Sharp 90° corners in traces are a relic of the *tape up* days of PCB layout. The rounding effects of CAD programs, however, still do not necessarily maintain constant width as the trace rounds the corner. Figure 17–10 shows progressively better techniques of rounding corners. Only the last example maintains constant trace width and minimizes reflections. Most CAD programs now support these methods, but they can entail a little more work to master.

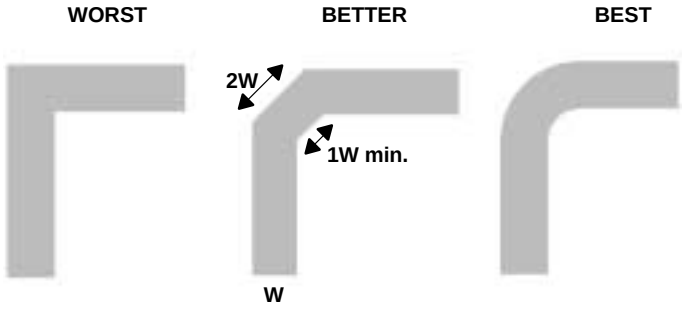

Figure 17–10. PCB Trace Corners

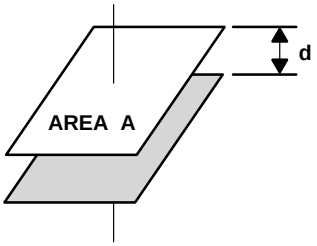
A suggestion for the advanced PCB layout engineer: leave rounding to the last step before tear-dropping and flood-filling. Otherwise, the CAD program will slow down doing numerical calculations as the traces are moved around during routing.

17.4.4.2 Trace-to-Plane Capacitors

PCB traces, being composed of foil, form capacitance with other traces that they cross on other layers. For two traces crossing each other on adjacent planes, this is seldom a problem. Coincident traces (those that occupy the same routing on different layers), form a long, skinny capacitor. The formula for capacitance is shown in Figure 17–11.



$$C = 0.0085 \times \epsilon_R \times \frac{A}{d}$$

where:

C = capacitance (pF)

ϵ_R = dielectric constant

A = area of plate (mm^2)

d = separation of plates (mm)

Figure 17–11. PCB Trace-to-Plane Capacitance Formula

For example, if the capacitance formula is applied to the following trace:

- 4 Layer board — signal routing next to ground plane
- Board layer thickness: 0.188 mm
- Trace Width: 0.75 mm
- Trace Length: 7.5 mm

A typical value for E_R of FR–4 PCB material is 4.5. Due to the variations of material from which an FR–4 board can be fabricated, this value is not guaranteed, but should be in the range of 4 to 5.

The capacitance between these traces would be 1.1 pF. Of course, the antenna effect on a 7.5-mm trace would be devastating, so this example is a bit extreme. Ignoring the antenna effects for now, there are cases in which even a very small parasitic capacitance like 1 pF is unacceptable. Figure 17–12 dramatically illustrates the effect of 1 pF capacitance occurring at the inverting input of the op amp. It causes a doubling of the output amplitude near the bandwidth limit of the op amp. This is an invitation to oscillation, especially since the trace is an efficient antenna above 180 MHz.

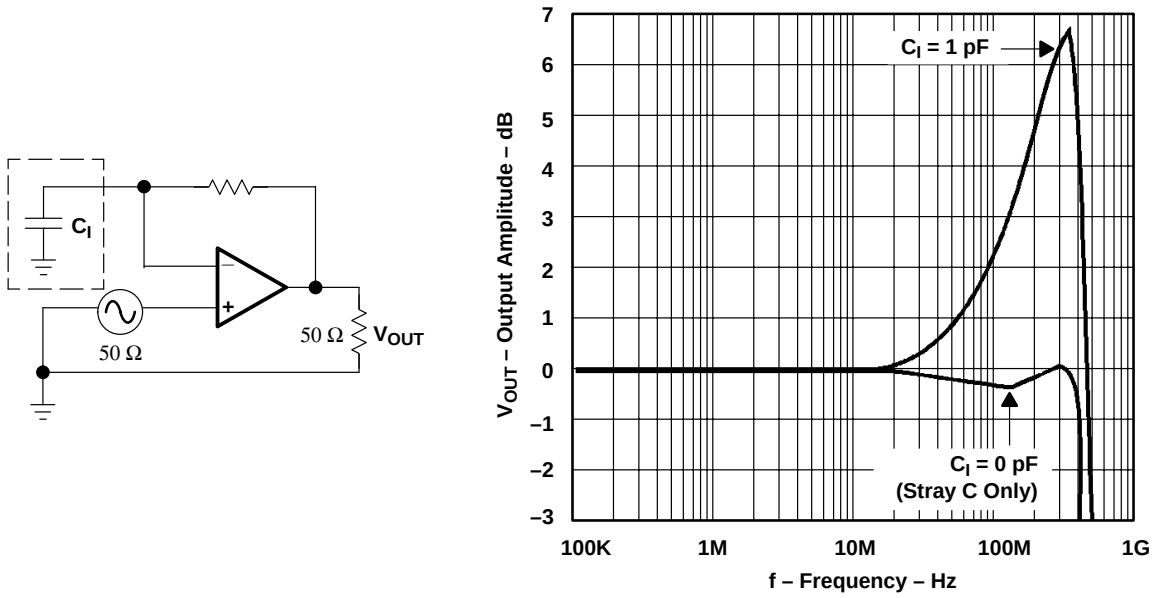


Figure 17–12. Effect of 1-pF Capacitance on Op Amp Inverting Input

There are numerous fixes to the problem above. The most obvious would be to shorten the length of the traces. Another not-so-obvious fix would be to use a different trace width. There is no reason why an inverting op amp trace has to be 0.75 mm wide — it carries almost no current. If the trace length is reduced to 2.5 mm (one third as long) and the trace width is changed to 0.188 mm (1/4 as wide), the capacitance becomes 0.1 pF — much less significant in the example above. Another fix is to remove the ground plane under the inverting input and the traces leading to it.

The inverting input of op amps, particularly high-speed op amps, is especially prone to oscillation in high gain circuits. This is due to unwanted capacitance on the input stage. It is important to minimize capacitance on this input by reducing trace width and placing components as close as possible to this input. If this input still oscillates, it may be necessary to scale the input and feedback resistors lower by a decade or two to change the resonance of the circuit. Scaling the resistors up will seldom help, as the problem is also related to the impedance of the circuit. If filter components are involved, they will also have to be scaled to avoid changing the filter characteristics of the circuit. The power consumption of the circuit will also increase if resistors are lowered.

17.4.4.3 Trace-to-Trace Capacitors and Inductors

PCB traces are not infinitely thin. They have some finite thickness, as defined by the *ounce* parameter of the copper clad foil. The higher the number of ounces, the thicker the copper. If two traces run side-by-side, then there will be capacitive and inductive coupling

between them (Figure 17–13). The formulas for these parasitic effects can be found in transmission line and/or microstrip references, but are too complex for inclusion here.

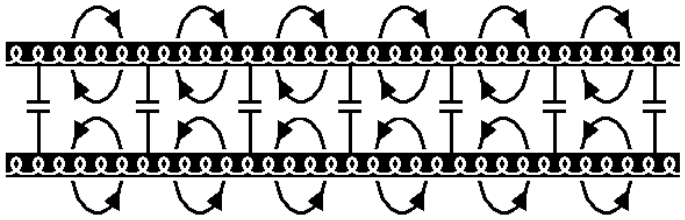

Figure 17–13. Coupling Between Parallel Signal Traces

Signal lines should not be routed parallel to each other, unless transmission line or microstrip effects are desired. Otherwise, a gap of at least three times the signal trace width should be maintained.

Capacitance between traces in an analog design can become a problem if fixed resistors in the design are large (several MΩ). Capacitance between the inverting and noninverting inputs of an op amp could easily cause oscillation.

17.4.4.4 Inductive Vias

Whenever routing constraints force a *via* (connection between layers of a PCB, FIgure 17–14), a parasitic inductor is also formed. At a given diameter (d) the approximate inductance (L) of an via at a height of (h) may be calculated as follows:

$$L = \approx \frac{h}{5} \times \left(1 + \ln\left(\frac{4h}{d}\right)\right) nH \qquad (17–5)$$

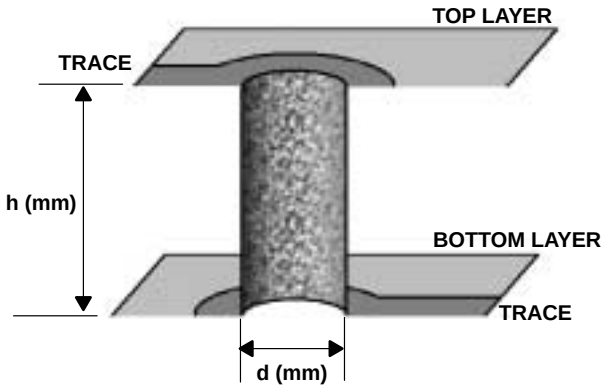

Figure 17–14. Via Inductance Measurements

For example, a 0.4-mm diameter via through a 1.5-mm thick PCB has an inductance of 1.1 nH.

Keep in mind that inductive vias combined with parasitic capacitance can form resonant circuits. The self-inductance of a via is small enough that these resonances are in the GHz range, but inductors add in series, lowering the resonant frequency. Do not put several vias on a critical trace of a high-speed analog circuit! Another concern is that the vias put holes in ground planes, potentially creating ground loops. They should be avoided — the best analog layout is one that routes all signal traces on the top layer of the PCB.

17.4.4.5 Flux Residue Resistance

Yes, even an unclean board can affect analog circuit performance.

Be aware that if the circuit has very high resistances — even in the low MΩ — special attention may need to be paid to cleaning. A finished assembly may be adversely affected by flux or cleansing residue. The electronics industry in the past few years has joined the rest of the world in becoming environmentally responsible. Hazardous chemicals are being removed from the manufacturing process — including flux that has to be cleaned with organic solvents. Water-soluble fluxes are becoming more common, but water itself can become contaminated easily with impurities. These impurities will lower the insulation characteristics of the PCB substrate. It is vitally important to clean with freshly distilled water every time a high-impedance circuit is cleaned. There are applications that may call for the older organic fluxes and solvents, such as very low power battery powered equipment with resistors in the 10s of MΩ range. Nothing can beat a good vapor defluxing machine for ensuring that the board is clean.

17.5 Decoupling

Noise, of course, can propagate into analog circuitry through the power pins of the circuit as a whole and op amp itself. Bypass capacitors are used to reduce the coupled noise by providing low impedance power sources local to the analog circuitry.

17.5.1 Digital Circuitry — A Major Problem for Analog Circuitry

If analog circuitry is located on the same board with digital circuitry, it is important to understand a little about the electrical characteristics of digital gates.

A typical digital output consists of two transistors connected in series between power and ground (Figure 17–15). One transistor is turned on and the other turned off to produce logic high and vice versa for logic low. Because one transistor is turned off for either logic state, the power consumption for either logic state is low, while the gate is static at that level.

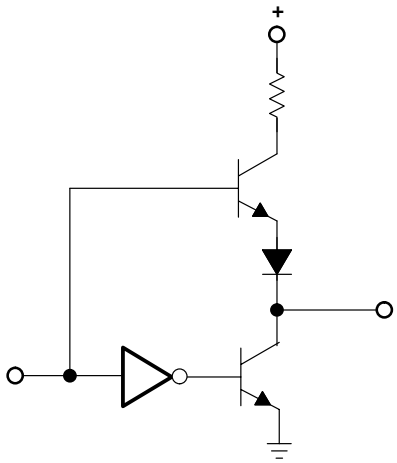

Figure 17–15. Logic Gate Output Structure

The situation changes dramatically whenever the output switches from one logic state to the other. There may be a brief period of time when both transistors conduct simultaneously. During this period of time, current drawn from the power supply increases dramatically — since there is now a low impedance path through the two transistors from power to ground. Power consumption rises dramatically and then falls, creating a droop on the power supply voltage, and a corresponding current spike. The current spike will radiate radio frequency (RF) energy. There may be dozens, or even hundreds of such outputs on a digital IC, so the aggregate effect may be quite dramatic.

It is impossible to predict the frequencies of these spikes, because the frequencies are affected by the propagation delays of the transistors in the gate. Propagation delay is affected by random factors that occur during manufacture. Digital switching noise will be broadband, with harmonics throughout the spectrum. A general rejection technique is required, rather than one that rejects a specific frequency.

17.5.2 Choosing the Right Capacitor

Table 17–2 is a rough guideline describing the maximum useful frequencies of common capacitor types.

Table 17–2. Recommended Maximum Frequencies for Capacitors

TYPE	MAX FREQUENCY
Aluminum Electrolytic	100 kHz
Tantalum Electrolytic	1 MHz
Mica	500 MHz
Ceramic	1 GHz

Obviously from the table, tantalum electrolytic capacitors are useless for frequencies above 1 MHz. Effective high frequency decoupling at higher frequencies demands a ceramic capacitor. Self-resonances of the capacitor must be known and avoided or the capacitor may not help, or even make the problem worse. Figure 17–16 illustrates the typical self-resonance of two capacitors commonly used for bypassing — 10 μF tantalum electrolytic and 0.01 μF ceramic.

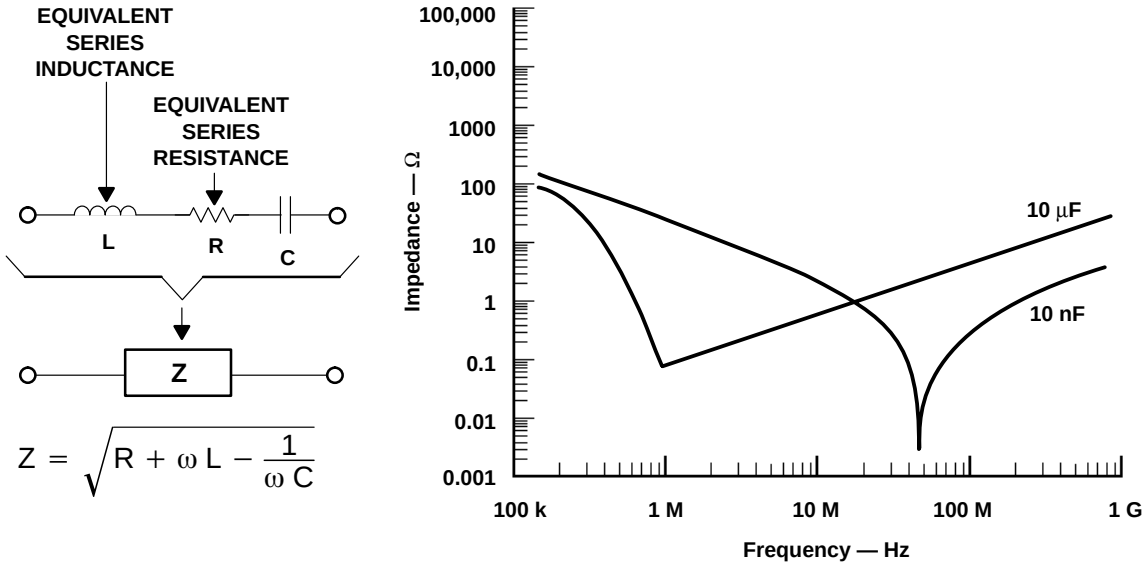

Figure 17–16. Capacitor Self Resonance

Consider these resonances to be typical values, the characteristics of actual capacitors can vary from manufacturer to manufacturer and grade of part to grade of part. The important thing is to make sure that the self-resonance of the capacitor occurs at a frequency above the range of the noise that must be rejected. Otherwise, the capacitor will enter a region where it is inductive.

Do not assume that a single 0.1-μF capacitor will decouple all frequencies. Smaller capacitors may work better at higher frequencies than larger ones. When poor decoupling at higher frequencies is suspected, try a smaller capacitor rather than a larger one.

17.5.3 Decoupling at the IC Level

The method most often used to decouple the high-frequency noise is to include a capacitor, or multiple capacitors connected from the op amp power pin to the op amp ground pin. It is important to keep the traces on this decoupling capacitor short. If not, the traces on the PCB will have significant self-inductance, defeating the purpose of the capacitor.

A decoupling capacitor must be included on every op amp package — whether it contains 1, 2 or 4 devices per package. The value of capacitor must be picked carefully to reject the type of noise present in the circuit.

In particularly troublesome cases, it may be necessary to add a series inductor into the power supply line connecting to the op amp. This inductor is in addition to the decoupling capacitors, which are the first line of defense. The inductor should be located before, not after the capacitors.

Another technique that is lower in cost is to replace the series inductor with a small resistor in the 10-Ω to 100-Ω range. The resistor forms a low-pass filter with the decoupling capacitors. There is a penalty to pay for this technique — depending on the power consumption of the op amp, it will reduce the rail-to-rail voltage range. The resistor forms a voltage divider with the op amp as a resistive active component in the lower leg of the divider. Depending on the application, this may or may not be acceptable.

17.5.4 Decoupling at the Board Level

There is usually enough low frequency ripple on the power supply at the board input to warrant a bulk decoupling capacitor at the power input. This capacitor is used primarily to reject low frequency signals, so an aluminum or tantalum capacitor is acceptable. An additional ceramic cap at the power input will decouple any stray high frequency switching noise that may be coupled off of the other boards.

17.6 Input and Output Isolation

Many noise problems are the result of noise being conducted into the circuit through its input and output pins. Due to the high-frequency limitations of passive components, the response of the circuit to high frequency noise may be quite unpredictable.

In situations in which conducted noise is substantially different in frequency from the normal operating range of the circuit, the solution may be as simple as a passive RC low-pass filter that rejects RF frequencies while having negligible effect at audio frequencies. A good example is RF noise being conducted into an audio op amp circuit. Be careful, though. A low pass filter loses its characteristics at 100 to 1000 times f_{3db}. More stages may be required to cover different frequency ranges. If this is the case, make the highest frequency filter the one nearest to the source of noise. Inductors or ferrite beads can also be used in a noise rejection filter network to eliminate conducted noise. Ferrite beads are inductive up to a specified frequency, and then become resistive.

The effect of radiated energy coupling into an analog circuit can be so bad that the only solution to the problem may be to completely shield the circuit from radiated energy. This shield is called a *Faraday Cage*, and must be carefully designed so that frequencies that

are causing the problem are not allowed to enter the circuit. This means that the shield must have no holes or slots larger that 1/20 the wavelength of the offending frequency. This can be a demanding requirement. It is a good idea to design a PCB from the beginning to have enough room to add a metal shield if it becomes necessary. If a shield is used, frequently the problem will be severe enough that ferrite beads will also be required on all connections to the circuit.

17.7 Packages

Op amps are commonly supplied one, two, or four per package. Single op amps often contain additional inputs for features such as offset nulling. Op amps supplied two and four per package only offer inverting and noninverting inputs, and the output. If the additional features are important, the only package choice is single. Be aware, though, that the offset-nulling pins on a single op amp package can act as secondary inputs, and must be treated carefully. Consult the data sheet on the particular device being used.

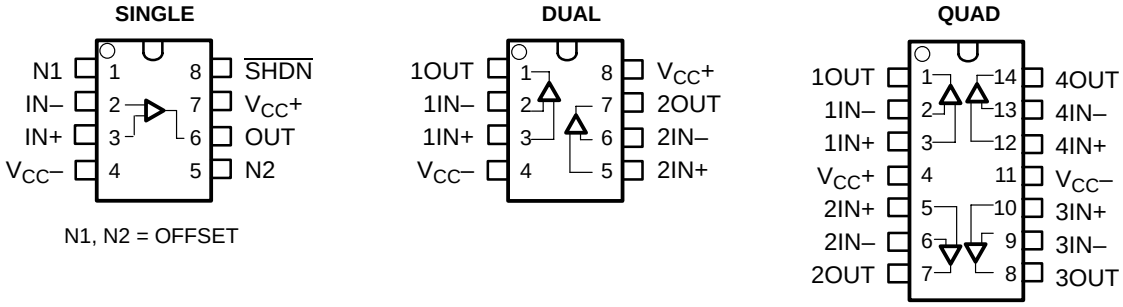

Figure 17–17. Common Op Amp Pinouts

The single op amp package places the output on the opposite side from the inputs. This can be a disadvantage at high speeds, because it forces longer PCB traces. One way to overcome this difficulty is to use a surface-mount package, and mount the feedback components on the rear of the board. This, however, adds at least two vias to the design, and places a hole in the ground plane for a 2-layer design. It may make more sense to use a dual op amp package, even if the second op amp is unused (remember to terminate it properly — see paragraph 17.7.3). Figure 17–18 is an illustration of trace length for an inverting op amp stage.

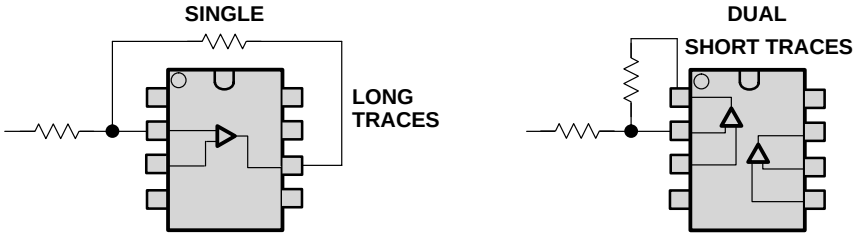

Figure 17–18. Trace Length for an Inverting Op Amp Stage

It is popular to use dual op amps for stereophonic circuits, and quad op amps for filter stages with many sections. There is a penalty for doing so, however. Although modern processing techniques provide high levels of isolation between amplifiers on the same piece of silicon, there will be some crosstalk. If isolation between amplifiers is important, then single packages should be considered. Crosstalk problems are not limited to the IC – the dual and quad packages place a high density of passive components in close proximity to each other. This proximity will lead to some crosstalk.

Dual and quad op amp packages offer some additional benefits beyond density. The amplifier stages tend to be mirror images of each other. If similar stages are to be laid out on the PCB, the layout only needs to be done once, then it can be mirror-imaged to form the other stage. Figure 17–19 illustrates this effect for four inverting op amp stages implemented in a quad package:

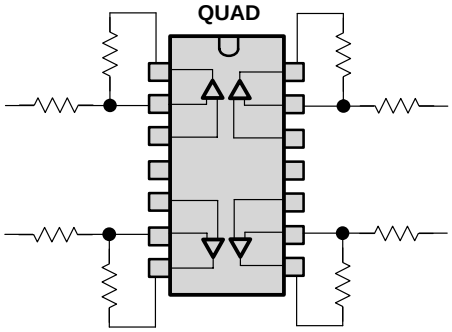

Figure 17–19. Mirror-Image Layout for Quad Op Amp Package

These illustrations, however, do not show all connections required for operation, in particular, the half-supply generator for single-supply operation. Modifying the diagram of Figure 17–19 to use the fourth op amp as a half supply generator is shown in Figure 17–20.

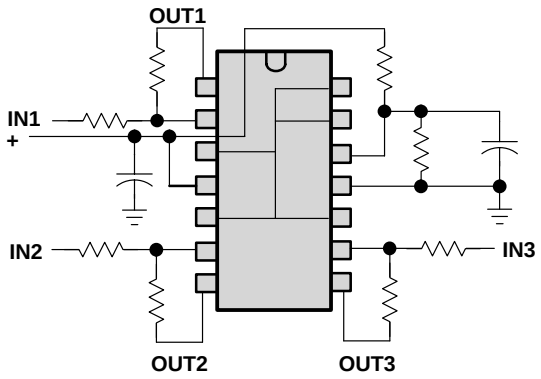

Figure 17–20. Quad Op Amp Package Layout with Half-Supply Generator

This example shows all of the connections actually required to produce three independent inverting stages. Note that the half-supply connection can be made entirely under the IC, keeping the trace length short. This example is not meant to be used as a suggested PCB layout, it merely illustrates what can be done. The half-supply op amp, for example, could be any one of the four. The passive components can be selected so that they span the lead pitch. Surface-mount 0402 packages, for example, span a width equal to or less than a standard SO package. This can keep traces lengths extremely short for high frequency applications.

Package styles for op amps include the dual-in-line (DIP) and small-outline (SO). Lead pitches for op amps have been continually decreasing, as has been the case for all ICs in general. Decreasing lead pitches have been accompanied by a decrease in the size of passive components as well. Decreasing the overall circuit dimensions reduces parasitic inductance, which should allow higher frequency circuits, but it also increases the potential for crosstalk by placing conductors closer to each other where capacitive effects increase.

17.7.1 Through-Hole Considerations

The older technology for op amps and other components is through-hole. Components are constructed with leads that insert through holes in the board — hence the name.

Through-hole components, due to their size, are more suited to applications where space is not an issue. The components themselves are frequently lower in cost, but the PCB is more expensive due to the fact that the PCB fabrication house has to drill holes for component leads. PCBs are primarily a mechanical fabrication — the number of holes and number of different drills have a big impact on the price.

The leads on a through-hole op amp are arranged on a 0.1-inch grid. Many PCB layout people like to maintain the 0.1-inch grid for the rest of the components as well. Resistors

and other passive components can even be purchased with leads pre-bent to land on a 0.1 inch grid. Some electrolytic capacitors have leads that are on a 0.025-inch grid.

These component sizes may force a lot of wasted area on the PCB. Components that ideally should be placed close to the op amp itself may be forced several tenths of an inch away, due to intervening components. Therefore, through hole circuitry is not recommended for high speed analog circuitry, or for analog circuitry in proximity to high speed digital.

Some designers attempt to overcome the long trace length caused by resistors by placing the resistors on the board vertically, one lead of the resistor bent close to the body of the part. This is common in older consumer electronics. This allows for denser placement of parts, and may help some with trace length — but each resistor exposes almost 1 cm of one component lead to radiated signals, and lead self-inductance.

An advantage of the through-hole approach of PCB layout is that the through-holes themselves can serve as feedthroughs, reducing the number of vias in complex circuits.

17.7.2 Surface Mount

Surface-mount circuitry does not require a hole for each component lead. Automated testing, however, may require vias on every node. The holes were never an issue with through-hole circuitry, because every component lead made a hole in the board. The PCB layout designer, who is used to designing a board with a minimum number of vias, now has to put a via on EVERY node of the circuit. This can make a Swiss cheese out of a nice continuous ground plane — negating many of the advantages it provides.

Fortunately, there is a close variation of the “via on every node” requirement. This requirement can often be met by putting a test pad on every node. The automated test station can then access the analog circuitry from the top of the board. A *clamshell* test fixture is significantly more expensive than one that accesses only one side of the board. The extra cost can be justified if there is documentation that circuit performance will be unacceptable with vias.

Signal connections to ground or the power supply may have to be made through a small fixed resistor instead, so the automated equipment can access that pin of the IC and test its function.

17.7.3 Unused Sections

In many op amp designs, one or more op amps may be unused. If this is the case, the unused section must be terminated properly. Improper termination can result in greater power consumption, more heat, and more noise in op amps on the same physical IC. If the unused section of the op amp is connected as shown in the **better** side of Figure 17–21, it will be easier to use it for design changes.

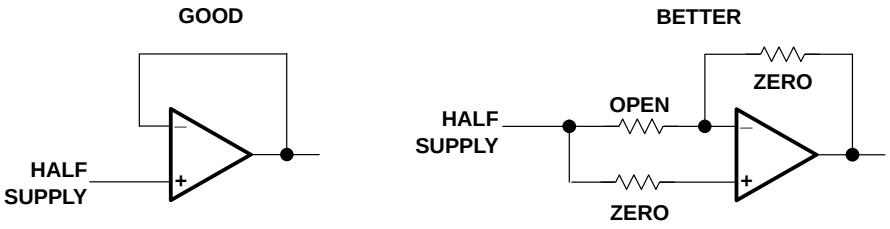

Figure 17–21. Proper Termination of Unused Op Amp Sections

17.8 Summary

Keep the following points in mind when designing a PCB for analog circuitry:

17.8.1 General

- Think of the PCB as a component of the design.
- Know and understand the types of noise the circuit will be subjected to.
- Prototype the circuit.

17.8.2 Board Structure

- Use a high-quality board material such as FR–4.
- Multi-layer boards are as much as 20-dB better than double-sided boards.
- Use separate, nonoverlapping ground and power planes.
- Place power and ground planes to the interior of the board instead of exterior.

17.8.3 Components

- Be aware of frequency limitations of traces and other passive components.
- Avoid vertical mounting of through-hole passive components in high-speed circuits.
- Use surface mount for high-speed analog circuitry.
- Keep traces as short as possible.
- Use narrow traces if long traces are required.
- Terminate unused op amp sections properly.

17.8.4 Routing

- Keep analog circuitry close to the power connector of the board.
- Never route digital traces through analog sections of the board, or vice versa.
- Make sure that traces to the inverting input of the op amp are short.
- Make sure that traces to the inverting and noninverting inputs of the op amp do not parallel each other for any significant length.
- It is better to avoid vias, but the self-inductance of vias is small enough that a few should cause few problems.
- Do not use right angle traces, use curves if at all possible.

17.8.5 Bypass

- Use the correct type of capacitor to reject the conducted frequency range.
- Use tantalum capacitors at power input connectors for filtering power supply ripple.
- Use ceramic capacitors at power input connectors for high frequency conducted noise.
- Use ceramic capacitors at the power connections of every op amp IC package. More than one capacitor may be necessary to cover different frequency ranges.
- Change the capacitor to a smaller value — not larger — if oscillation occurs.
- Add series inductors or resistors for stubborn cases.
- Bypass analog power only to analog return, never to digital return.

Chapter 18

Designing Low-Voltage Op Amp Circuits

Ron Mancini

18.1 Introduction

In one respect, voltage is like water: you don't appreciate its value until your supply runs low. Low-voltage systems, defined here as a single power supply less than 5 V, teach us to appreciate voltage. We aren't the first electronic types to learn how valuable voltage is; about 15 years ago the audio console design engineers appreciated the relationship between voltage and dynamic range. They needed more dynamic range to satisfy their customers; thus, they ran op amps at the full rated voltage, not the recommended operating voltage, so they could squeeze a few more dB of dynamic range from the op amp. These engineers were willing to take a considerable risk running op amps at the full rated voltage; but their customers demanded more dynamic range. The moral of this story is that dynamic range is an important parameter, and supply voltage is tied directly to dynamic range.

Knowing how to obtain and use the maximum dynamic range and input/output voltage range is critical to achieving success in low voltage design. We will investigate these subjects in detail later, but for now it is useful to review the history of op amps. Knowing how op amps evolved into the today's marvels is interesting, and it gives designers an insight into system problems that they encounter as they design in the low voltage world.

When power supplies were ±15 V, the output voltage swing of an op amp didn't seem important. When the power supply was 30 V the typical circuit designer could afford to sacrifice 3 V from each end of the output voltage swing (this was because of transistor saturation or cutoff). The transistors in the op amp need enough voltage across them to operate correctly, so why worry about 6 V out of 30 V. Also, the input transistors required base bias, so an op amp with 30-V supplies often offered a common-mode input voltage range of 24 V or less. These numbers come from the μA741 data sheet; the μA741 (about 1969) is the first internally compensated op amp to achieve wide popularity.

A later generation op amp, the LM324, had better dynamic range characteristics than the μA741. The LM324's output voltage swing is 26 V when operated from a 30-V power supply, and the common-mode input voltage range is 28.5 V. The LM324 was big news because it was specified to operate with a 5-V power supply. The LM324's output voltage

swing at V_{CC} = 5 V is 3.48 V, and this presented problems for the early low voltage circuit designers because the output voltage swing was smaller than most analog-to-digital converter (ADC) input voltage ranges. You must fill the ADC input voltage range to obtain its full dynamic range. The LM324 had an input voltage common-mode range of (V_{CC}–1.5 V) to 0 V; at least this op amp could work with transducers connected to the lower power supply rail if the transducer did not have an ac output voltage swing.

The next incremental improvement in op amps was the LM10 because it operated on 1.1-V power supplies. It was introduced almost as an afterthought because there was no pressing demand for it. Its brilliant designer, Robert J. Widlar, wrote “IC op amps have reached a certain maturity in that there no longer seems to be a pressing demand for better performance.” There were no pressing demands for a low voltage op amp in 1978 because portable (portable means battery applications that are almost always single supply) did not become popular until the late 1980s or early 1990s.

Cell phones, calculators, and portable instruments — not new battery technology — opened the market for low-voltage op amps, and when the portable concept caught on, the demand for low-voltage op amps increased. The increasing demand did not breed new companies committed to low-voltage IC design; rather, the established IC manufacturers threw a few low voltage op amps into their portfolio. These op amps, like the LM324, could operate on a low voltage, but they were severely lacking in input common-mode voltage range and output voltage swing. Circuit designers had to be satisfied with this generation of op amps until something better came along. Well, something better is here now!

The next generation of low-voltage op amps has much better specifications. The TLV278X operates off a power supply ranging from 1.8 V to 3.6 V, and it has an output voltage swing of 1.63 V (when the power supply is 1.8 V) coupled with an input common-mode voltage range of –0.2 V to 2 V. The TLV240X operates off a power supply ranging from 2.5 V to 16 V, and it has an output voltage swing of 2.53 V when the power supply voltage is 2.7 V. Also, when it is operated off a 2.7-V power supply, it has an input common-mode voltage range of –0.1 V to 7.7 V. These new op amps are far superior to their predecessors when evaluated on the their merits, which are extended output voltage swing and input common voltage range.

The latest op amps make it possible to design more accurate and cost effective electronic equipment, but there is one problem that they don’t solve. Low-voltage applications are defined here as single-supply applications, and in single-supply design, the op amp input voltage and output voltage is referenced to the midpoint of the power supply (V_{CC}/2). Unfortunately, most transducers are not connected to the midpoint of the power supply because, in the majority of cases, this requires a third wire beyond V_{CC} and ground. It doesn’t help to create V_{CC}/2 at the transducer location (to save a wire) because it is not identical to the midpoint of the power supply (unresolved errors enter because of the reference voltage difference). When the transducer in a single supply design is referenced to any voltage other than the midpoint of the power supply, the reference voltage is amplified with the transducer voltage.

The trick to designing single supply op amp circuits is using external biasing to strip off or null out the reference voltage. Designing op amp circuits with biasing normally involves an iterative cut and try approach where the designer assumes a circuit configuration, solves equations, changes the configuration, and repeats the process until a solution is found. A technique that solves the problem the first time is presented later.

18.2 Dynamic Range

It is extremely hard to define dynamic range (DR) for an op amp, so lets start with a digital-to-analog converter (DAC) where DR is defined as the ratio of the maximum output voltage to the smallest output voltage the DAC can produce (least significant bit or LSB). Dynamic range is usually expressed in dB using the formula given in Equation 18–1.

$$DR = 20\ \mathrm{Log}_{10}\left(\frac{V_{OUT(MAX)}}{V_{OUT(MIN)}}\right) \tag{18–1}$$

The same definition of DR can be used for an op amp, and the maximum output voltage swing equals V_{OUTMAX}. This output voltage swing is defined as the maximum output voltage the op amp can achieve (V_{OH}) minus the minimum output voltage the op amp can achieve (V_{OL}). V_{OH} and V_{OL} are easily obtainable from an op amp IC data sheet. Normally, V_{OH} and V_{OL} are guaranteed minimum and maximum parameters respectively. This yields Equation 18–2.

$$V_{OUT(MAX)} = V_{OH(MIN)} - V_{OL(MAX)} \tag{18–2}$$

Equation 18–2 can be used to illustrate the role that power supply voltage plays in limiting the DR. $V_{OH(MIN)}$ is the most positive power supply voltage minus the voltage drop across the upper output transistor, thus $V_{OH(MIN)}$ is directly proportional to the most positive power supply voltage. For any op amp, the output voltage swing is directly proportional to the power supply voltage, thus, in the same op amp, the DR is directly proportional to the power supply voltage.

At first thought, one might think that the smallest output voltage that an op amp can have is zero, and the natural conclusion based on this assumption is that the DR is equal to infinity. This is never the case because op amp and external circuit imperfections ensure that the smallest op amp output voltage is greater than zero. It turns out that $V_{OUT(MIN)}$ is actually determined by a series of error terms. These error terms are the op amp's internal noise (V_n and I_n), external resistor noise (V_{nR}), power supply rejection ratio (k_{SVR}), voltage offset (V_{IO}), current offset (I_{IO}), common-mode rejection ratio (CMRR), and closed loop gain (G). Each of these error terms is referred to the input of the op amp, so they must be multiplied by the closed loop gain to be referred to the output (see Figure 18–1).

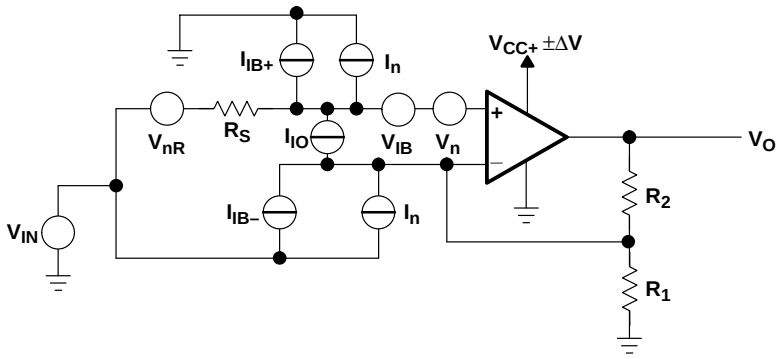

Figure 18–1. Op Amp Error Sources

The error sources are taken into account in Equation 18–3, and this equation refers them to the op amp output by multiplying them by the op amp's closed loop gain.

$$V_{OUT(MIN)} = \\ = G_{CL}\left(V_{IO} + I_{IO}R_S + \alpha V_{IO}\,\Delta T + \frac{V_{IN} + I_{IB}R_P}{CMRR} + \frac{\Delta V}{k_{SVR}} + V_n + I_nR_{EQ} + I_{nR}R\right) \quad (18–3)$$

The maximum DR that can be achieved by an op amp is given in Equation 18–4.

$$DR = 20\,Log_{10}\left(\frac{V_{OH(MIN)} - V_{OL(MAX)}}{V_{OUT(MIN)}}\right) = 20\,Log_{10}\frac{V_{OUT(MAX)}}{V_{OUT(MIN)}} \quad (18–4)$$

The DR is reduced by the sum of the error terms, so it is proper to conclude that the maximum power supply voltage and the op amp choice (this defines the error magnitude) both establish the DR of an op amp. The first two terms in Equation 18–3 are dc error terms, thus, they can be adjusted to zero by one of several methods not mentioned here. The input offset current and input bias current error terms were big factors with older generation ICs, but today's technology render them much less significant (see Table 18–1).

Table 18–1. Comparison of Op Amp Error Terms

PARAMETER	LM324	TLV278X	TLV240X	UNITS
V_{IO}	9	1.5	4.5	mV
αV_{IO}	No spec	8	3	μV
I_{IB}	500,000	100	350	pA
I_{IO}	50,000	100	300	pA
CMMR	50	50	65	dB
k_{SVR}	65	70	100	dB
Vn	No spec	18 (1 kHz)	500 (100 Hz)	$\frac{nV}{(Hz)^{1/2}}$
In	No spec	0.9 (1 kHz)	8 (100 Hz)	$\frac{fA}{(Hz)^{1/2}}$

The data in Table 18–1 indicates that older low voltage op amps are not capable of yielding the DR that that later technology op amps are.

18.3 Signal-to-Noise Ratio

Noise sets a limit on the information and signals that can be handled by a system. The ability of an amplifier, receiver, or other device to discern a signal is degraded by noise. Noise mixed with the incoming signal, noise generated by the op amp, resistor noise, and power supply noise ultimately determine the size of the signal that can be recovered and measured.

Noise fluctuates randomly over a period of time, so instantaneous signal or noise levels don't describe the situation adequately. Averages over a long period of time (root mean squared or RMS) are used to describe both the signal and the noise. Signal-to-noise ratio (SNR) was initially established as a measure of the quality of the signal that exists in the presence of noise. This SNR was a power ratio, and it was established at the output of a circuit. The SNR that we are interested in is a voltage ratio because the impedance is constant, and it is established at the input to the op amp. This means that all noise voltages, including resistor noise voltage, must be calculated in RMS volts at the op amp input. The SNR is given in Equation 18–5.

$$SNR = 20 \, Log_{10}\left(\frac{V_{SIGNAL}}{V_{NOISE}}\right) \tag{18–5}$$

The signal is established by a transducer; a device that senses a change in a variable and converts that change into a voltage change. Transducers also convert some of their physical surroundings into a noise voltage that is combined with the signal. Noise from the physical surroundings of the transducer, unless its nature is well known, is almost impos-

sible to separate from the transducer signal. When transducers are connected to the electronics, cabling picks up noise, and some transducers like thermocouples can pick up noise from the connecting junctions. Thus, the signal is never clean as it enters the electronics. The noise generated by the op amp was defined in the previous section as V_n, I_nR_{EQ}, $I_{nR}R$, and $\Delta V/k_{SVR}$, and this noise is added to the signal.

The transducer often has a very small output voltage swing, so when the transducer output voltage swing is converted to least significant bits (LSB) the noise voltage should be very small compared to an LSB. Consider a temperature transducer that has a 10-mV swing over its range. When the transducer output voltage swing is considered to be the full-scale voltage (FSV) of an ADC, the LSB is very small as is shown in Equation 18–6 for a 12-bit (N) ADC.

$$\text{LSB} = \frac{\text{FSV}}{2^N} = \frac{10\text{ mV}}{2^{12}} = \frac{10\text{ mV}}{4096} = 2.44\ \mu\text{V} \qquad (18\text{–}6)$$

The op amp for this application must be a very low noise op amp because an op amp with a 20-nV/(Hz)$^{1/2}$ equivalent input noise voltage and a bandwidth of 4 MHz contributes 40 μV of noise. This high noise contribution is why extensive filtering and “optimally” low bandwidth is found desirable in the input stages of some electronic systems. If there is power supply noise, some of that noise passes through the op amp to its input. The power supply noise is divided by the power supply rejection ratio, but there is always a residual noise component of the power supply on the op amp input as shown in Equation 18–7 where k_{SVR} is 60 dB.

$$V_{PS(INPUT)} = \frac{V_{PS}}{k_{SVR}} = \frac{10\text{ mV}}{1000} = 10\ \mu\text{V} \qquad (18\text{–}7)$$

18.4 Input Common-Mode Range

Years ago the op amp’s input common-mode voltage range (V_{ICR}) did not include the power supply rails. The best V_{ICR} that was available was (V_{CC} +|V_{EE}|–6 V), and when the input voltage approached V_{ICR}, distortion occurred. If the input voltage exceeded the power supply rails, the output stage might invert phase (it sometimes latched in the inverted position causing control problems) or the IC might self destruct. The vast majority of transducers were connected to ground (0 V) because it was easy to make a ground connection and because a split supply op amp has inputs referenced to ground. In a split supply application with the transducer connected to ground, latch-up or self destruction is unlikely.

In special cases, transducers are connected to a power supply rail (usually V_{CC} when power supply current sensing) or some other voltage, and in this special case, additional bias circuitry was added to split power supply designs to keep the input voltage swing within V_{ICR}. Bias circuitry in conjunction with external components removed the effects of the power supply rail connection.

Many low voltage op amp input signals come from transducers connected to a power supply rail like the circuit shown in Figure 18–2.

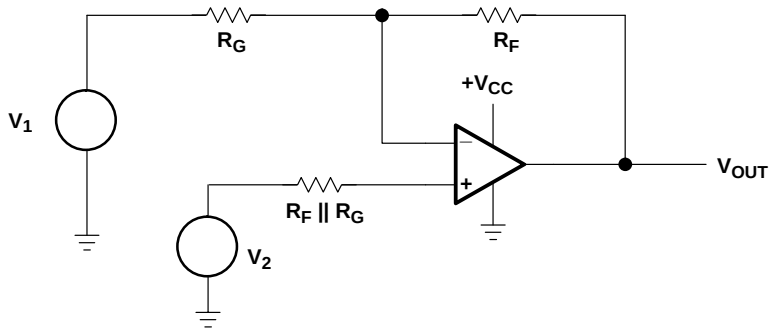

Figure 18–2. Noninverting Op Amp

When $V_1 = 0$ and V_2 is the transducer input, the op amp must be capable of handling input voltages that go to 0 V. Furthermore, the transducer voltage may be ac, so it swings above and below ground, thus the transducer voltage drops below the low power supply rail. This situation requires that the op amp's V_{ICR} exceed the power supply voltage. Rail-to-rail input (RRI) voltage capability is a necessary requirement for a low-voltage op amp that handles transducers connected to a power supply rail.

When the input voltage is connected to ground and the input voltage swing is very small, a standard op amp like the LM324 suffices. Referring to Figure 18–3 it can be seen that the PNP input transistors are biased by the emitter current source. If the positive input is connected to ground bias current still flows and the transistor stays active. If the input transistors are selected very carefully for operation with low collector-base junction reverse bias, the input voltage can go slightly below ground (–200 mV for the TLV278X) and the op amp will still operate correctly. The circuit operation is one sided though because when the input voltage approaches the positive supply rail, the emitter current source and input transistors turn off. This type of circuit does not offer rail-to-rail operation, but it does offer from rail to (V_{CC} –1.5V) operation.

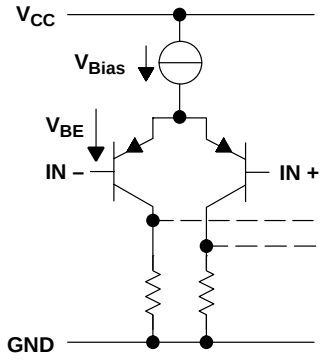

Figure 18–3. Input Circuit of a NonRRI Op Amp

An op amp with a NPN input stage works in a similar way around the positive supply rail. It can sense voltages close to V_{CC} and maybe slightly above V_{CC}, but it won't work when it is within 1.5 V of ground. The solution for this problem is to include parallel input circuits as shown in Figure 18–4.

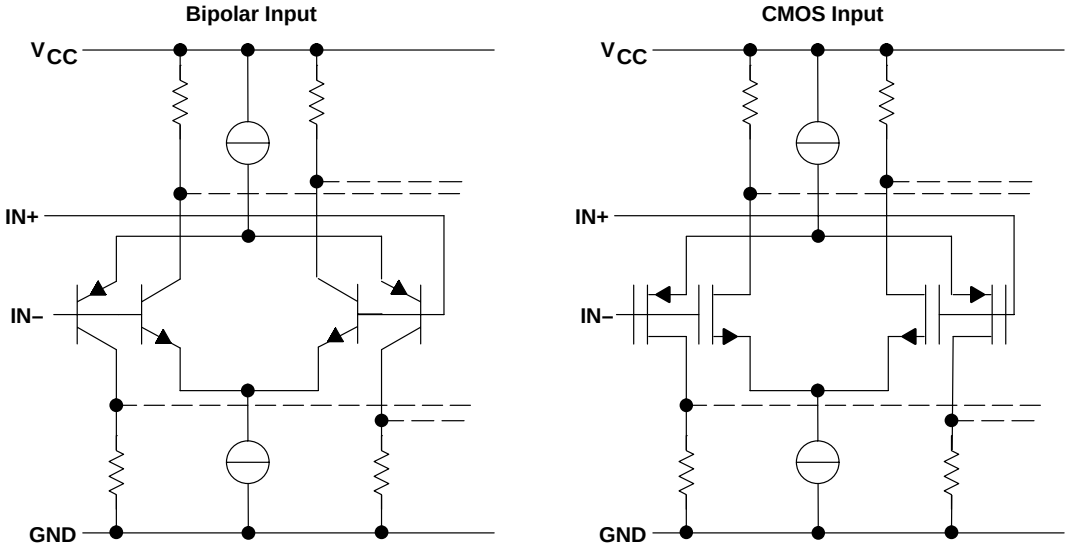

Figure 18–4. Input Circuit of an RRI Op Amp

The RRI op amps have parallel input stages. There are both PNP and NPN differential amplifiers used in the input stages of the RRI op amp, thus the RRI op amp can operate above and below the power supply voltage. As Figure 18–4 shows, the parallel input stages can be made in bipolar or MOS technology.

The input stages operate in three different ranges. When the input voltage ranges from about –0.2 V to 1 V, the PNP differential amplifier is active and the NPN differential amplifier is cutoff. When the input voltage ranges from about 1 V to (V_{CC} –1 V), both the NPN and PNP differential amplifiers are active. When the input voltage ranges from about (V_{CC} –1 V) to (V_{CC} + 0.2 V), the NPN differential amplifier is active and the PNP differential amplifier is cut off. Inclusion of complementary differential input amplifiers achieves V_{ICR} exceeding the power supply limits, but there is a penalty to pay in input bias current, input offset voltage, and distortion. Figures 18–5 and 18–6 show the input bias current and input offset voltage as a function of the input common-mode voltage.

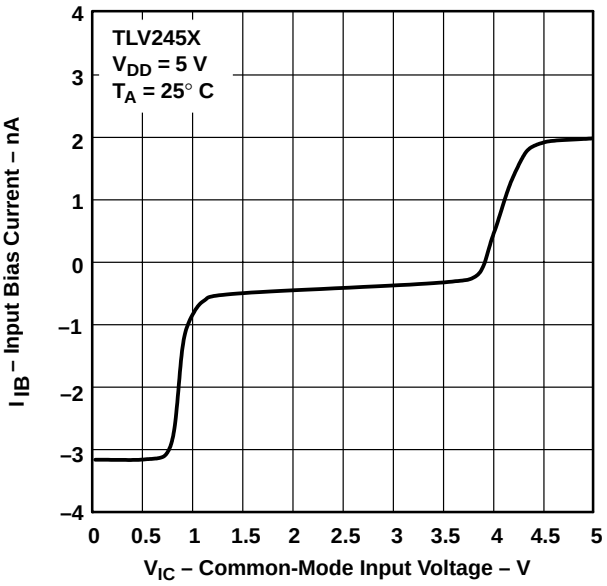

Figure 18–5. Input Bias Current Changes with Input Common-Mode Voltage

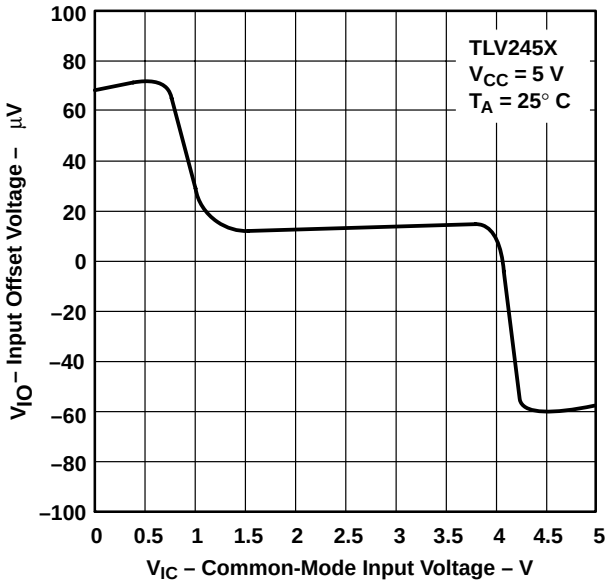

Figure 18–6. Input Offset Voltage Changes with Input Common-Mode Voltage

When both transistors are conducting current the input bias currents have a tendency to cancel, so in the range of ±1 V, the bias current is extremely low even when bipolar transistors are used to make the op amp. Above this range, the PNP differential amplifier cuts off so the full bias current requirement of the NPN transistor becomes apparent. The same action happens below this range when the NPN differential amplifier cuts off. Notice that the PNP bias current is significantly larger than the NPN bias current; this is expected because NPN transistors have better gain characteristics than PNP transistors. The base-emitter voltage of the NPN and PNP transistors is well matched because the magnitude of the input offset voltage at the extremes is almost equal.

The bias current and offset voltage variation with input signal amplitude cause errors and distortion of the input signal. Inserting a resistance equal to the parallel combination of R_F and R_G into the positive op amp lead minimizes the effect of input bias current. The resistor, R_P, has the same voltage drop across it that the parallel combination of R_F and R_G has, hence the bias current is converted to a common-mode voltage. The common-mode voltage is normally in the µV-range because I_{IB} is in the fractional nA range and R_P is in the tens of KΩ. The CMMR is approximately 60 dB, so the input bias current effect is reduced to the nV range where it is insignificant compared to the offset voltage. The input offset current is multiplied by R_P, and it shows up as an input error. If the design can't tolerate these errors it is wise to switch to a CMOS op amp because its input currents are in the pA range.

Another type of error creeps in when complementary differential amplifiers are used to obtain DR, and this error is results from the different gain of the PNP and NPN transistors.

Op amps always suffer to a limited extent from distortion introduced by different gains when operating in different quadrants The positive quadrant is above $V_{CC}/2$ where NPN transistors operate, and the negative quadrant is below $V_{CC}/2$ where the PNP transistors operate. Normally, this is a very minor effect because only the gain of the output stage changes with quadrant, but with complementary input stages the input and output gains change with quadrant. These errors are small, and they are accepted as the sacrifice required for obtaining RRI operation.

18.5 Output Voltage Swing

Rail-to-rail output voltage swing (RRO) is desirable for at least two reasons. First, the DR can achieve the maximum obtainable value if the op amp is RRO. Second RRO op amps can drive any converter connected to the same power supply if the impedance is compatible. The schematic of a RRO op amp output stage, part of the TLC227X, is shown in Figure 18–7.

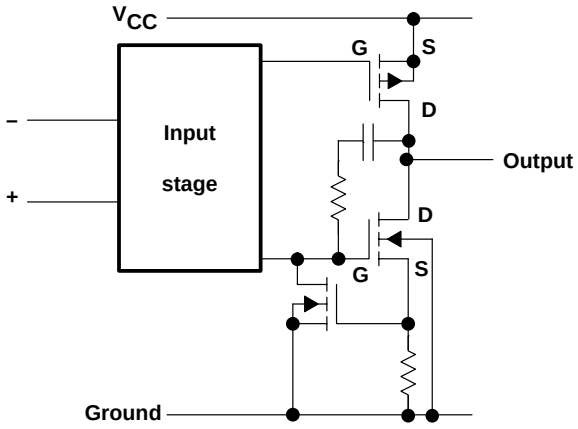

Figure 18–7. RRO Output Stage

The RRO characteristic is achieved in the construction of the op amp output stage. A totem pole design that has upper and lower output transistors is used, and the output transistors are a complimentary pair. Each transistor in the pair is a “self-locking” type of transistor operating in the common-source mode. Consider the p-channel output transistor; as long as this transistor has a drain-source resistance it forms a voltage divider with the load resistance. When the load is a very large resistor or if the output current flow is very small, the voltage drop across the output transistor can be neglected. Output current flows through the output transistor, and because current drops a voltage (V_{DS}) across the drain-source resistor, the output voltage swing is reduced. The voltage drop subtracts from the power supply voltage, reducing the output voltage to less than RRO.

RRO op amps can’t drive heavy loads and maintain their RRO capability because of the voltage dropped across the output transistors. Load resistance or output current is a test

condition when the measurement of an op amp's output voltage swing is made. The size of the load resistor or output current is a measure of the op amp's ability to retain its RRO capability while sourcing or sinking an output current. When selecting a RRO op amp, the designer must consider the load resistance or output current required because these conditions control the output voltage swing.

When an op amp is made that has RRI and RRO capability, it is called a rail-to-rail input/output op amp. This long name is shortened to RRIO.

18.6 Shutdown and Low Current Drain

Low voltage design often is accompanied by a requirement that the power supply current drain be low. The power supply current drain is kept low to decrease battery size and prolong battery charge so recharging can be put off as long as possible. Many methods are employed to keep the current drain low including using high-value resistors, low bias current regulators/references, slow speed logic, keeping logic transitions to a minimum, low voltage power supplies, selecting op amps for low current drain, and shutting off unused ICs.

High-value resistors have less current flowing through them than low value resistors do, and they can be used effectively in ratio applications, but there are some downsides to using high-value resistors. When resistor values exceed 2 MΩ to 10 MΩ, depending on the type of resistor, the temperature drift, vibration, and time-induced drift increases rapidly compared to that of lower value resistors. The input resistor to an op amp, R_G, works with the stray capacitance from the input node to ground to form a pole in the loop gain. As the resistance increases, the pole moves towards the zero frequency intercept and the circuit overshoots, rings, or becomes unstable. The feedback resistor, R_F, works with stray capacitance in parallel with R_F to form a low-pass filter. Sometimes this filter action is desirable, but the filter often distorts the signal.

Very often, low bias current regulators and references are just standard ICs specified at a lower current. These devices generally do not have the same small tolerances at low bias currents that they had at high bias currents. Although they are more often costly, redesigned low bias current regulators and references are becoming available. Ensure that the reference or regulator bias current used in the application is the same as that used to specify the device, because sometimes the error curves for references are nonlinear. Also, investigate the reference noise voltage to ensure that low bias current has not moved the device to a noisy portion of its operating curve.

Saturated logic is the choice for low current drain applications because nonsaturated logic stays in the active region and has a higher current drain. Always pick the slowest logic gates that you can get away with. Speed in saturated logic requires enough current to drive low impedance loads, and that means high power supply currents coupled with logic-generated noise. High-speed logic has a low impedance totem pole output stage, and

every time the output is switched, both totem pole transistors are on causing a current spike through the power supply. Large decoupling capacitors are required to localize the current spike at the logic IC, thus preventing noise propagation. CMOS logic draws the least quiescent current, and if the logic transitions are kept at a minimum, the current drain stays small. One method of minimizing logic transitions is to use asynchronous logic.

The op amp should be selected with current drain in mind. Three rail-to-rail op amps have widely differing current drains because they are designed for different applications. The TLV240X is designed for micropower applications, and its current drain is 1.29 μA. The TLV411X is designed high output drive, and its current drain is 800 μA. The TLV287X is designed for high speed, and its current drain is 820 μA. These three op amps are low-voltage op amps, but they each serve a different application.

The best method of conserving current is to shut the op amp down if you are not using it. Most op amps designed for low voltage applications have shutdown pins. A typical op amp that draws 820 μA when operating, draws 1.7 μA when it is shut down. The problem with shutdown is the time that it takes to wake the op amp up and knowing when to wake the op amp up. A typical low-voltage op amp turns on in less that 1 μs, but the system designer usually has to choose the variable that eventually wakes the op amp up.

18.7 Single-Supply Circuit Design

The op amp is a linear device, so it follows the equation of a straight line. The equation of a straight line has four forms as shown in Equation 18–8.

$$Y = \pm mx \pm b \tag{18–8}$$

These four forms can be implemented with four single supply circuits. When the designer discovers the form of Equation 18–8 that yields the transform function required, it is a small task to find the corresponding circuit. Once the circuit and transfer function are established, the task reduces to matching coefficients between the transfer function and the circuit equation, and then calculating the resistor values. The key required to unlock the puzzle is to determine the form of Equation 18–8 that yields the required transfer function. This key is found in simultaneous equations because they define the equation of a straight line. Several examples of using simultaneous equations to determine the required form of the op amp transfer function are given in the next two sections.

18.8 Transducer to ADC Analog Interface

An example is a transducer that needs to be interfaced to an ADC. The transducer specifications are V_{MIN} = 0.2 V, V_{MAX} = 0.5 V, and R_{OUT} = 600 Ω. The ADC specifications are $V_{IN(LOW)}$ = 1.5 V, $V_{IN(HIGH)}$ = 4.5 V, and R_{IN} = 20 kΩ. The system specifies a 5-V power supply and 5% tolerance resistors. The transducer is connected to input of the amplifier

(see Figure 18–8), so its output voltage swing is renamed V_{IN}, and the ADC is connected to the output of the amplifier, so its input voltage range is renamed V_{OUT}. Now, two data points are constructed as V_{IN1} = 0.2 V @ V_{OUT1} = 1.5 V and V_{IN2} = 0.5 V @ V_{OUT2} = 4.5 V. The data points are substituted into the equation Y = mX + b; m is named the slope and b is named the X axis intercept or just the intercept for short. Don't worry about the sign of m or b because it is determined by the math, and it is substituted into the equation that determines the transfer equation. The simultaneous equations are given below.

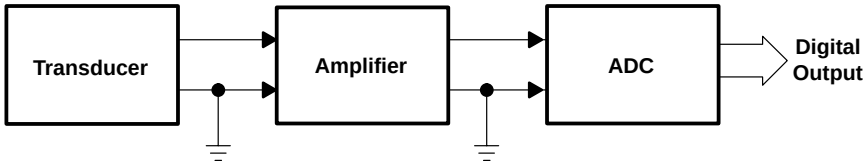

Figure 18–8. Data Acquisition System

$$1.5 = 0.2m + b \tag{18–9}$$

$$4.5 = 0.5m + b \tag{18–10}$$

From these equations we find that b = –0.5 and m = 10. The slope and intercept values are substituted into Equation 18–8 to get Equation 8–11.

$$Y = 10X - 0.5 \tag{18–11}$$

The mathematical terminology in Equation 18–11 is replaced by electronics terminology in Equation 18–12, and this is the transfer function required for the amplifier. The next step is to select the op amp, and this isn't a hard task because there are many candidates that could do the job with these undemanding specifications, so let us not dwell on the selection process. Assume that the selected op amp operates on a 5-V power supply, can drive the ADC input resistance of 20 kΩ with no voltage divider action, and that the op amp input impedance is so big that it doesn't load the transducer.

$$V_{OUT} = 10V_{IN} - 0.5 \tag{18–12}$$

The circuit that produces the desired transfer function is given in Figure 18–9.

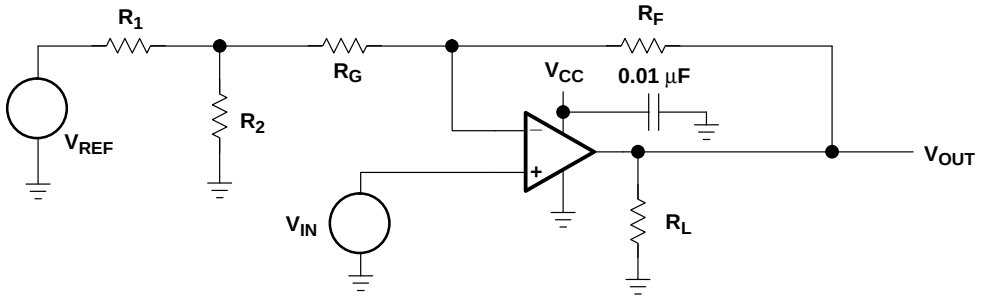

Figure 18–9. Schematic for the Transducer to ADC Interface Circuit

The circuit equation is obtained with the aid of superposition.

$$V_{OUT} = V_{IN}\left(\frac{R_F + R_G + R_1 \| R_2}{R_G + R_1 \| R_2}\right) - V_{REF}\left(\frac{R_2}{R_1 + R_2}\right)\left(\frac{R_F}{R_G + R_1 \| R_2}\right) \quad (18–13)$$

Comparing terms between Equations 18–12 and 18–13 enables the extraction of m and b.

$$m = \left(\frac{R_F + R_G + R_1 \| R_2}{R_G + R_1 \| R_2}\right) \quad (18–14)$$

$$|b| = V_{REF}\left(\frac{R_2}{R_1 + R_2}\right)\left(\frac{R_F}{R_G + R_1 \| R_2}\right) \quad (18–15)$$

Making the assumption that $R_1||R_2 << R_G$ simplifies the calculations.

$$m = 10 = \frac{R_F + R_G}{R_F} \quad (18–16)$$

$$R_F = 9R_G \quad (18–17)$$

Let R_G = 20 kΩ, and then R_F = 180 kΩ, add, and let $V_{REF} = V_{CC}$.

$$|b| = V_{CC}\left(\frac{R_F}{R_G}\right)\left(\frac{R_2}{R_1 + R_2}\right) \quad (18–18)$$

$$R_1 = \frac{1 - 0.01111}{0.01111}R_2 = 89R_2 \quad (18–19)$$

Select R_2 = 0.82 kΩ and R_1 = 72.98 kΩ. Since 72.98 kΩ is not a standard 5% resistor value, R_1 is selected as 75 kΩ. The difference between the selected and calculated value

of R_1 introduces about 3% error in the b coefficient, and this error shows up in the transfer function as an intercept rather than a slope error. The parallel resistance of R_1 and R_2 is approximately 0.82 kΩ and this is much less than R_G which is 20 kΩ, thus the earlier assumption that $R_1||R_2<<R_G$ is justified. R_2 could have been selected as a smaller value, but the smaller values yielded poor standard 5% values for R_1. The final circuit is shown in Figure 18–10.

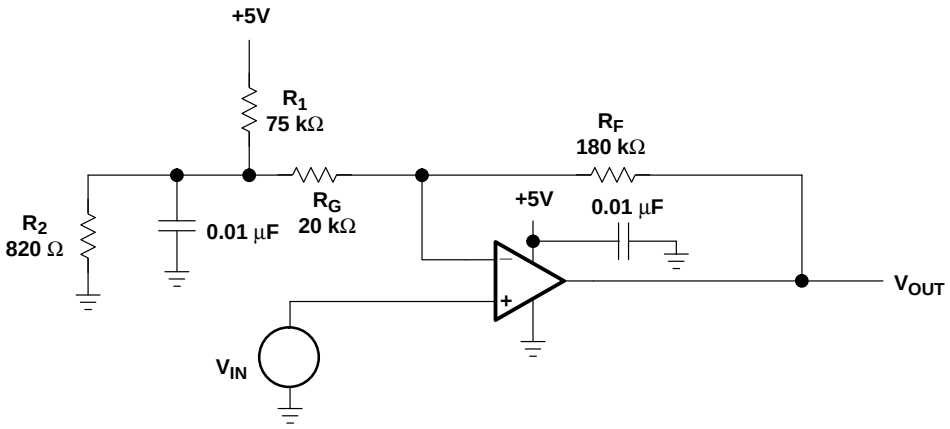

Figure 18–10. Final Schematic for the Transducer to ADC Interface Circuit

18.9 DAC to Actuator Analog Interface

An amplifier is also used to interface a DAC with an actuator (see Figure 18–11).

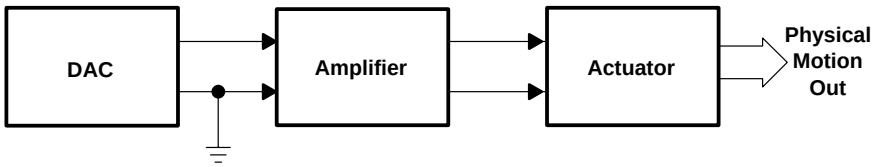

Figure 18–11. Digital Control System

The interface is different from the ADC interface because the DAC output signal is usually current rather than voltage. The first inclination is to stuff the DAC output into a current-to-voltage converter like we have always done with split power supplies. This doesn't always work because the DAC current can be sinked or sourced from ground or the power supply. If a current sourced from the positive power supply is put into a standard current-to-voltage circuit, it wants to drive the op amp output negative, and you need a negative resistor to counter this. The alternate solution for a sourced current from the positive power supply

is to terminate the DAC output in a resistor that converts current into voltage, and then level shift and amplify the terminated voltage. The circuit that performs this function is shown in Figure 18–12.

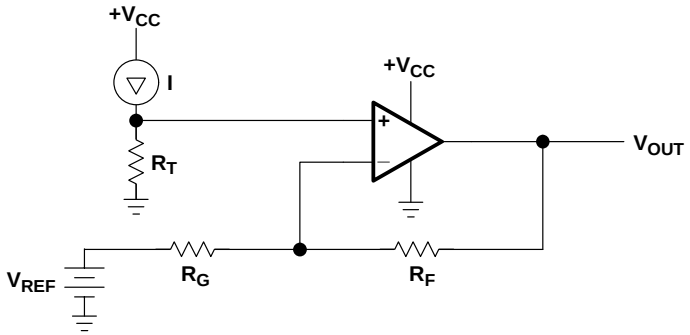

Figure 18–12. DAC Current Source to Actuator Interface Circuit

The DAC output current sources from $I_{OUT(ZEROS)}$ = 1 mA to $I_{OUT(ONES)}$ = 2 mA at an output compliance of 4.33 V. The actuator requires an input voltage swing of V_{IN1} = 1 V to V_{IN2} = 4 V to drive it, and its input resistance is 100 kΩ. The system specifications include one 5-V power supply and 5% resistors. The DAC is connected to input of the amplifier (see Figure 18–11), so its output current swing is renamed I_{IN}, and the actuator is connected to the output of the amplifier, so its input voltage range is renamed V_{OUT}. Now, two data points are constructed as I_{IN1} = 1 mA @ V_{OUT1} = 1 V and I_{IN2} = 2 mA @ V_{OUT2} = 4 V. The data points are substituted into the Equation 18–20. Don't worry about the sign of m or b because it is determined by the math, and it is substituted into the equation that determines the transfer equation. The simultaneous equations are given below.

$$V_{OUT} = mI_{IN} + b \tag{18–20}$$

$$1 = m + b \tag{18–21}$$

$$4 = 2m + b \tag{18–22}$$

From these equations we find that b = –2 and m = 3. The slope and intercept values are substituted into Equation 18–20 to get Equation 18–23.

$$V_{OUT} = 3I_{IN} - 2 \tag{18–23}$$

The equation for the circuit shown in Figure 18–12 is derived with the aid of superposition, and it is given below in Equation 18–24.

$$V_{OUT} = I_{IN}R_T\left(1 + \frac{R_F}{R_G}\right) - V_{REF}\frac{R_F}{R_G} \tag{18–24}$$

Comparing terms between Equations 18–20 and 18–24 enables the extraction of m and b.

$$|b| = V_{REF}\frac{R_F}{R_G} \tag{18–25}$$

$$m = R_T\left(1 + \frac{R_F}{R_G}\right) \tag{18–26}$$

$$\frac{R_F}{R_G} = \frac{2}{5} \tag{18–27}$$

$$R_T = \frac{5\frac{R_F}{R_G} + 1}{\frac{R_F}{R_G} + 1} = 2.14 \tag{18–28}$$

These equations are written in terms of mA and kΩ, so R_T = 2.14 kΩ. There is no 2.14-kΩ resistor in the 5% standard values; thus, R_T is split into 1.8-kΩ and 0.33-kΩ resistors. R_G is selected as 51 kΩ, so R_F = 20 kΩ. When I_{IN} = 2 mA V_{RT} = 4.28 V, so the compliance of the DAC is not violated. You might find that standard DACs are not so generous with their compliance specifications.

When the current is sinked from the power supply by the DAC its sign reverses and the previous circuit is not usable. Consider these specifications: the DAC output sinks current from the power supply $I_{OUT(ZEROS)}$ = –1 mA to $I_{OUT(ONES)}$ = –2 mA at an output compliance of 4.33 V. The actuator requires an input voltage swing of V_{IN1} = 1 V to V_{IN2} = 4 V to drive it, and its input resistance is 100 kΩ. The system specifications include one 5-V power supply and 5% resistors. The DAC is connected to input of the amplifier (see Figure 18–11), so its output current swing is renamed I_{IN}, and the actuator is connected to the output of the amplifier, so its input voltage range is renamed V_{OUT}. Now, two data points are constructed as I_{IN1} = –1 mA @ V_{OUT1} = 1 V and I_{IN2} = –2 mA @ V_{OUT2} = 4 V. The data points are substituted into the Equation 18–20. Don't worry about the sign of m or b because it is determined by the math, and it is substituted into the equation that determines the transfer equation. The transfer function for the current sink DAC is given in Equation 18–29.

$$V_{OUT} = I_{IN}m + b \tag{18–29}$$

The simultaneous equations are given below.

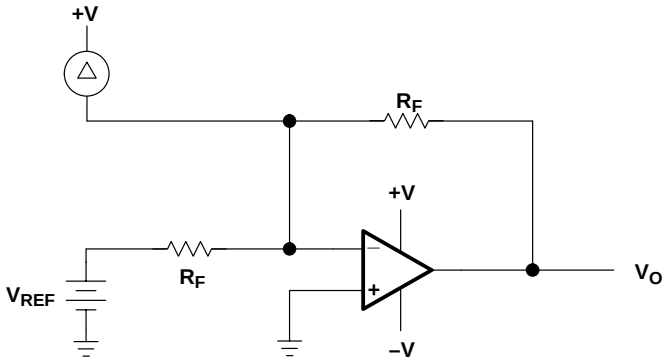

Figure 18–13. DAC Current Sink to Actuator Interface Circuit

$$1 = -m + b \tag{18–30}$$

$$4 = -2 + b \tag{18–31}$$

From these equations we find that b = –2 and m = –3. The slope and intercept values are substituted into Equation 18–28 to get Equation 18–32.

$$V_{OUT} = -I_{IN}(-m) - b = mI_{IN} - b \tag{18–32}$$

The current equation for the circuit shown in Figure 18–13 is given below as Equation 18–33, and after algebraic manipulation it becomes Equation 18–34.

$$\frac{V_{OUT}}{R_F} = I_{IN} - \frac{V_{REF}}{R_G} \tag{18–33}$$

$$V_{OUT} = I_{IN}R_F - V_{REF}\frac{R_F}{R_G} \tag{18–34}$$

Comparing terms between Equations 18–29 and 18–34 enables the extraction of m and b.

$$R_F = |m| = 3 \tag{18–35}$$

$$|b| = V_{REF}\frac{R_F}{R_G} \tag{18–36}$$

$$\frac{R_F}{R_G} = \frac{2}{5} \tag{18–37}$$

These equations are written in terms of mA and kΩ. R_G is selected as 51 kΩ, so R_F = 20 kΩ. When I_{IN} = 2 mA, the compliance of the DAC is 0.0 V.

When DAC interface circuits are designed, two parameters that have not been considered in detail can control the design. The DAC has a compliance voltage requirement, and that requirement must be met regardless of the circuit demands. If the DAC compliance requirements are not met, the DAC saturates or is starved for current, and either of these situations introduces considerable error. The actuators driven in these examples are quite benign because most actuators require considerably more current or voltage than is available from an op amp. This fact does not negate the analysis given here. Regardless of the actuator current or voltage requirements, the design procedure is similar. Very often the low voltage device is plugged into a booster that supplies power to the actuator.

One last item to consider is the output capacitance of DACs. The DAC output can have large amounts of stray capacitance that shows up as a capacitor across the op amp inverting input node when the DAC is interfaced into circuits as shown in Figure 18–13. The DAC capacitance from the inverting node to ground acts with R_G to form a pole in the op amp loop gain. Adding a pole to the op amp loop gain leads to overshoot, then ringing, and finally oscillation. The effect that the DAC capacitance has on stability must be investigated. Also, the DAC output capacitance is a function of the digital number addressing the DAC. This capacitance can range from near zero to hundreds of pF, thus the op amp must be compensated for the worst case which is the largest capacitance.

Compensation schemes include connecting a capacitor across the feedback resistor. This compensation scheme is called a compensated attenuator, and if the RC time constants are equal, there will excellent performance at that DAC output capacitance. Alas, the circuit can only be ideally compensated at one point, and this point is normally chosen as the highest DAC output capacitance. The remainder of the DAC range suffers from poor bandwidth because of overcompensation.

18.10 Comparison of Op Amps

Since the author is only familiar with Texas Instruments op amps, a comparison involving actual op amp parameters would be unfair to other op amp manufacturers. Also, any comparison using today's production op amps becomes invalid in a short period of time. I write about Texas Instruments op amps, so I get plenty of samples, and the new product introductions come so fast that I have a hard time keeping up with them. The other point to consider is that teaching how to make the op amp comparison is a much more powerful tool, thus a table containing the op amp parameters is established, and each of the parameters is discussed only in terms of low-voltage design.

Table 18–2. Op Amp Parameters

PARAMETER	RANGE OF VALUES	UNITS	DISCUSSION
V_{IO}	25 to 8000	mV	DC parameter that can be adjusted out.
αV_{IO}	3 to 1000	μV/°C	Drift parameter that ends up as an error.
I_{IB}	0.1 to 9999	pA	Input bias current that can be cancelled out.
I_{IO}	0.1 to 9999	pA	Input offset current that can be adjusted out.
R_{IN}	0.0002 to 1	GΩ	Acts as a voltage divider with driving circuit.
CMRR	0 to 90	dB	Common-mode voltage is a nonlinear error.
A_{VD}	20 to 140	dB	Determines high-frequency errors.
V_{ICR}	V_{CC} –1.5 V to V_{CC} +0.5 V	V	Input voltage range over which op amp works correctly with specified error.
V_{OH}	V_{CC} –1.5 V to V_{CC} +0.5 V	V	Maximum high output voltage swing. Load resistance or current is important. Limits dynamic range.
V_{OL}	0 + 1.5 V to 0 – 1.5 V	v	Minimum low output voltage swing. Load resistance or current is important. Limits dynamic range.
I_O	1 to 100	mA	Current available to drive loads.
I_{CC}	0.1 to 10000	μA	Power supply current.
k_{SVR}	20 to 120	dB	Power supply noise rejection.
$I_{CC(SHDN)}$	0.01 to 100	μA	Power supply current in shutdown mode.
V_n	1 to 1000	$\frac{nV}{(Hz)^{1/2}}$	Noise voltage limits dynamic range.
I_n	0.01 to 100	$\frac{fA}{(Hz)^{1/2}}$	Noise current limits dynamic range.
$t_{(ON)}$	0.5 to 10	μs	Op amp wake up time.
$t_{(OFF)}$	0.1 to 5	μs	Time until power supply current reaches $I_{CC(SHDN)}$.

As the table shows, there are a lot of parameters to be considered in the selection of a low voltage op amp. The application weeds out some of these parameters thus easing the selection process. If the application is measuring the output from a low-bandwidth transducer such as a thermocouple, bandwidth is not a parameter of interest, so speed can immediately be sacrificed for power supply current.

When the maximum supply voltage available is 3 V, rafts of op amps requiring more than 3 V operating voltage are eliminated. Taking this concept further, if dynamic range is an important specification in the 3-V design, those op amps that operate on 3 V without RRIO specifications can be eliminated. Because dynamic range is important, the noise voltage and current that detract from dynamic range are important parameters. If this 3-V application requires very low power supply current, the choice is narrowed down to a few candidates. The application selects the op amp, and if this application puts a few more requirements on the 3-V op amp, we may have to design a new IC.

Always start the selection process with the parameter that absolutely can't be wavered. The next parameter considered in the selection process should be the next most important parameter, and this process is continued parameter by parameter until all requirements are exhausted. Sometimes the supply of op amp candidates runs out before the parameter requirements do. When you reach this point, it is time to renegotiate the design specifications, find a new op amp, negotiate with op amp manufacturers, or announce that you won't meet specifications. These designs are hard to work because the low power supply voltage requirement and the specifications usually leave very little room to work. As time marches on, more low power supply voltage op amps will come on the market, and these designs will get easier to work.

18.11 Summary

It is extremely hard to achieve large dynamic range when the application is limited to a low power supply voltage. In an attempt to approach the dynamic range obtained by ± 30-V power supply designs, the new op amp designs put increased emphasis on the output voltage swing. The ratio of output voltage swing to power supply voltage was 0.8 for ± 30-V powered op amps, 0.7 for the first 5-V powered op amps, and it has risen to 0.9 for the newest family of 1.8-V powered op amps. The ratio output voltage swing to power supply voltage has increased with each new generation of low power supply voltage op amps, but this improvement has reached the point of diminishing returns.

The op amp's dc offset diminishes the output voltage swing, but in most cases the offsets are adjusted out, so they have less importance in the design. New op amp technology is not being pushed hard to improve in this area because the passive components continue to require the adjustments. Drift and noise continue to decrease the dynamic range. Op amp noise has decreased in new-generation op amps, and another decrease should put noise in the category of "don't care" parameters.

The signal-to-noise ratio has several components that have to be analyzed. The signal comes to the op amp with a noise burden caused by the transducer, cabling, and connections. Making the op amp a filter/amplifier combination eliminates some of this noise. The biggest drawback to making the op amp a filter is the time required to charge the ADC input capacitance. ADC charging has not been investigated here because of scope limitations, but suffice it to say that filters slow down op amps. The internally-generated op amp noise is multiplied by the closed loop gain, and the SNR should be established in the front end, so the closed loop gain hurts one way and helps the other way. There is always system noise, and a portion of this noise propagates through the op amp into the signal. The system noise is minimized by extensive use of decoupling capacitors and a high power supply rejection ratio. In higher voltage systems, a resistor is placed in series with the power supply, thus making the decoupling capacitors more effective; low power supply voltage designs usually can't afford that trick.

RRI op amps are able to work with transducers connected to the power supply rails. As long as the ac component of the transducer output voltage does not exceed the input com-

mon-mode range of the op amp, the design is reliable. RRI op amps are troubled by distortion introduced by the change in bias current, input offset voltage, and gain, but their contribution to the system's signal handling capability is invaluable. RRO op amps yield the highest output voltage swing of any series of op amps. Beware: RRO op amps are specified at a load resistance or current, and the output voltage swing decreases dramatically when the load resistance or current is increased. RRIO op amps contain the input and output features of RRI and RRO op amps. They also contain the drawbacks of both features.

Shutdown is a current-saving feature that is becoming standard on RRIO op amps. When you are working off a battery, there is no reason to waste power when the electronics is not busy, and the shutdown feature accomplishes the power savings by turning the op amp off when it is not needed. The shutdown feature has a disadvantage in that it has a finite wakeup time that the designer must allow for. Don't just depend on shutdown to reduce current drain because there are other ways to reduce current drain, and some of these ways are using high value resistors, low speed logic, fewer logic transitions, and using low bias current regulators/references.
